anvil with flatters and swages, at the sacrifice of much time and labor. Hence, long before the practice of *producing* forgings by stamping existed in the blacksmith shops, the practice had grown of *correcting* and *finishing* anvil-made forgings in dies under the power hammer. The dies were often of a sectional form, as they are still to-day when heavy forgings are in question. Thus, a die or pair of dies would include a boss only, on a lever, Figs. 1, 2 and 3; the lever ends standing out beyond the dies; or a die would be used to punch a hole, and correct the boss at the same time, Fig. 4. Lever ends, either forked or solid, are suitable objects for

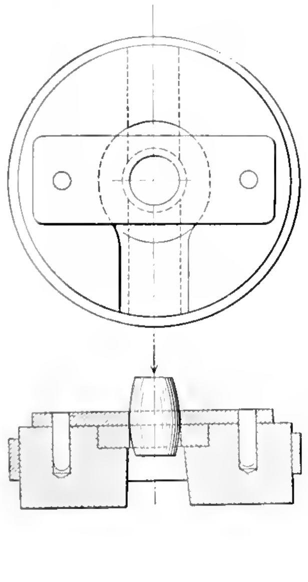

Fig. 4. Die used for Punching Hole through Boss, correcting Shape of Boss at the same Time.

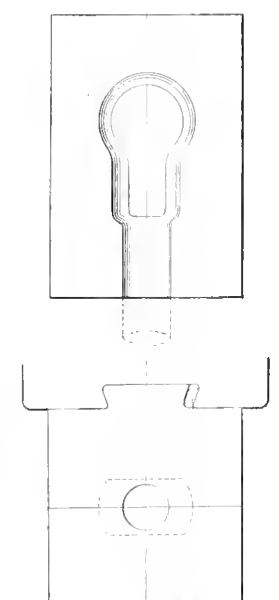

Fig. 5. Die for Finishing the End of a Connecting-rod.

finishing in this way. So are the ends of connecting-rods, Fig. 5, the eyes of the tie rods, and the bridles or loops of slide valves. In the old practice, as to a large extent now, these were made of wrought iron, bent, and welded. These operations were done at the anvil, and the correction and finish done at another heat in dies. These dies were and are made of cast iron from a pattern. Later, cast steel has been often used with a view either to increase the strength, or to lessen the weight.

Even on the anvil, in little shops where there was not as yet a steam hammer, the old Oliver was utilized in finishing the heads of bolts in dies, and the writer remembers seeing these

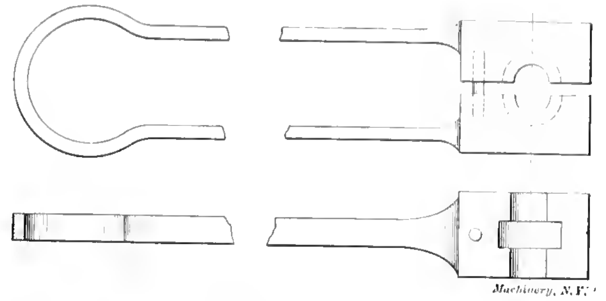

Fig. 6. Device for Shaping Bosses on Work, made on the Principle of the Spring Swage.

in operation. And on the anvil, little devices were rigged up for finishing bosses, and punching holes, the type of which was the spring swage, Fig. 6, the jaws of which were fashioned independently of aid from the machine shop, by a process of *typing*, or *hubbing*, from a dummy, or a duplicate forging. Very many simple forms can be and are done in this way still as a legitimate and suitable method. Light swages are used on the anvil, just as the heavier ones are operated under the steam or drop hammer.

The sectional dies are used very extensively now in the blacksmith shop for the purpose of final correction and finishing only. But along with the use of these, there has grown the practice of stamping wholly, either as a sub-department of the shop, or carried on in a distinct shop. Generally, however, the merely corrective dies are used for the

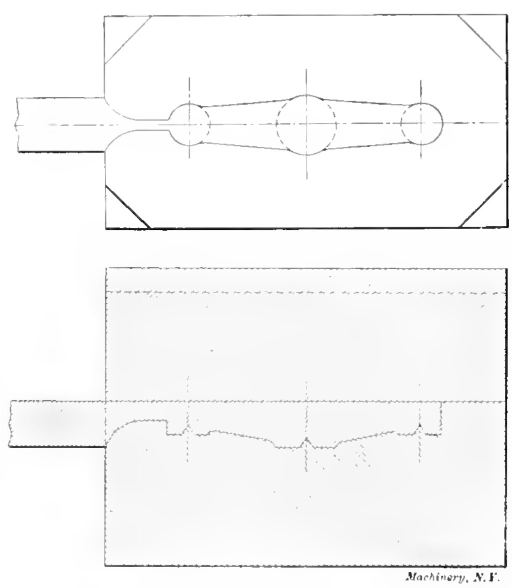

Fig. 7 Example of Forging Die, forming Center Holes in the Bosses of the Work.

heavier forgings, and the regular stamps for the smaller class, as in Figs. 7 to 10. To make the larger forgings entirely by stamping operations would often require heavier hammers and appliances than most shops are equipped with, and the numbers wanted of the large forgings might not be sufficient to render heavier installation remunerative. But a heavy forging may be corrected in dies when it would not be practicable to produce it entirely from a rude lump. Among work of this kind may be instanced large tie-rod eyes, large bossed levers, Figs. 1 and 2, rings, pillars, and such like. Some of these are too long to be embraced wholly in a single die. A long two- or three-bossed lever, for example, is then corrected only on its bosses, and for an inch or two away therefrom. A pillar for handrailing would have its bossed portions corrected separately, and the body corrected by swaging at the anvil, or in other dies.

Materials Used for Dies.

The number of similar castings required is often insufficient to justify a large outlay for cut steel dies. But dies made in cast iron are not costly, and therefore they are frequently made when only half a dozen or a dozen of similar articles are required. They may, of course, be kept for future use, and should be, when a job is likely to be repeated, but, apart from that, a very small number of forgings will pay the cost of cast dies.

The growth of stamping has been gradual and natural. The mere fact of having cast dies lying by from previous jobs

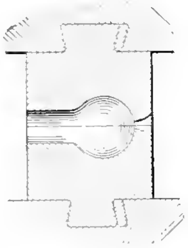

Fig. 8. Type of Die for Forming the End of a Ball Crank.

Fig. 9. Forging made in Dies from a Bar.

has been the cause of their utilization for pieces of work which might not otherwise have been thought to justify the expense of new dies. But being in stock, slight and unimportant alterations in some dimensions in new jobs would often render the dies available. In this way the beginnings of standardization arose. For as the dies began to accumulate, one pair or set was made to do duty for work for which it was not originally intended. Thus, the difference of half a ton or a ton of crane power was not allowed to involve the making of minute differences in the forged work for the cranes, but one standard set was used for both. So in engine and pump work the same standard sets came to be used for powers and sizes of mechanisms that were not very dis-

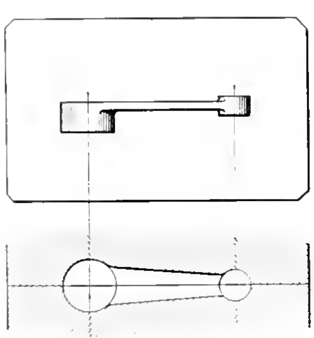

Fig. 10. Dies for a Lever with Hubs at Both Ends.

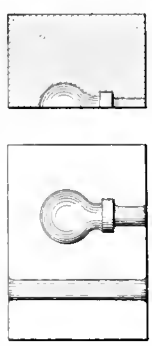

Fig. 11. Dies for Forging an Eye-bolt.

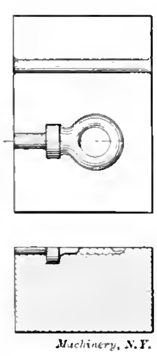

Fig. 12. Dies for Finishing the Eye-bolt.

similar, and when the difference of 1/4 inch, or so, in dimensions could make no possible difference in the proper operation or strength of the forged details.

Principles of Drop Forging and Stamping.

Comparatively few articles can be produced in one pair of dies, and those are chiefly circular forms, the diameters of which at different sections do not vary greatly. If they do vary, some preliminary reduction or "breaking down" is necessary. And if a portion of the article takes the form of an eye, or a boss, three or four successive operations may be necessary to produce the forging, as in the eye-bolt produced in Figs. 11 and 12. The die maker has then to settle how the work shall be done, whether in one or more pairs of dies, and whether under one hammer or two. As a rule, to which there are exceptions, it is desirable to do all the work at a single heat. Then, if several operations are required they must be done either in one set of dies, or in separate dies. For small forgings it is easy to get three or four recesses in one pair of dies, for roughing down, for formation, and for cutting off, or nicking for breaking off. In larger pieces it is necessary to have two hammers adjacent, so that the stamper can use them both without walking away from either. But a few hammers are made double headed, with two anvils, and tups to facilitate such work. When two heats are necessary, then it may be convenient to perform the earlier operations on a large number of similar pieces, and then change the dies for the subsequent work. This, perhaps, is more often done in the regular machine shops than in the stamping works, in which the work is divided between two adjacent hammers.

Though the smith working at the anvil endeavors to gage by a very rough mental estimation the amount of material

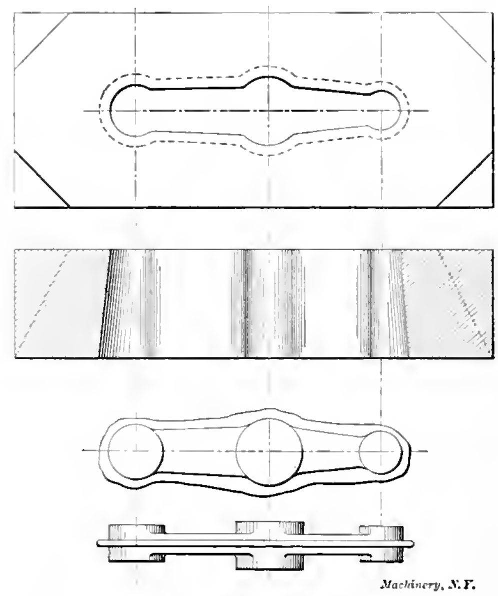

Fig. 13. Stripping Die for Removing Fin produced by Forging Process, and Work for which it is used.

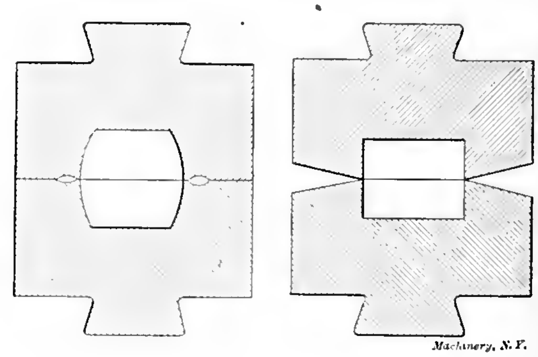
which is required for a forging, in order to lessen labor, the stamper may be comparatively indifferent to that consideration. He will not, of course, have much excess of metal if it can be avoided, yet he is much in the same position as the anvil smith who has a steam or drop hammer available adjacent to the anvil. The power hammer is often resorted to for roughing down an odd lump quickly, in place of taking a smaller section, which would involve the alternative of upsetting, or of welding. The shapeless lump is simply roughed down rapidly in far less time than would be occupied in fullering on the anvil, or in performing the alternative operations of upsetting, or welding. In this way, too, very many odds and ends, cropped from iron or steel bars are utilized, which would otherwise go to swell the scrap heap.

The case of stamping is analogous. Though forgings having considerable differences in cross-sectional areas, are, as a general rule, broken down in one or more operations, preliminary

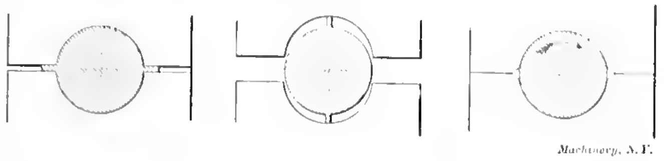


Figs. 14 and 15. Dies provided with Space for Receiving the Fin.

to finishing, yet a great deal of work is done without this step-by-step process. A cubical lump is taken and put into the dies and reduced. A large amount of fin being squeezed out in the process, this is removed in an adjacent stripping die, Fig. 13, and the forging put back, and finished in the first, or in another, recess, followed sometimes by a final stripping. This heavy reduction is only possible, first, because the lump is raised to a high temperature, and second, because the mechanical work done on it maintains the heat until the reduction is completed. At the anvil, two or three heats would often be required to accomplish the same amount of work which is done in one heat in stamps.

Removal of Fin Produced in Drop Forging.

The formation of fin, it will be noted, is peculiar to stamping; it does not occur in anvil work. Sometimes dies are cut like Figs. 14 and 15 to receive the fin. In Fig. 14 a wide and shallow groove is cut all around the recess to receive the fin. In Fig. 15 the faces are sloped away with the same object. Work which is of cylindrical form does not neces-



Figs. 16 and 17. Showing how Fin produced on Round Work is forged into the Bar by rotating it.

Fig. 18. Die with Rounded Edges to receive Fin.

sarily involve the formation of permanent fin, because it can be rotated, as the reduction is going on, and such excess of metal which is squeezed out laterally is removed at once when a partial rotation is given to the piece, as in Figs. 16 and 17. In Fig. 16 the fin is shown squeezed out; in Fig. 17 it is being driven into the forging again. Such being the case, Fig. 18 is the shape given to circular dies in cases where the circular form is not hampered by the proximity of shapes which would interfere with rotation. When the work can be rotated, the result is a fine, smooth, polished surface, which in many classes of work renders any subsequent machining unnecessary, or, if finish is essential, a little grinding may suffice. In some forgings a portion only, a stem or shank, can be so treated, the remainder consisting of an eye, or a flattened portion, or a square shape.

Difference between Treatment of Steel and Wrought Iron.

In the blacksmith shop, wrought iron is still used as extensively as steel for common forgings. But many forms when made of wrought iron must not be stamped from a solid lump

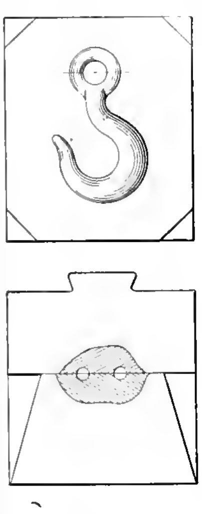


Fig. 19. Dies for Crane Hook.

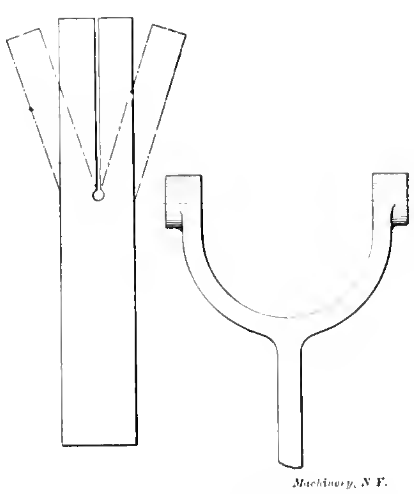

Fig. 20. Fork Lever, and Wrought Iron Bar from which it is made.

because of the loss of strength which occurs across the grain Large thin rings and curves of light section should always be bent. But if these are made of steel, no such reason exists, because steel has practically no difference in strength with or across the direction of rolling. The partial substitution of steel for wrought iron has therefore been favorable to the development of stamping. Many jobs are now stamped from a solid bar, or lump of steel, which were formerly made from wrought iron by bending and welding. Hence, while wrought iron is still extensively used for anvil made forgings, steel is employed much more for stampings. The crane hook, Fig. 19, when made of wrought iron, is always bent from bar before being finished in the dies. Made from steel, it is stamped from a solid lump. For the forked end, Fig. 20, if made of wrought iron, a bar is slit, and opened out, and bent over a form, and finished in dies. When made of steel, it may be stamped from a solid mass. The flange, Fig. 21, is stamped in steel from a solid chunk, handled by a porter bar temporarily.

Work with Holes Forged through it.

The old method of punching holes is that shown in Fig. 4, in which the punch is guided by a plate doweled on the body of the die. This is suitable for large holes. Frequently, for small holes, the punch is separate, and driven through a hole in an upper die as in Fig. 22; in Fig. 23, a hole without its punch is shown. But punches are also often included solidly in the die, as in Fig. 26, half in top, and half in bottom, and not quite meeting at the center. In a shallow boss the punch may be in one half of the die only, as for a forging like Fig. 24. The metal becomes squeezed into the boss, and is improved by consolidation. Often, when holes are left to be drilled, the centers are stamped by small conical projections

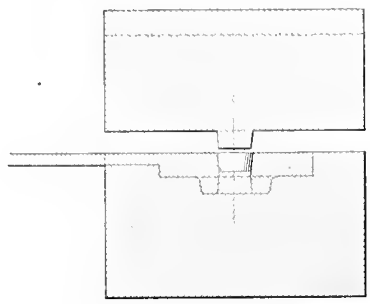

Fig. 21. Dies for a Circular Loose Hub.

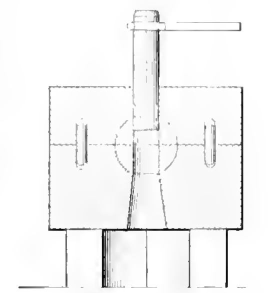

Fig. 22. Punching a Small Hole through the Work in the Dies.

in the dies which serve as accurate guides to the driller. Sometimes holes are punched only through a portion of the metal, Fig. 25, when the central part has to be bored out subsequently, as indicated by the dotted lines.

Methods of Applying Impact or Pressure on Dies.

Formerly all die work was done with hammer blows. As the demand grew for an extension of the system to heavier forgings, and to articles involving the bending of plates and sheets, the steam and drop hammers were not able to deal so well with these. The demand was met by the presses, which are actuated by hydraulic power or by gears, cranks, and toggle levers. These will easily deal with dies and articles of several feet in length, many of which are too intricate to be dealt with by hammers, even if their dimensions did not set a limit to such treatment. They are practicable on the hydraulic presses, because two rams can be utilized, one acting in the vertical, the other in the horizontal direction, so working at right angles with each other. This is utilized for bending, welding, and punching, for closing up joints, for dealing with undercut designs, and with hollow spaces formed

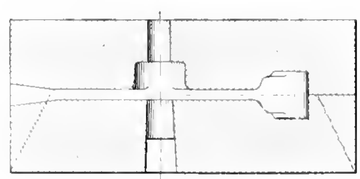

Fig. 23

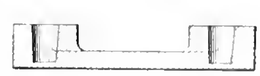

Fig. 24

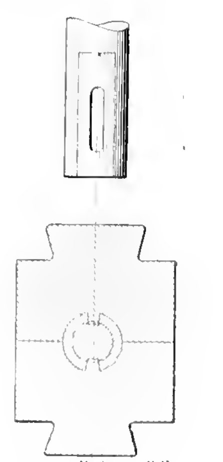

Fig. 23. Dies for Punching Holes through Bosses. Fig. 24. Holes punched by Punches Integral with Die.

Fig. 25. Method of Forging the Slots in Collets

by bending and welding, or by stamping. Typical of much work of this class is the die and punch used for stamping the rings for uptakes of vertical boilers and the man-hole and mud-hole seatings for boilers, Fig. 27, from a plain piece of steel plate. Fig. 28 shows the dies for forging a crank by pressure. A large amount of work of this kind is done in the railway car shops.

Stamped forgings thus diverge into two great groups, according as they are produced by hammer blows, or by grad-

nal pressure. Broadly, the first group includes articles of small and medium dimensions, the latter those of a massive character, and all large work done in plates. This is now a generally accepted division, and one which harmonizes with the difference in hammer blows delivered on comparatively small masses, and of pressure on thicker bodies. Where mass is the condition present, slow pressure is more penetrating than impact, just as it is in large shafts and forgings. Moreover, the blows delivered from a very heavy hammer are

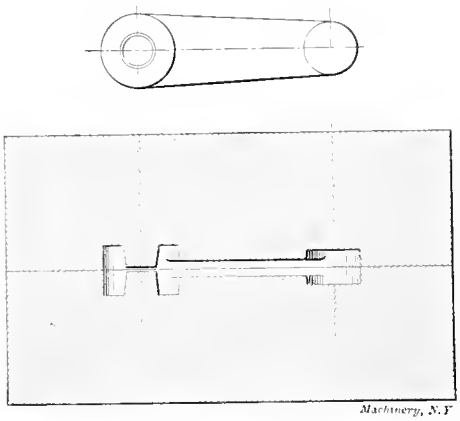

Fig 26. Construction of Die for Forging a Hole through a Boss.

destructive to dies, and if they are made massive enough to withstand these blows, then they are too heavy for convenient handling. Massive dies are, of course, required to resist pressure, but that is not nearly so destructive as the violent, incessant jarring action of a hammer.

Methods Used for Making Dies.

The stamps or dies used are as varied in their details and cost as the forgings themselves are. A great advantage of stamping dies is, that like machine molding, they are as readily adaptable to the demands for a very few identical articles, say ten or a dozen, as to hundreds or thousands. But the amount of work put into the dies, and the patterns and the materials used for them have to bear a definite relation to the number of pieces required. Hence, we have at extremes, dies of cast iron made cheaply, and those of mild steel cut out with care and hardened. Except in name and function,

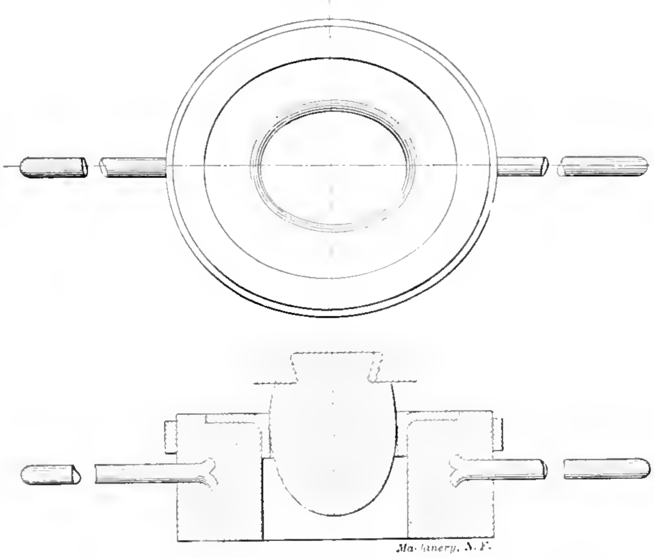

Fig 27. Die used for Forging and Bending Man-hole Seatings.

the examples at each extreme have little in common. They are not made in the same way, and the periods of their service are much less in the first than in the second case.

The cast dies are molded from suitable patterns. They may have to be cleaned up a little by the machinist. As they are liable to fracture, unless made very massive, they are frequently encircled with bands of wrought iron, shrunk on, as in Figs. 1 and 4. They are, when small, lifted with circular tongs, Fig. 29, or by the hands, but larger dies have handles cast in for lifting them, Fig. 27. Or, alternatively, holes are cast in for the insertion of rods for the same purpose. Some cast dies will endure long service, others fracture soon. Dies of cast steel are stronger, but are more liable to inaccuracy.

Dies of forged steel are marked out on their faces, and recessed by various machine tools, and by hand work. All the aids afforded by machine tools are utilized, as boring, slotting, milling, and shaping. But often very much is left for the chisel and file to complete. There are several special machines designed wholly or chiefly for the use of die sinkers, but much can be done by the ordinary tools in the shops. Templets are used to check the progress of the work, including those of sheet metal for local sections, and those which represent the actual forgings which have to be stamped. These are made of lead, or tin, or a first sample forging is prepared. Contact is insured by the transference of red lead from the templet to the recesses which are being cut.

Reference has been made to the typing or hubbing process. It bears an essential resemblance to the operation of stamping medals and coins by a hard blow. Only the operation is reversed, the die itself being produced by stamping it, while white hot, from a cold forging. It has the advantage of being cheaper than cutting dies, and in circular outlines is accurate enough, but is not well adapted for intricate shapes. The spring swages are frequently made in this way. In

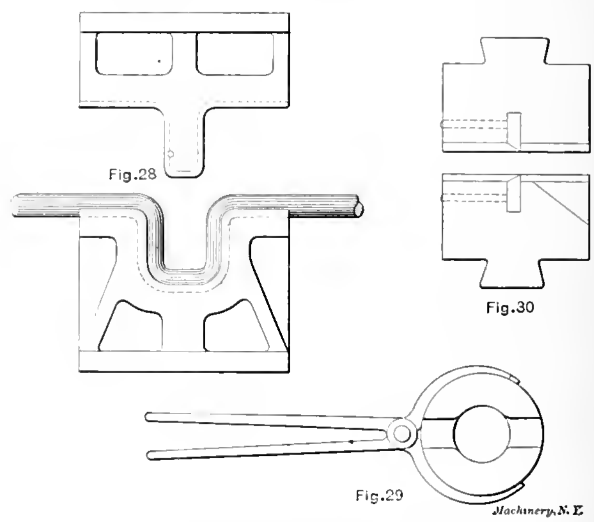

Fig. 28. Die for forging Crank. Fig. 29. Tong for Holding Dies. Fig. 30. Cutters for Nicking the Stock, fitted at the End of the Dies.

obtaining circular shapes thus, the hub or type is rotated between each successive blow, so correcting any inaccuracies that might form. The edges are of necessity produced with a slight convexity, Fig. 18. But this is an advantage in producing circular forgings which are rotated in the dies. It is not necessary to have complete circles in such a case, because metal squeezed out laterally, and what would soon form a fin, becomes obliterated by the next blow when the rotation into a new position takes place.

In one of the illustrations, Fig. 3, dowels are shown, which are inserted to serve as guides to secure the alignment of top and bottom dies. These are only used when the dies are not attached in any way to the anvil below, and tup above, as is often the practice in heavy dies. But generally the dies are secured by dovetails and keys, as in Fig. 5. In some cases locating screws are used on the anvil for dies cut at the corners, like Figs. 13 and 19, and the dovetail is only on the tup. The locating screws permit of making slight adjustments.

Forgings are often included wholly in their dies, and are knocked out by a kicker device, or are pried out, or pushed out. Often a porter bar is used, generally the plain length of the bar from which the forgings are being stamped, as in Figs. 7 and 9. Then the forging is easily nicked off by reducing the eye at the neck, as shown in Figs. 7 and 9; or a pair of cutters is fitted at the end of the dies, as in Fig. 30.

The foregoing is an outline of the methods of stamping in use, from which it is seen that the practice is divisible into three great groups; that done under hammers, and that in presses, and a further subdivision between the methods of the general shops, and the drop forgers who work for the trade.

THE SETTING UP AND OPERATION OF THE POTTER & JOHNSTON AUTOMATIC CHUCKING MACHINE—2.

This installment completes the article relating to the setting up and operation of the Potter & Johnston automatic chucking machine. Owing to the frequent unavoidable references to Figs. 1 to 7, it should be read in connection with the first installment, published in the April issue of MACHINERY.

As explained, the third turret face is empty, the cutting off of the collar being done during this portion of the cycle of operations. It has been taken for granted, of course, that in setting the turret slide for position, room has been left between it and the chuck for the cross slide. The cross slide is clamped in a convenient longitudinal position on the bed for the cutting-off operation, which will be done with a tool in the rear tool-post, so as to leave the front unobstructed for the operator. Where forming and cutting-off are to be done, forming is generally done at the front and cutting-off at the back, since heavier and more accurate forming work can be done with the work revolving downward toward a tool in the front tool-post, than with a tool at the back which is subjected to a lifting action.

The layout of the cross-slide cams is shown in Fig. 5. The rear feed cam is the one we have to use. Since this cutting-off operation is a short one, it may be done during the return of the turret for face No. 3. The cam drum is therefore rotated by hand until the turret for face No. 3 has begun to return. The cross-slide cams are loosened and the rear feed cam swung around to just touch the roller, the cross slide having been adjusted out to nearly the limit of its forward travel for cutting off, leaving approximately enough motion for cutting down the rear face of the collar and through the shell. The rear feed cam is then clamped in this position. A cutting-off tool is next placed in the rear tool-post at the proper height. The rear tool-post slide is adjusted to bring the point of the cutting-off tool up to the work, and the cam drum is revolved by hand until the piece is cut off. The cross-slide tool is, of course, set in the proper position to make a collar of the desired thickness.

Stopping the hand feeding when the roll is on the point of the cam, the cutting-off tool slide is permanently set on the cross slide so that the point of the cutting-off tool enters the bore just barely enough to completely sever the collar from the bushing. The motion of the cam drum is continued by hand until the roll is over the point of the feed cam. The cross slide is then pushed back by hand until the cam and roll are again in contact, when the rear return cam is brought up and clamped in position, so that there is just room for the roll between the feed cam and the return cam. The rear return cam, as the hand feed of the cam drum is continued, brings the cross slide back to its central position. Since there is no front tool used in the final layout of operations (Fig. 2 to the contrary, notwithstanding) the first feed and return cams are allowed to remain wherever they happen to be. These cam adjustments can all be made from the front of the machine.

Continuing the feeding of the turret slide, we next make sure that the cutting-off tool is returned to its normal position before the next face of the turret is presented for its operation, and then we proceed to set the recessing tool. This recessing tool, which is shown diagrammatically in Fig. 8, is a model of simplicity of design and action, as compared with the somewhat complex operation it has to perform. It may be said, in the first place, that this recess is for clearance only, and accurate dimensions and fine finish are not necessary. Assuming this, it will be seen that the operation of this recessing tool should be eminently satisfactory. The device consists simply of a slender boring-bar held in the turret, carrying a cutter suitably located about midway of the bar, the forward end of which is adapted to enter a bell-mouthed bushing held in the chuck. This boring-bar is bent to one side far enough so that the cutter clears the hole as the bar enters, but is forced into the work as the bell-mouth of the bushing engages the end of the bar and deflects it into its working position. The upper diagram shows the condition of the bar as it enters the hole, and the lower one its condition after it has entered the bushing and is engaged in turning the recess. This bar being properly designed as to its length, the position of the cutter with relation to the length of the recess in the work, and the location of the work with relation to the bell-mouthed bushing, it has merely to be set in the turret so that at the extreme forward travel of the turret slide the cutter is the same distance from the face of the chuck that the rear end of the completed recess will be when made to the desired dimensions. The cutter, of course, has been set out to give the recess the required diameter.

The final facing of the bushing by cam and turret face No. 5, so far as the setting of the tool is concerned, is merely a repetition of the facing operation on turret face and cam No. 1. This completes the setting of the cutting tools.

Making the Adjustments for Speeds, Feeds, Etc.

We have now to set the machine to perform automatically the desired changes of spindle speed, and fast and slow cam movements. Placing a new piece of work in the machine (the first one having been completed in the setting-up operations) the cam-shaft is revolved by hand until the turning tool in turret face No. 1 is just about to commence its cut. Hand-wheel D (Fig. 6) is now rotated in its normal direction until its next graduation marked "slow" is in line with the index mark on the base casting of the machine. Then the nearest pin M (see also Fig. 12) is moved up until it bears against

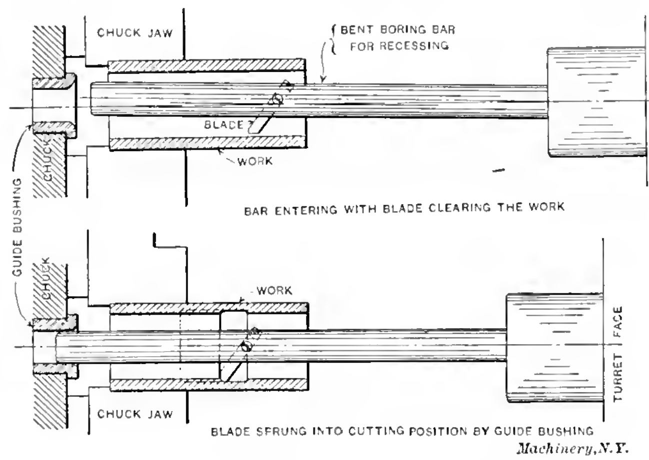

Fig. 8. The Tool used for Recessing the Work; shown also in Fig. 3.

the teeth of the star-wheel, when it is clamped in position. This should set it properly. To see if it is so set, return the cam-shaft by hand and throw in the automatic feed by moving lever H to the right, and watch the cut. The drum should slow down just before the tool commences to work. If it does not do this, the pin may be adjusted a little either way, as may be required. (In going over a piece for the first time, it is best to have the feed set to the smallest rate; that is to say, feed change handle K should be in position No. 1.)

After the cut has been completed and the turret feed cam roll is on the high point of the cam, the power feed may again be stopped, and the hand-wheel revolved until the next graduation mark "fast" is opposite the index mark. The next stop-pin is then moved up until it just touches the star-wheel, where it is clamped in position. The feed being again thrown in, the turret will be rapidly returned, indexed and moved forward for the second operation. Stopping the automatic movement, the pins are set for this face, and so on for all the operations, including that in which the cross slide is used for cutting off.

Operations 1, 2, and 3, being done on large diameters, should be done at the slow speed, handle J (Fig. 6) being set to give that speed. While, however, the turret slide is being returned between operations 3 and 4, one of the spindle speed changing dogs N should be clamped to the rim of disk D so as to change the spindle speed to the fast movement. This is continued until the last operation is completed, when a second dog of this kind is clamped in place to again throw in the slow movement.

The feed knock-off dog should also be clamped in place on the disk to stop the machine at the completion of the fifth operation, when the turret is in its rear position.

This completes the setting up of the machine. It is best for the operator to watch the operation the first time it is done automatically. If, as was the case with the parts shown, the feed is finer than is necessary, the feed change was found possible to use No. 3. If at any time the tools show signs of distress, the feed may be lowered instantly by changing this handle; or if the work seems to be done without distress, it may be increased as easily.

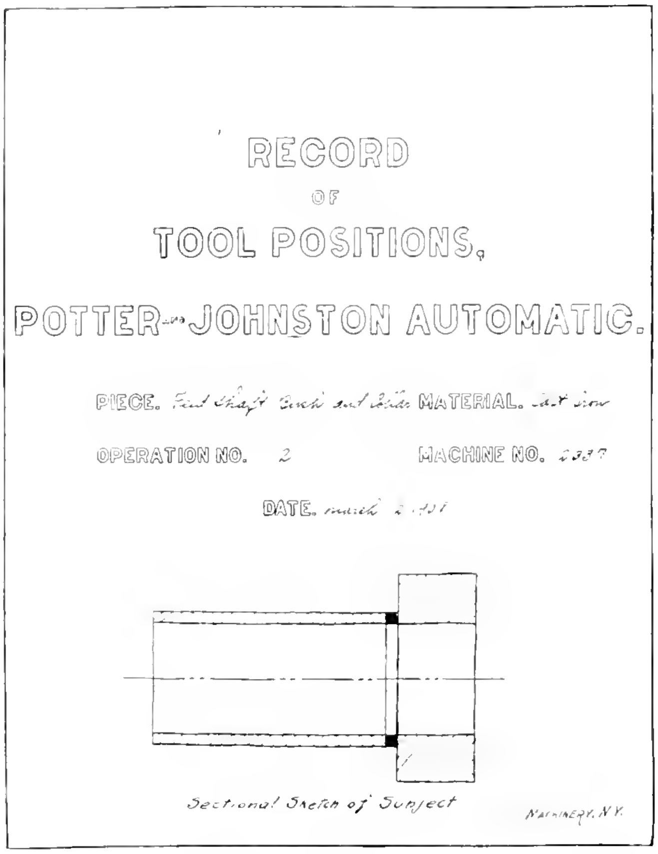

Fig. 9. The First Page of the Tool Record Sheet for Recording the Operations shown in Figs. 2 and 3.

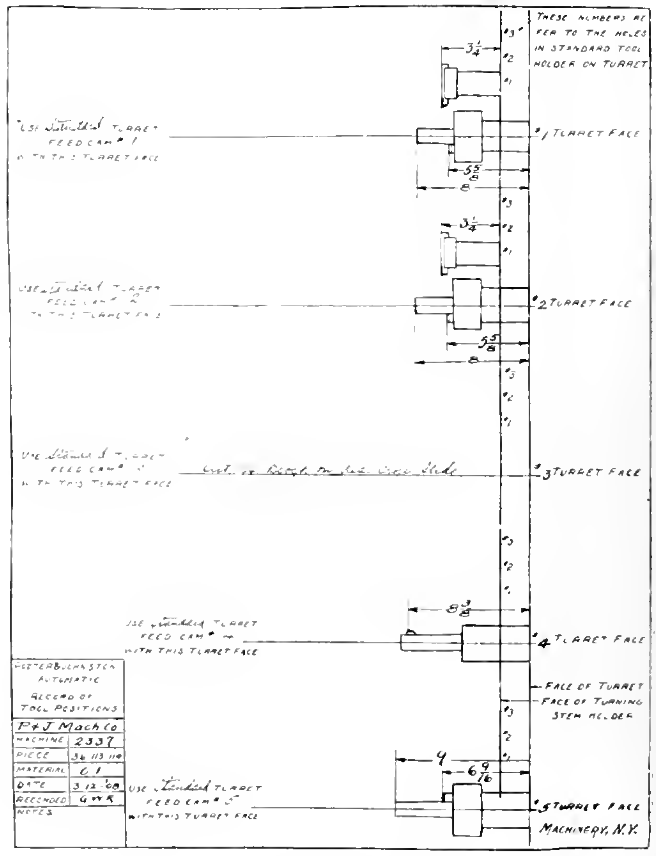

Fig. 10. Second Page of Tool Record, giving the Setting of Cutting Blades.

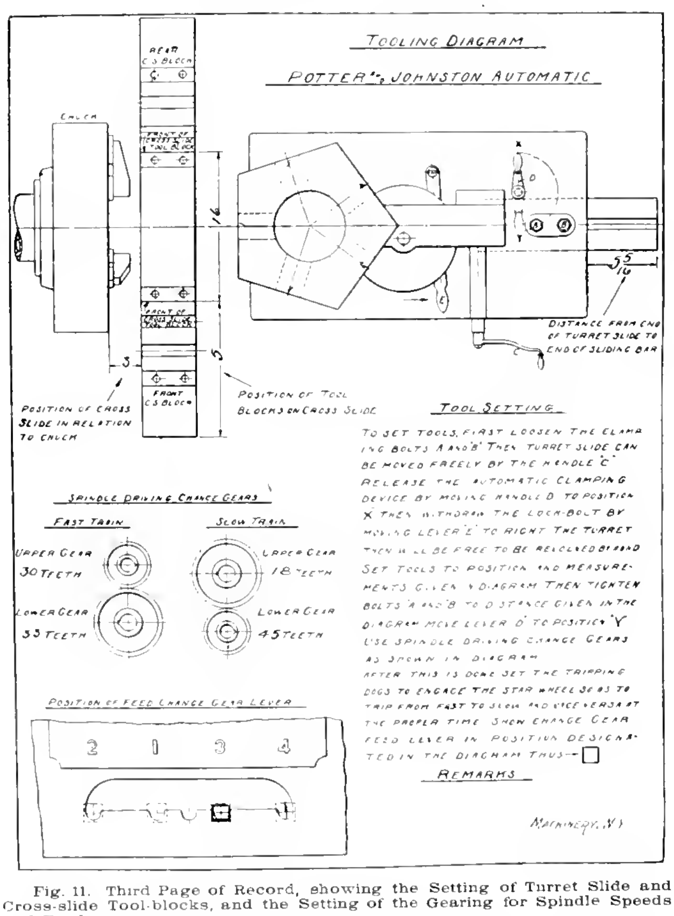

Fig. 11. Third Page of Record, showing the Setting of Turret Slide and Cross-slide Tool-blocks, and the Setting of the Gearing for Spindle Speeds and Feeds.

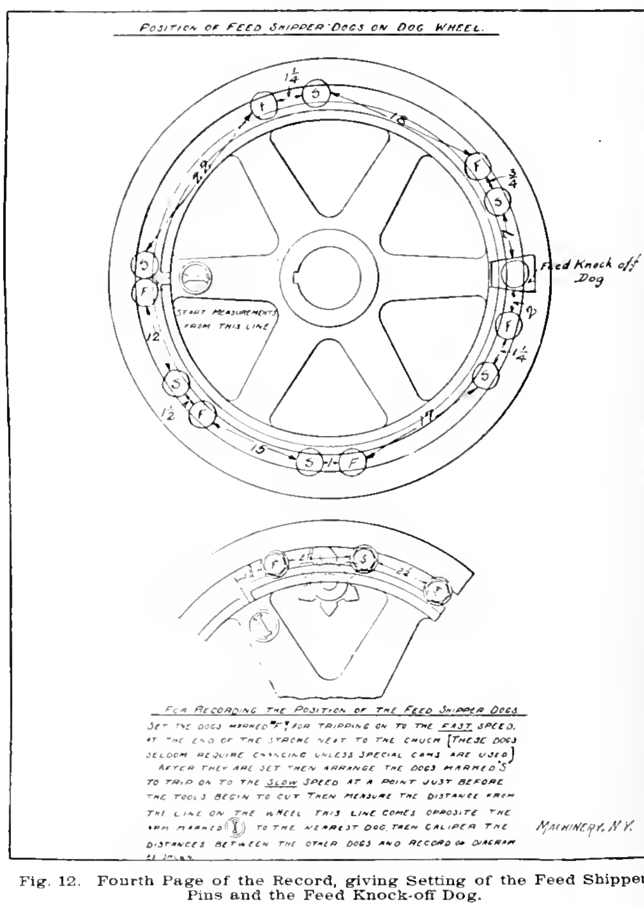

Fig. 12. Fourth Page of the Record, giving Setting of the Feed Shipper Pins and the Feed Knock-off Dog.

handle may be moved to the position which will give the greatest feed which it is possible to use with the work in hand. In the present case, as shown in Figs. 6 and 11, it

It has taken some little time to describe the setting up of the machines for this simple operation. In reality, however, in the hands of a competent operator, the setting up takes

little, if any, more time than the setting of a single piece in the lathe. There are no more tool settings to make than with the ordinary type of turret lathe, and the extra changes, such as the setting of the pins and dogs for the speed and feed changes, are made so quickly as to consume little time in comparison with the cutting movements. With the exception of the recessing tool, which is of simple construction, all the tools are a part of the regular equipment of the machine.

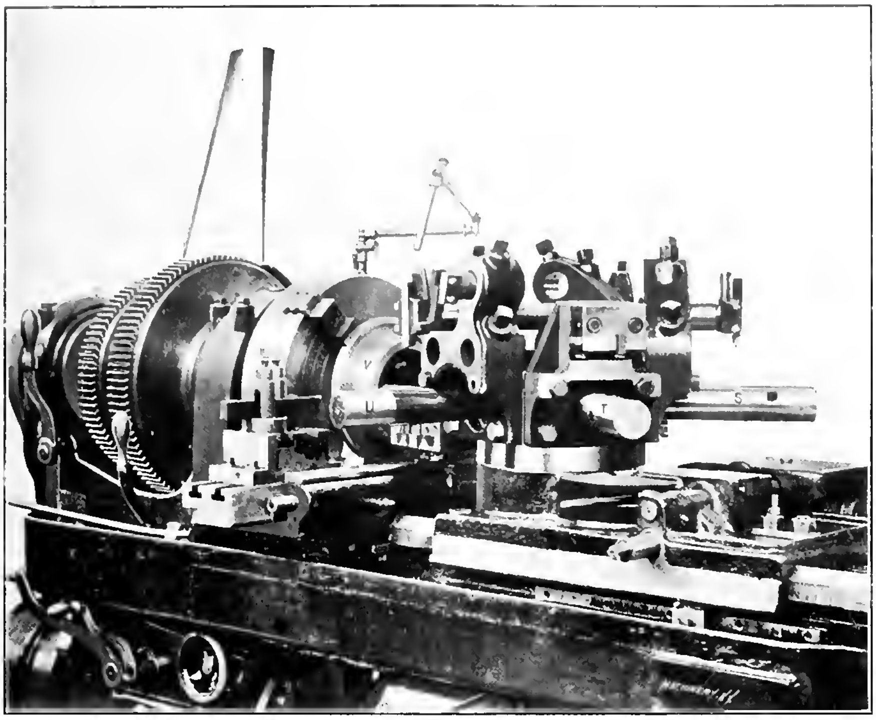

Fig. 13. Front View of Machine engaged in Finishing a Flanged Sleeve, made from a Steel Casting.

Tool Record Sheet.

The builders of this machine furnish a convenient form for recording the settings of a piece of work after they have once been obtained. We show the four pages of one of these records in Figs. 9, 10, 11, and 12, made out for the piece whose machining we have just described. It is printed in ink resembling India ink, in which the blanks are filled out by hand. The first page, as shown, gives the name of the piece, the material and the number of operations performed—this being a second operation, as previously explained. The number of the machine is also given for convenience in identifying it with the following operations. The fact that the part is cut in two to make two pieces of work, is plainly shown in the sketch.

The second page is taken up with sketches of the various tool-holders and cutting tools used. The distance of each of the cutting edges from the face of the turret or the face of the tool-holder is given. The tool-holder may thus be set at once without going through the trial settings we have mentioned as being necessary the first time the work is done. Tools held in the standard tool-holder have their distances measured from the face of the holder, while tools held in the face of the turret have their cutting edges located by the turret face. The feed cam used for each of the operations is also indicated. In recording work on which special cams might have to be used, the number of the cam employed for a given operation would be indicated in place of the word "standard," which we have for all five operations in this case.

On the third page of the pamphlet are shown diagrams giving the measurements for the setting of the cross slide longitudinally of the bed with relation to the chuck, and for the setting of the turret slide with relation to the cam roll. The latter measurement is taken, as indicated, from the end of the turret slide to the end of the sliding bar. The setting of the cross-slide blocks and cross slide is also given. The change gears for the fast and slow trains are recorded as shown, as well as the position of the feed change gear lever which was found the most suitable for the work. General instructions for tool setting are also given.

The last page of the record is occupied by a diagram in which the settings of the feed shipper pins are noted. These settings are obtained by using inside calipers in measuring the distance between consecutive pins. These distances, after being recorded, may be used in again setting pins for new work, thus making unnecessary the trial operations we have described. In actual practice, however, with competent workmen, this page of the record is not ordinarily filled out, it being as simple a matter to set the pins by trial as to measure them. For workmen not used to the machine, however, this record will be found very helpful. Regular use of the other features of these records will be found to save considerable time on work which has to be done repeatedly.

The Tools and Operations for a More Complicated Job.

The operations we have just shown are comparatively simple. In Figs. 13 and 14 are shown front and rear views of another machine in operation at the time of the writer's visit, in which many more tools are used, and in which much greater accuracy is required.

The machine is of the same type as the one shown in Figs. 1, 2, and 3, though of a somewhat older design. The part being machined is made from a steel casting. It is intended to be a sleeve for use in holding bushings in the chucks of the automatic machine for guiding the pilot bars of tools held in the turret. The face of the chuck which carries the sleeve is recessed, like the one shown in Figs. 13 and 14 holding the work, though a smaller sized sleeve would be used with that chuck. The lip on the flange of the sleeve enters this recess, in which it must be carefully fitted. The body of the sleeve is also very carefully fitted to the bore of the chuck. It will be seen that this sleeve ties the sections of the chuck together, so that on large, heavy work the clamp-

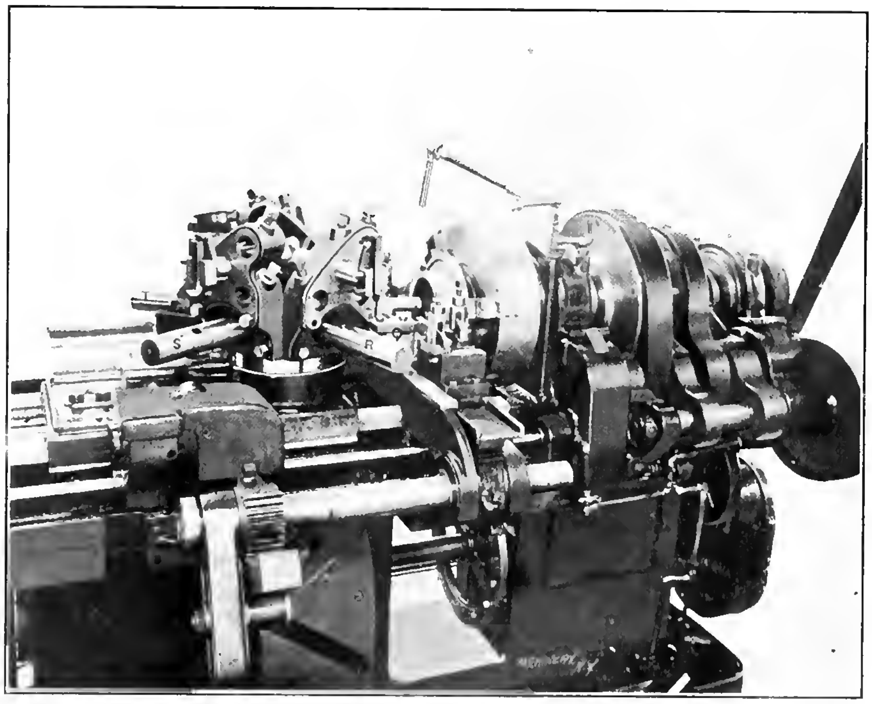

Fig. 14. Rear View of the Machine, set up as shown in Fig. 13

ing of the jaws down on the work will not spring the body of the chuck so as to distort it, and cause the pilot bushing within the sleeve to run out of true.

The first operation is performed by the turret face shown at *U*. It consists in rounding the corner of the large diameter of the flange, rough turning the outside diameter of the body, and facing the outer end of the body. This operation, like all the others, is steadied by the pilot bar shown, which is supported by a bushing in the chuck. The tool for facing the end of the body is not plainly shown in the engraving. The second operation, on turret face *T*, recesses the flange to form the lip, using a facing tool held in a special tool-holder, as shown. The third operation on face *S* finish turns the outside diameter of the body. The fourth operation, on turret face *U*, finish turns the inner side of the lip to the exact diameter desired. In the last operation, the hole is bored by a taper attachment *Q*, as will be explained, and the lip is finish faced by a tool held in the cross slide.

The bore of the sleeve is tapered, and one of the most interesting of the tools is that used in the final operation for boring this taper. It is shown in action in the two views of the machine given, but is best seen in Fig. 14. It consists simply of a cross slide carried by the turret, and provided

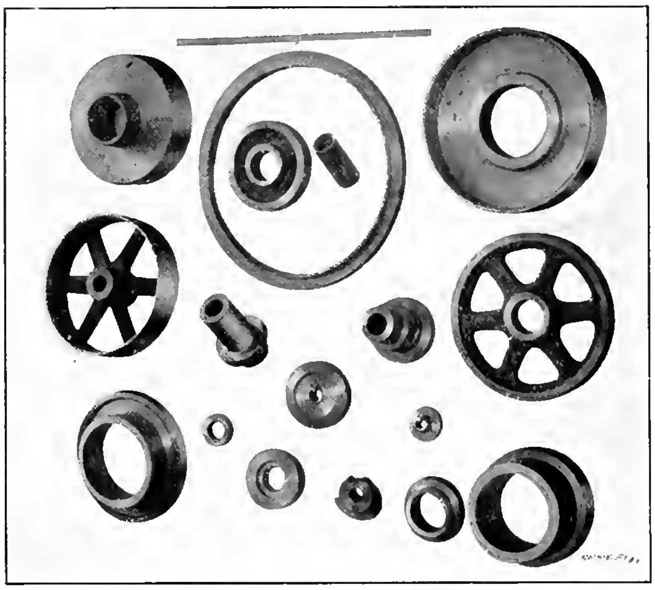

Fig 15. Group of Parts, showing the Variety in a Typical Day's Work, as done on the Machines in the Builders' Shops.

with a spring which tends to keep it forced toward a stop at the rear end of its travel. In the T-slots of the cross slide on the back end is clamped a hardened plate *Q*, with a ground straight-edge which is set to the desired taper. The end of a tool in the tool-post held in the rear cross-slide block is brought up against the edge of this plate by the cross-slide cam. The cross slide remains in this position throughout the operation. During the forward feeding of the turret, the action of the shank of this tool on the tapered plate forces the cross slide toward the front slowly, in such a way as to reproduce the taper of the plate in the bore of the hole. This simple arrangement produces tapers of a high grade of accuracy, as revealed by the usual test of finding the bearing in the hole produced, of the standard taper plug to which it has to be fitted.

The operation on this part takes something like three-quarters of an hour to perform, as compared with the very few minutes required for machining the bushing and collar shown in the first series of operations.

Range of Work for which the Machine is Fitted.

The wide range of work for which the machine is suited may be realized by referring to Fig. 15, which shows the work being done on the machines at the time of the writer's visit. The two upper parts at the right and left are cast iron, being clutch bodies for the spindle clutches of the chucking machines. The large cast iron ring shown is of a diameter that nearly taxes the machine to the limit of its swing. Inside the ring are shown a cast iron gear blank and the recessed bushing whose making we have described. The collar of this bushing is shown near the bottom of the group. The steel sleeve whose making is shown in Figs. 13 and 14 is at the lower left-hand corner of the group. A bevel gear blank and a cam are also shown, as well as a pulley and several miscellaneous pieces.

This group gives a favorable idea of the variety of the work possible on the machine, but it does not include any bar work or any work on composition metals, like brass and bronze, for both of which the machine is successfully used. For brass and bronze, the spindle is usually driven directly, instead of through gearing, to give the higher rotative speeds required.

Among the operations possible on the machine by the use of tools which have not been described, may be mentioned tapping, for instance, which may be done either right- or left-hand without reversing the spindle. Another device with which the machine may be provided is the "back facing" attachment, which is operated from a separate cam, applied to the cam-shaft, acting through levers on a back facing bar, which passes through a hole in the spindle, in a position to act on the rear face of the work inside the chuck jaws. In this may be mounted drills, cutters, facing tools, etc. Where extreme accuracy is required, a double back facing attachment may be used, arranged with cutters for taking both roughing and finishing cuts. A large proportion of the machines sent out by the builders are fitted with this attachment, whose use, in the general run of chucking work, will usually save a second operation.

Bar work up to 6 inches in diameter is also handled to good advantage, floor stands being provided for supporting the outer end. For bar work, as well as for steel castings and forgings, in which the holes are not cored, an oiling arrangement is provided for the turret, which forces the oil through the drill under heavy pressure to the cutting point. The oil flows only through the hole in the turret, which may be at the moment presented to the work.

Other such special arrangements as cam turning devices, two-position chucks, etc., will be provided as may be required by the purchaser. A large field of complicated operations is opened up by employing these, many of the combinations possible being of great ingenuity. The builders have developed a thriving business in the design of special tools for special operations. The possibilities of the machine with regular equipment, however, are evidently very great in the ordinary run of machine shop work.

It is not unusual to see as many as ten cutting tools in simultaneous operation on a piece, being carried by the turret, cross slide, and back facing holder. When such a tooling arrangement can be employed, it will be understood that the machine will show a saving over the ordinary type of hand lathe.

* * *

An interesting method for reproducing drawings, maps, etc., is mentioned in *Teknisk Tidskrift*. This method is termed "helios printing," and by the use of this method it is possible to take copies from drawings on any kind of white drawing paper, if the lines are simply drawn heavy enough so as to give resistance to the light. Not only is it possible to make copies from drawings on any kind of paper, but it is also possible to reproduce these copies on any kind of paper, as for instance, on tracing paper, white Whatman paper, ordinary yellow drawing paper, tracing cloth, etc. It appears that a great number of copies can be produced in a very short time. The method by means of which the work is carried out, however, is kept secret by the concern in Stockholm, Sweden, which makes a business of printing from other firms' drawings. It is stated that the price charged at the present time is about 20 cents a square yard for copies reproduced on good white paper, when several copies are ordered from the same drawing.

* * *

In the course of a lecture on the drive of machine tools, presented before the Pomeranian section of the Society of German Engineers, it was mentioned that for high speed cutting steel the proper cutting speed for cast iron is 66 feet; for machine steel 82 feet; for tool steel and steel castings 59 feet, and for nickel steel from 10 to 33 feet.

MONNET & MOYNE MACHINE FOR BENDING TUBING.

In bending a tube by the usual process, it is filled with sand or some similar substance, after which the ends are capped to hold the material in place; the bending is then performed by any suitable means, generally around forms of suitable radius to give the desired curve. The filling with sand is done to prevent buckling or flattening of the tube while it is being bent. The fact that the ends of the pipe are capped, maintains the pressure of the sand, and prevents such decrease of the interior volume as is necessary for flattening or buckling.

Messrs. Monnet & Moyne, of 11 Rue Torricelli, Paris, have recently perfected a machine for bending tubing which performs the operation satisfactorily without flattening, buckling or other deformation of the work, and without requiring the usual filling with sand. This interesting machine we show in diagrammatic form in the accompanying line engraving. Fig. 1 shows a vertical section through the column of one of the smaller machines. Fig. 2 shows a plan view of the top of the machine and Fig. 3 shows the operation in progress. The same reference letters apply to each of the three diagrams.

To the top of the column is clamped a bracket *A*, carrying at its outer end a fixed pivot *B*, and provided with a slide and adjusting and clamping screws for locating a second pivot *C*, at any desired distance from pivot *B*. Pivot *C* carries a rectangular block *D*, having semi-cylindrical grooves in its face, made to the radius of the pipe it is desired to bend. Above and below it, about the same pivot, are mounted bars *E*, which extend out to the side of the machine, where they are pivoted to a brace *F*, which is clamped in a swivel *G* at the top of the column of the machine.

Pivot *B* has mounted on it a former *H*, provided with a lever *J* for swinging it about its center in the forming operation. This former is turned to the radius to which it is desired to bend the tubing, the groove provided being of a circular section to match the diameter of the work. Attached to *H* is a clamp *K*, formed of a stirrup and thumb-screw,

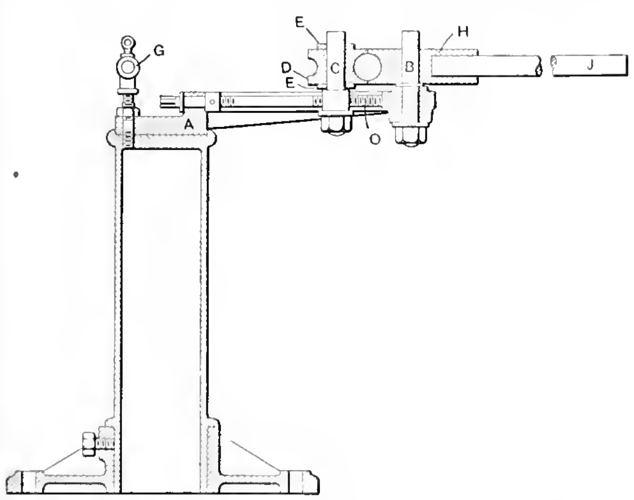

Fig. 1. Vertical Section of Monnet & Moyne Tube Bending Machine.

which clamp together serrated jaws, adapted to firmly hold the pipe and apply the pressure to it from all sides, so that it is not deformed. At the outer end of the frame-work (formed by bars *E* and brace *F*) is a support *L* for a bolt *M*, which is threaded into the right-hand end of the mandrel *N*.

In the peculiar construction of mandrel *N* lies the novelty of this bending process. As may be seen in Figs. 2 and 3, it has a solid body, but its left-hand end is composed of three articulated sections, forming a flexible extension of the full diameter of the hole in the pipe, so joined together as to be able to follow a curve of the shortest radius to which the tube can be bent. This is most plainly shown in Fig. 3.

The method of operation is as follows: The interior of the tube *P* is first cleaned with a wire brush. The tube is next placed in the groove of former *H*, and gripped tightly in the jaws of the holding clamp *K*. Mandrel *N* is next oiled and inserted inside of the tube, its position being so adjusted by the nut at the end of bolt *M* that the extremity of the solid body of the mandrel lines up with axis *X Y* of former *H*, as shown in Fig. 2. Guide block *D* is next adjusted by

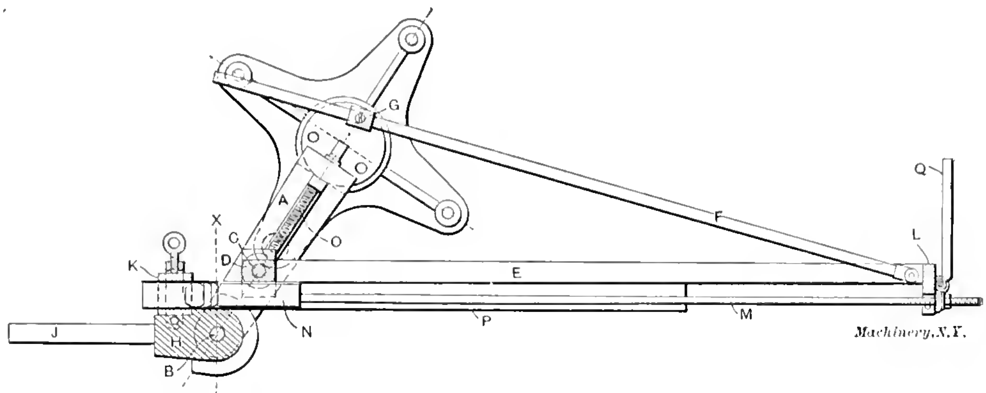

Fig. 2. Plan View of Machine, showing Forming Dies and Method of Holding the Articulated Mandrel.

means of a screw *O* to such a position that the distance from its face to the axis *X Y*, when it is brought in contact with the work, is equal to the diameter of the tube. This being done, pivot *C* and screw *G* are tightened, rigidly securing the framework formed by base *A* and members *E* and *F*.

The tube is now bent to the angle required, by operating handle *J*, which may be lengthened, as required, by the use of a piece of pipe of suitable diameter. When the tube has been bent to the required angle, the mandrel is withdrawn, being started by pressing on lever *Q*, after which it may be easily removed. The vise *K* is then loosened and the jaws removed, when the work can be taken out of the machine. The position of the mandrel during the bending is shown in Fig. 3.

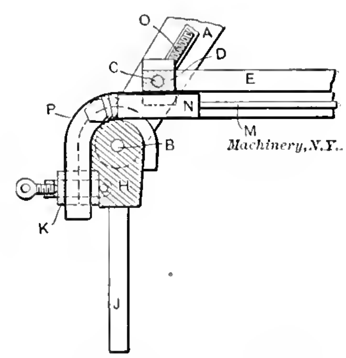

Fig. 3. Action of the Articulated Supporting Mandrel during the Bending Operation.

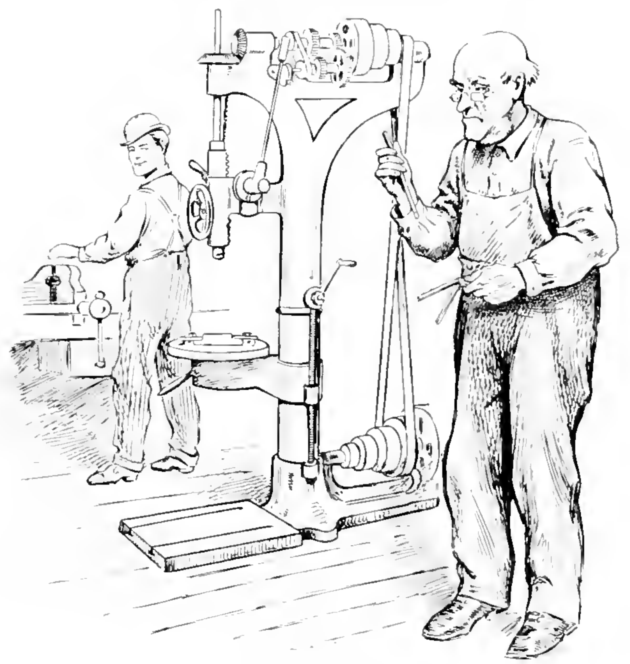
After the device has once been set up, it is only necessary to brush out the tube, clamp it into place, oil and insert the mandrel, and oil the guide, after which the work is bent and removed as previously described. Two operations per minute are easily possible on work of medium size. This, it will be seen, is a great saving over the old method in which it was required that the tube be filled with sand previous to bending. Even very thin tubes may be curved with this device, since the flexible mandrel prevents all possibility of the collapsing of the walls. The action is that of a drawing out of the fibers on the outside radius of the curve, combined, possibly, with a slight compression of those on the other side. Owing to the flow of metal which takes place, the material is hardened appreciably, thus increasing its resistance to deformation.

Different formers *H* are required for different radii of curvature and for different diameters of pipe. Special formers have sometimes to be provided for tubes curved in two places. Guide *D* may be used on all radii of curvature within the range of the machine, but must be changed for different diameters of pipe. The machine is made in five sizes, for the following maximum diameters: $\frac{3}{4}$, $1\frac{1}{2}$, $2\frac{3}{8}$, 4 and 6 inches, respectively. The smaller sizes are hand operated, as is the case with the $1\frac{1}{2}$-inch machine, of which we show diagrams. Larger sizes are operated by power. This machine is said to have found extensive application in automobile, boiler and railway shops in England and on the Continent.

HOW BILLY CAME TO USE TWIST DRILLS.

It was mighty difficult for old Billy Brown to give up his belief that a well forged and ground flat drill was not superior to a twist drill. He had been using flat drills for 40 or 50 years, beginning, in fact, long before the twist drills were originated, and when the younger hands came up and began to talk to him about some improvements of this or that kind, Billy Brown would smile in a superior way and explain to them that he was experienced in the business long before they were born. In particular, the flat drill was one of Billy Brown's hobbies, and unless the force of circumstances prevailed, he would never consent to use a fluted twist drill. Billy had been working in this same shop for so many years that he had become something of an old inventory, and the boss did not care much about Billy's queer ideas, particularly as he was a pretty good tool-maker, notwithstanding his opposition to new wrinkles. Billy's favorite boast was that no one in the whole shop could grind a flat drill just as he did it, as none of the others had the experience, because of using



"What ails the d—— thing?"

these new-fangled drills. Billy's boasting finally led to his downfall, and as usual a shop "kid" was the cause.

It happened one day that Billy was going to drill a ¼-inch hole on the upright drill press, and while he was grinding his drill, young Jimmy Smith went up to Billy's machine and crossed the driving belt. Billy put his drill into the socket and started off drilling, but, to his dismay, he found that his drill would not cut. The reverse motion of the drill spindle was not very apparent, because of its high speed, and then, too, Billy's eyesight was not as good as it was once. He hardened his drill again, and ground it very carefully, put it in the drill press, and still it would not work. A thing like this had never happened to Billy before, and he began to worry about not being able to grind a flat drill so that it would cut. So sudden was the loss of a boasted ability that Billy might well be pardoned for getting a little flustered.

He finally hardened his drill for another trial, and ground it even more carefully than before to the angles that had never failed him before, but strange to say the drill still would not make any impression whatever on the piece of work. Then he tried the work with a file to see whether it was not hardened, but it was nothing but ordinary soft machine steel. Then he tried the drill with his file and found that it was just as hard as it could be, so the fault evidently must be with the grinding of the drill. Then Billy totally lost confidence in himself, and went up to one of the younger men, explaining to him his troubles. Jimmy, the innocent, who was always around when he was not wanted, came up and looked at Billy's drill, and said: "Why, Billy, of course that drill wouldn't cut. Don't you see you haven't ground to the right angles at all?"

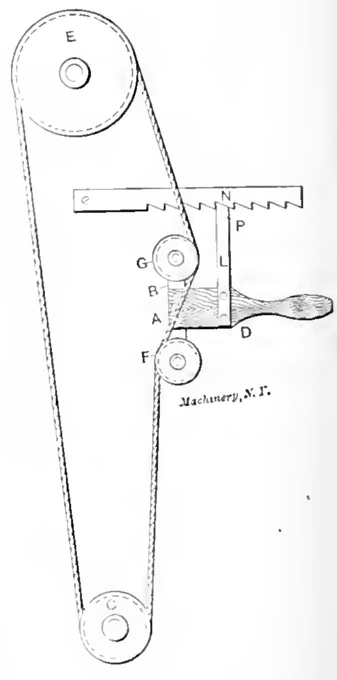
I won't try to repeat what Billy said to the apprentice, for that would not look good in print, but Jimmy, unabashed, snatched the drill from Billy and ran over to the grindstone, pretending that he was grinding the drill to its proper angles, while, of course, he left the cutting surfaces undisturbed. During this grinding operation, however, somebody kindly put the belt right again on the drill press, and Jimmy, placing the drill in the socket, fed it down and it cut through the piece of work as though it were butter. Billy stood dumbfounded, and that noon, he went up to the foreman and said: "I guess I am getting too old to work in the shop." The foreman, however, who by this time had heard the story of Billy's trouble with the drill, persuaded Billy that he could not spare him, and Billy, greatly gratified to hear that, concluded that thereafter he would use a twist drill, and now Billy thinks that twist drills are far superior to the old flat drills.

I often think of Billy and his flat drill hobby. We laugh at him and his ignorance or perversity, but aren't most of us about as foolish on some pet notion? We often need a jolt to knock out old delusions, so that new ideas can get in. Billy got a hard one, but the old man, after all, was more sensible than lots of young men would be.

* * *

A BELT TIGHTENER.

An interesting tightener for a small belt or rope drive is shown in the *Practical Engineer*. It often happens that it is desirable to arrange one or more machines, so that they can be conveniently stopped and started, without reference to the running of the rest of the machinery. Of course, this problem is usually solved with friction clutches, loose pulleys, etc., but there sometimes occur cases where a pulley is driven directly from the line shaft and there is no room to put in any of these extra appliances. In a problem of this kind, where it is desired to arrange a drive for the machine so that it could be stopped and started at any time, the arrangement shown in the accompanying illustration was devised. In the cut, *C* is the driving and *E* is the driven pulley. The pulley *E* may be started and stopped by means of the twin idlers *F* and *G*, which are mounted on a bar of iron, *B*, of suitable size, the pulleys running on studs, screwed into this bar. The bar *B*, in turn, is fastened to a wooden piece *D*, which, with the bar *B* is pivoted on a suitable stud at *A*. Thus it will be seen, that when the handle on the end of *D* is pressed down, it will tighten the belt without a very great swing of the idlers, and when the handle is lifted it will release the belt and allow it to hang free from the bottom pulley *C*. The belt is held at proper tension by means of the locking device shown, consisting of the iron bar *L*, attached to the block *D*, the upper end *P* of which engages in suitable notches in bar *N*, and holds the idler frame wherever set. This locking device is conveniently released by simply raising up bar *N*. It is evident of course that on a large belt, a certain amount of power is wasted by this arrangement, and it may not be advisable to use with large belts.



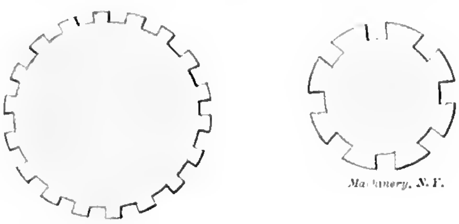
* * *

In almost every shop and factory in the country, men and women are just aching to be interested in the firm's welfare, if the employers would only let them. Any man or woman would rather be interested in his work than not be, for when the heart is in it, work is easy, and easy work is work done right.—*The Silent Partner*.

ITEMS OF MECHANICAL INTEREST.

GROOVED SHAFTS FOR MOTOR CARS.

The Lanchester Motor Co., Ltd., of Birmingham, England, employs a rather interesting means of securing driving parts of automobiles to their respective shafts. The principle employed is clearly illustrated by the two sections of shafts shown in the accompanying cut. The shafts are grooved as indicated, and the corresponding female parts are provided with grooves to fit. This system of connecting the shafts with the rotating parts was adopted by this company over eight years ago, and has stood the test of long time of service. In

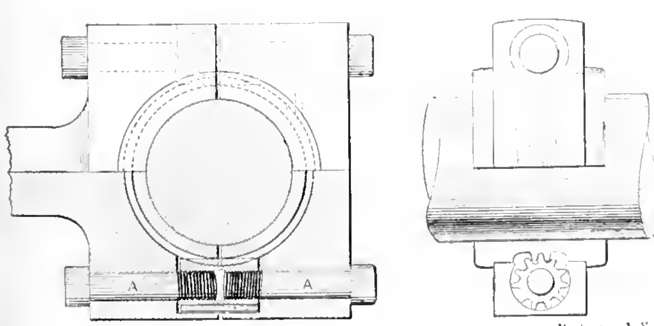


Grooved Motor Car Shafts over which Hubs with Corresponding Grooves Fit.

the first place, the use of this kind of shaft was restricted to cases where keys were awkward or difficult to arrange, but the results proved so satisfactory that in the modern Lanchester car this system of connecting shafts and rotating parts has been adopted almost exclusively for all cases where there was any reasonable gain from having the shaft and the rotating parts so firmly connected, and the system has also been adopted by several other British motor car firms. It would appear, on first sight, that this kind of joint would be rather expensive, but it is claimed that the shafts and the corresponding holes can be produced comparatively cheaply. The slots are cut to the necessary depth on a milling machine, with ordinary milling cutters, and the corresponding female part is cut with a series of broaches. The first cost of the broaches is, of course, rather high, but the amount of work they will perform before worn out is so considerable that the unit cost per each detail finished is very small. The actual fit of the parts takes place on the external diameter of the shaft. The grooves are so milled that they will provide for as close a fit as possible on their sides, but a small clearance is allowed in the bottom of the grooves.

TIGHTENING DEVICE FOR CONNECTING-ROD BRASSES.

An automatic device for connecting-rod brasses has recently been brought out by Messrs. Tangyes, Ltd., Smethwick, England. This device is shown in the accompanying cut, which is taken from the *Mechanical Engineer*, issue of February 28. The bearing brasses, instead of being fixed in the usual manner, are given freedom to rotate, when too loose, under the friction of the crank-shaft, and this rotation of the brasses is utilized to effect the tightening of the screws *A* in the con-



Rod Connection in which the Wear of the Brasses is Automatically taken up.

necting-rod end and its cap. On the outside circular surface of the bearing brasses a worm thread is cut as shown, and small worm-wheels are arranged in recesses in the cap and connecting-rod end. The holes through these worm-wheels are threaded right- and left-hand to engage with the tightening bolts *A* as shown. By this arrangement it is evident that if the brasses revolve slightly, they will cause a slight motion of the small worm-wheels, and this in turn will tighten up the cap of the connecting-rod against the end, by means of the right- and left-hand threads in the small worm-wheels. Should the bearing brasses be loose enough so that the friction between the crank-shaft and the brasses has a tendency to effect a rotation of the brasses, the pressure between the head and cap of the connecting-rod being insufficient to hold the brasses in place, a rotary motion of the brasses will take place and the worm-wheels will be rotated in the proper direction for drawing the screws inward, thereby tightening up the cap. When the pressure of the cap is sufficient to prevent the rotary motion of the brasses, these will remain stationary, and the crank-shaft will revolve as usual in its bearing. It will be seen that the bearing is thus automatically tightened whenever it becomes loose, and accident from the unfastening of the bearing is rendered impossible.

A SIMPLE CALCULATOR.

The accompanying cuts, reproduced from *Der praktische Maschinen-Konstrukteur* show a rather interesting and ingenious calculator of a simple and cheap design, intended for rapid multiplication. The construction is easily comprehended directly from the cuts. There are five stationary slides, provided with numbers from 1 to 99, and between each of these

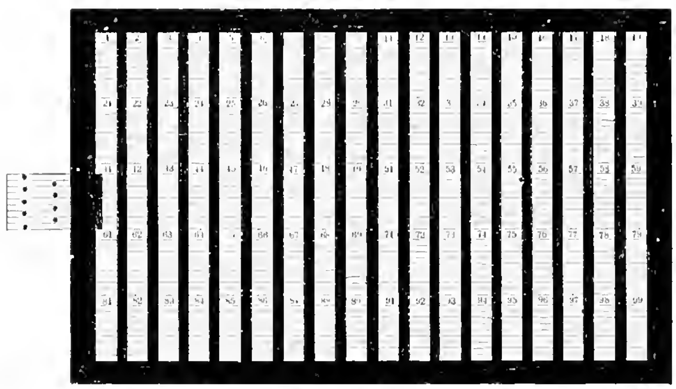


Fig. 1. Calculator for Rapid Multiplication.

rows of numbers there are nine movable slides which are numbered at the ends, 1, 2, 3, 4, etc. These movable slides are provided with figures, placed in a certain way, so that, by setting the slide, as indicated in Fig. 2, the product of the number on the stationary slide, and the number at the end of the movable slide can be read off at once; thus, for instance, 4×44 is 176. In the case in Fig. 2, the number 6,543 is to be multiplied with any of the numbers on the stationary slide. The product of each of the figures in 6, 5, 4 and 3 times 44 will be found directly under 44, as 132, 176, 220 and 264; the

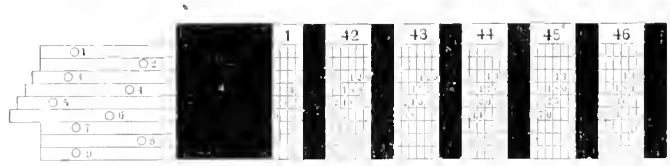

Fig. 2. Method of using the Calculator

movable slides being set in proper order, all that is necessary to get the multiplication is to add, the same as in ordinary multiplication, getting the product 287,892. It is, however, not necessary that the one number with which another is multiplied should have only two figures. It is possible to figure with factors having four figures a great deal easier than by ordinary multiplication. Take a case, for instance, of $6{,}543 \times 4{,}546$. In this case, 4,546 is divided up in two parts, 45 and 46, and we have:

$$6543 \times \,..46 = \quad 300978$$
$$6543 \times 45.. = 294435$$
$$\overline{29{,}744{,}478}$$

The products of each part of the number 4,546 with 6,543 are found directly on the scale in Fig. 2, by simple addition, and the time required for multiplication is but a fraction of that ordinarily necessary, if we multiply in the usual way. The instrument is made by the Rechenapparate-Fabrik Fr. Schneider, München, Germany.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,

NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

MAY, 1908.

PAID CIRCULATION FOR APRIL, 1908, 23,179 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

A FAULT OF HANDLING FOREIGN TRADE.

It is a more or less common fault of machinery dealers to become indifferent to the fate of machines sold, after they are once accepted and paid for. This applies with special force to foreign trade, and one very serious mistake made by a few of our American machine tool builders is their selection of indifferent foreign representatives. The builder of a machine tool should not forget that the ability to handle it so as to secure its maximum efficiency is fully as important as the design itself. Very often the fate of a new design depends as much on the way the first operator handles it as on the general design. In a foreign field, where conditions are quite different from those under which the machine was designed, it is specially desirable that prejudice be not aroused because of misunderstanding the various functions of a new machine. We were deeply impressed with this view by a letter lately received from a foreign subscriber who is trying to do deep-hole drilling with certain American equipment. He wrote, in part, as follows:

"We depend greatly on American machine tools in this country [Belgium], but we never get, during the first months, the full value of the machine we buy. Everybody has to go through costly experiments before he learns to use the machine to its best advantage. The agent will sell you everything you order, but he does not take the least interest in whether you get the right tool for your use or not. He rarely knows the machine sufficiently well to point out what you want to know. He will give you a catalogue *printed in English*, and that is all. Lucky is the man who understands this language!"

This man wrote to us for specific instruction on deep-hole drilling that would enable him to use the equipment he had purchased. Is it not a serious condition of affairs when a foreign buyer and user of an American product finds it necessary to write to an American trade journal for help rather than to appeal to the manufacturer himself? This man probably felt that there was little opportunity of getting help from that direction, because he dimly realized that his equipment was not well-suited to his work. But why was not the proper equipment sold to him? Simply because the agent did not know his business, or, if he did know it, he apparently did not care enough about future sales to help this man out of his predicament.

OVERTIME, A CASE OF MISDIRECTED ENERGY.

A few weeks ago there was some discussion in Great Britain regarding the practice of certain firms working their men overtime, while most firms were laying off help, not having been able to run full time. The trade unions contended that because of the number of unemployed, firms having a greater amount of work to do than could be performed by their regular workmen in the stipulated number of working hours, should employ additional help rather than work overtime. In a case like this it may be difficult to say whether or not the contention of the labor unions was reasonable, for the rush in the shops which were working overtime may have been only temporary, and it might have been inadvisable to hire new help only to lay off such men within a few weeks.

However, it cannot be disputed that our industrial system under which men work in the shops one year, say, for ten, twelve, and even thirteen hours a day, only to find themselves the next year either thrown out of employment altogether, or only working five days a week, seven to eight hours per day, is very unsatisfactory. It is greatly to be doubted if this way of conducting a manufacturing business is more profitable than if the work were divided more evenly over the times of prosperity and depression. The majority of well-established firms could, without injury to their business and without fear of the future, prepare somewhat more than is common in this country for the day when the orders come in faster than the facilities of the shop enable them to be filled. If this were done, there would be less feverish overtime work in prosperous times, and during times of depression the results all around would be less disastrous. The great sums paid out for overtime work could be partly saved, and the saving invested to good advantage in keeping things going at a more even pace all the time. It may be said that this proposition is impracticable, but if it were, the general uniform balance of industrial conditions which is maintained on the European continent would not be possible. We can learn a profitable lesson from the way that such conditions are handled across the water—a lesson that would be greatly to our advantage. It may be added, however, that there are some indications that certain Continental firms are on the verge of adopting our methods, and running their works on the hand-to-mouth plan, but they will, without doubt, find this policy a decidedly inferior one.

* * *

INATTENTION.

The writer has just returned from an auction sale of tickets where large signs were displayed stating that, in every case, bids were a premium to be paid in addition to the basic price of tickets. To make assurance doubly sure, the fact was announced and explained from the platform. In the face of all this, no less than three persons bid in seats, and prepared to pay for them only the specified amount of the premium. Such experiences are repeated everywhere and every day, in the shop, the office, the school. They seem to be almost chronic. It is hard to define the cause. Is it due to mere inattention, or heedlessness, or to real lack of comprehension, or what? At all events, its results are disastrous to the prospects of many a young man whose mind is not upon his work.

Attention to business is the first sound law of success. The boy who does not have to be told twice, who carries "the message to Garcia," and brings back what he was sent to get, is the one who counts. It would be interesting, though saddening, to discover the aggregate annual loss in the average shop through inattention: The things done over because the first attempt was wrong; the things done wrong because the workman was not attentive enough to learn how to do them right; the piece spoiled because the feed was jammed in too deep; the drawings ruined because of miscalculation or error in layout. It would be a sorry exhibit. We are all looking for the boy who thinks; for him there is a prospect, but he is scarce in these days of the multitude who seem to think that the world owes them a living. If our education is to accomplish anything of which we can boast, it must create a feeling of personal responsibility and an attitude of careful attention.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

Official statistics place the number of automobiles in use in Germany at a figure of 36,022. Of these nearly 1,800 are trucks. Of the vehicles intended for carrying passengers more than half were used for business purposes.

The Cunard steamer, *Mauretania*, crossed the ocean last March during an eastward voyage, at an average speed of 24.42 knots, which is the highest speed ever attained by any steamer across the Atlantic.

The imports of Austrian petroleum into Germany are constantly increasing, while the imports of petroleum from Russia have decreased considerably. In the year 1902 Germany imported 16,800 tons of petroleum from Austria, and in 1906 the figure was 59,800 tons, while during the first half of 1907 the imports exceeded 45,000 tons.

A Dutch scientist, Kamerlingh-Onnes, has succeeded in producing helium in solid form; in other words, in freezing helium. There is now not a single element known which cannot be transformed into solid form. The temperature at which helium will freeze is claimed to be —272 degrees C, which is only one degree C. over absolute zero.

In the *Consular and Trade Reports* for February 20, it is stated that the tariff duties on catalogues, price lists, and advertising matter of similar character, which, as we mentioned in a previous issue, have hitherto been imposed by the commonwealth of Australia, have been removed, and that matter of this character will hereafter be admitted to the country free of duty.

The Italian ambassador at Washington has given out official information to the Department of State regarding an international exposition, to be held at Rome and Turin, Italy, in 1911, in commemoration of the 50th anniversary of the proclamation of the kingdom of Italy. The exposition in Rome will include art and history, and the Turin exposition will be devoted to the productive industries.

A new motor record, according to the *Practical Engineer*, was established on the Brooklands motor tracks in England by a 60 H. P., 6-cylinder Napier car, which covered 50 miles in 35 minutes and 15 seconds, and 150 miles in one hour and 46 minutes. In two hours the space covered was 169 miles, the average speed for this time having been 84½ miles an hour. The previous best record was 151 miles in two hours.

The preliminary work for the electrification of portions of the main lines of the Swedish State railways, to which we have referred several times, has now progressed to the point where orders have been placed for some of the machinery for the power stations. To begin with, two water turbines, designed to deliver 12,500 H. P. each, have been ordered. These turbines will work with a head of 100 feet, and will deliver the required power at 187 revolutions per minute.

Flying machines built according to the same design as the Farman prize-winning aeroplane, fitted with 50-H.P. motors, can now be bought in England at a price of $6,000, or in America for $8,400, the latter figure including the import duty to this country of 40 per cent *ad valorem*. In this particular case the tariff seems to fill its place of protecting an infant industry, inasmuch as the manufacture of flying machines surely still is in its infancy in the United States.

We mentioned in our Engineering Review section last month that an international industrial exhibition is to be held this summer in Toulouse, France. According to *Industritidningen Norden*, the Permanent German Industrial Exposition Committee has pointed out that it does not seem advantageous for German manufacturers to take part in this exhibition. The reason is not given, although it may be assumed that the scope of the exhibition and its advertising value would not warrant the expense incurred by sending machinery for exhibition.

A radical departure along the line of making use of the surplus heat from electric generators will be made at the large electric power station at Trollhättan, Sweden. We have previously mentioned that the equipment will consist of generators which will carry a normal load of 10,000 H.P. The heat evolved from the generators, it is estimated, will be equivalent to 400 H.P. In order to prevent this heat from escaping into the engine room, a partition of iron has been placed within the machine, and each generator will be furnished with a fan so placed that it will draw cold air through a duct from the outside atmosphere. The air then passes through the generator, and will be driven in its heated state into various parts of the building where artificial heating is required. It is believed that sufficient heat can thus be supplied from the generators for heating all the adjoining rooms and buildings by hot air.

The growth of the ocean steamship continues. The *Lusitania* and *Mauretania* are not long to hold the palm for great size. The White Star Co. has made plans for two new ships 1,000 feet long and of 60,000 tons displacement. These new monsters, however, will not be ocean greyhounds. They will be comparatively slow boats, the promised speed rating being about 20 knots. The economy of the large vessel where plenty of business is assured is fully recognized, and the probabilities are that even larger boats than 1,000 feet length will be built within the next twenty years. Mr. Lewis Nixon, a naval expert of some reputation, prophesies ocean steamers a quarter of a mile long, driven by producer gas engines. The new White Star boats will be driven by reciprocating engines and turbines, the turbines being low pressure and driving screws in the center while the high pressure reciprocating engines are connected to side screws.

An interesting instance of the bending of a large steel pipe in a short time, by heating with an oil burner, is mentioned in the *Iron Trade Review*. The work was carried out in an eastern mining shop. A 10-inch steel pipe, 18 feet in length, was bent to right angles with a radius of 30 inches, without filling with sand or other material, in one hour and ten minutes. Three men were required for the work. One end of the pipe was fastened by wedges, and at the other end of the pipe a tackle was attached for pulling the pipe at the proper time. The burner was then applied to the pipe, at the point selected for the beginning of the bend, and a 20-inch section was heated, this operation requiring about six minutes. Then the pipe was pulled to the desired radius, the wedges were loosened, and the pipe was shifted for bending further down on the arc, until it was bent the required 90 degrees. With an air pressure of 60 pounds, the entire oil consumption was about 2½ gallons.

Fly-wheels with rims of reinforced concrete are a novelty which, according to *Industritidningen Norden*, has been introduced at a pumping station at Zwartkopjes in Transvaal, where ten pumps are installed, each having fly-wheels of a diameter of about 14 feet. These fly-wheels are provided with cast iron hubs, to which are screwed 16 spokes made of 4-inch pipe. The rim consists of a casing of sheet iron, in which is placed the actual rim of reinforced concrete, having a section 13 inches square. The concrete is reinforced with ¼-inch steel wire. The rim weighs about 6,000 pounds, and the whole fly-wheel weighs about 8,000 pounds. On the ten fly-wheels, this construction permitted a saving of nearly $10,000, most of which saving, however, is due to the enormously high transportation costs that would have been necessary to pay for the transport of fly-wheels of this size, if they had been made

entirely of cast iron, and shipped to the pumping works. Under the present conditions the rims, of course, were completed right at the pumping station.

A novel gas engine starter has been developed by the Oil City Gas Engine Co., consisting of a flash boiler furnishing superheated steam at high pressure which may be used in a gas engine in the same manner that compressed air is used for large engine units. According to a description in the *Engineering Record*, the boiler is of the coil type of small capacity, and is heated by a large gas burner. When in operation, the coil is heated to a red heat, and then a small quantity of water is injected by a hand pump. This water instantly flashes to steam of from 400 to 500 pounds pressure, and is then admitted to the engine cylinder. The first heating of the coil will furnish sufficient steam for turning the crank a number of revolutions, and if the engine then should fail to get in operation, a second heating of the coil will give another number of turns, and so on. A safety valve set at 500 pounds pressure protects the device from excessive pressure.

The extent of the automobile business in the United States can be comprehended from some figures which have been compiled by the Association of the Licensed Automobile Manufacturers for the year 1907. It is stated that the number of automobile factories amounts to more than 200, but it is extremely difficult to get any figures in this respect, as many so-called manufacturers of automobiles work on a very small scale, merely assembling a few machines from parts bought from part makers, and other factories, so far, only experiment. The number of employes in the factories is estimated at 58,000, the capital invested, $94,000,000, and the value of the product for the year mentioned, over $105,000,000. The increase in these last three years is remarkable. In 1904 the number of factories was given as 121, the number of employes as about 10,000, the capital invested as $20,500,000, and the value of the product as $26,650,000, approximately.

A writer in *Stahl und Eisen* states that China has enormous possibilities as an iron-producing country. Although as yet the country has not been thoroughly explored, enormous deposits of high grade ore are known to exist. It is estimated that the total ore resources are not much less than those of the United States. Coal is also available in fairly extensive quantities. The Chinese, however, have passed a law preventing foreign capital from being employed directly in mining operations in China. Foreign capital can be used only for the purchase of stock in Chinese companies. While this provision is by no means cheerfully accepted by foreign capitalists who see an opportunity for exploitation on a large scale in the newly-developed Chinese ore deposits, this provision may be a very wise one from the Chinese point of view. It is at least in harmony with the time-honored idea of protection, which the Chinese applied for many centuries before the western world conceived of this efficient means for the stifling of trade and the building up of monopolies.

On March 19, the two long cantilevers of the Blackwells Island Bridge across the East River, at New York City, were brought together above the middle of the stream. As regards capacity, this bridge will be the largest cantilever structure in the world, although there are some cantilever bridges that have a considerably longer span between the towers. The bridge will be double-decked and is 8,419 feet in length between terminals. The length of the main span is 1,182 feet (the span of the famous Forth Bridge in Scotland is 1,710 feet, and the span of the Quebec Bridge, one cantilever arm of which recently collapsed, is to be nearly 1,800 feet). On the Blackwells Island Bridge there will be a roadway wide enough for four three-horse teams to pass abreast. On each side of this roadway there will be two trolley tracks. The upper deck will carry two elevated railroad tracks, and two footbridges. The six tracks across the bridge are estimated to have a capacity of between 400,000 and 500,000 passengers a day. The total cost of the bridge, it is estimated, will be more than $20,000,000.

ELECTRIC TRANSMISSION OF PHOTOGRAPHS.

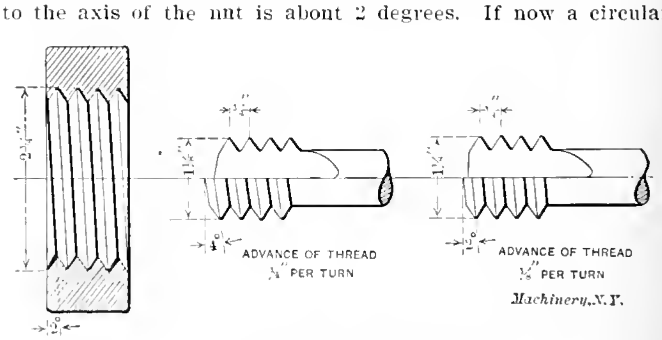
Electrical Engineering, January 2, 1908.

In the May, 1907, issue of MACHINERY, engineering edition, the principles of the Korn system of transmitting photographs by means of electricity, were explained. Another system for transmitting photographs electrically has been worked out by a Frenchman, Mr. Pascal Berjonneu. During experiments undertaken lately in Paris, wires were connected so that the photographs were transmitted through the line from Paris to Marseilles and back again to Paris, a distance of over one thousand miles. Pictures were successfully transmitted over this line. The apparatus was also connected to a wireless telegraph outfit, and the receiving apparatus placed in the same room as the transmitting apparatus, and the pictures were transmitted from the one to the other, wirelessly, this being the first time that this has been done. The new system differs from the Korn system in that use is not made of selenium. The principle of this system is that the picture to be sent is etched on a thin metal plate, which is rolled up to form a cylinder, and is mounted on a traveling drum, similar to that on a phonograph. An insulated platinum point is placed in front of the drum, so that it will come in contact with those portions of the cylinder only which stand in relief, that is, those portions which have not been influenced by the etching process. When the drum revolves, and contact is made between the metal plate and the platinum point, a current will pass through the transmitting wire for longer and shorter periods. The receiving apparatus consists of a film, sensitive to light, mounted on a cylinder, and a ray of light, controlled by a small shutter moved by a magnet through which the current passes, falls upon the film, thus reproducing the original picture. The reproduction, of course, consists of lines of dots and dashes corresponding to the etching.

CIRCULAR CHASERS FOR INTERNAL THREADING.

Mechanical Engineer, March 20, 1908.

Circular chasers for internal threading, such as shown in Fig. 2 of the accompanying cut, have been more or less used instead of ordinary inside thread tools, but when the difference in diameter between the hole to be threaded and the diameter of the chaser itself is considerable, there is a serious objection to the use of these internal chasers, particularly on coarse pitches. Referring to Figs. 1 and 2, it is evident that if the nut to be threaded is provided with four threads per inch, and the diameter of the thread equals 2¼ inches, then the actual angle of the thread with a line perpendicular to the axis of the nut is about 2 degrees. If now a circular



Figs. 1, 2 and 3. Section through Nut, Objectionable, and Improved Forms of Circular Chasers.

chaser is made, being 1¼ inch in diameter, and having four threads per inch, it will be seen that the angle of this thread with a line at right angles to the axis of the chaser is 4 degrees. It is plain that when such a chaser is used for cutting the thread in the nut shown, there will be an interference between the part of the thread in the chaser which is below the cutting edge and the thread already cut in the nut, the side of the thread in the chaser rubbing up against one side of the thread in the nut. In order to overcome this defect, and at the same time offer the advantages inherent in the chaser form of thread-cutting tool, S. N. Brayshaw, Mulberry Street, Hulme, Manchester, England, has brought out an improved form of circular chaser. For cutting a nut of the kind shown in Fig. 1, a chaser such as shown in Fig. 3 would be used. In this, the flute or notch in the chaser which provides the cutting edges, is milled first, before any threads

are cut, and then the threads are cut by a milling cutter in a thread-milling machine with such a lead that the angle of the thread in the chaser will be the same as the angle of the thread in the nut to be cut, the shape of the thread, of course, still remaining the same as before. The thread is not a continuous thread, but each thread simply extends around the chaser from one edge of the flute or groove to the other. By this means a chaser is provided which will cut the thread required without interference. It is clear, of course, that different chasers will have to be made for various internal diameters, but on fine pitches, in particular, each chaser can take in a considerable range of different diameters without meeting with the objections that would prevail if the chaser simply had a thread of the regular pitch cut continuously around it.

THE QUEBEC BRIDGE DISASTER.

The chief conclusions of the royal commission, appointed by the Canadian government to investigate the cause of the failure of the Quebec Bridge, which collapsed on August 29, 1907, have been submitted to the Canadian Parliament. The summary of the findings of the commission are as follows:

A. The collapse of the Quebec bridge resulted from the failure of the lower chords in the anchor arm near the main pier. The failure of the chords was due to their defective design.

B. Stresses that caused the failure were not due to abnormal weather conditions or accident, but were such as might be expected in the regular course of erection.

C. The design of the chords that failed was made by P. L. Szlapka, the designing engineer of the Phœnix Bridge Co.

D. This design was examined and officially approved by Mr. Theodore Cooper, consulting engineeer of the Quebec Bridge & Railway Co.

E. The failure cannot be attributed directly to any cause other than errors in judgment on the part of these two engineers.

F. These errors of judgment cannot be attributed either to lack of common professional knowledge, to neglect of duty or to a desire to economize. The ability of the two engineers was tried in one of the most difficult professional problems of the day and proved to be insufficient for the task.

G. We do not consider that the specifications for the work were satisfactory or sufficient, the unit stresses in particular being higher than any established by past practices. The specifications were accepted without protest by all interested.

H. A grave error was made in assuming the dead load in the calculations at too low a value and not afterwards revising this assumption. This error was of sufficient magnitude to have required the condemnation of the bridge even if the details of the lower chords had been of sufficient strength, because, if the bridge had been completed as designed, the actual stresses would have been considerably greater than those permitted by the specifications. This erroneous assumption was made by Mr. Szplaka and accepted by Mr. Cooper and tended to hasten the diaster.

I. We do not believe that the fall of the bridge could have been prevented by any action that might have been taken after August 27, 1907. Any effort to brace or take down the structure would have been impracticable, owing to the manifest risk of human life involved.

J. The loss of life in August, 1907, might have been prevented by the exercise of better judgment on the part of those in responsible charge of the work for the Quebec Bridge & Railway Company and for the Phœnix Bridge Company.

K. The failure on the part of the Quebec Bridge & Railway Company to appoint an experienced bridge engineer was a mistake. This resulted in a loose and inefficient supervision of all parts of the work on the part of the Quebec Bridge & Railway Company.

L. The work done by the Phœnix Bridge Company in making the detail drawings and in planning and carrying out the erection, and by the Phœnix Iron Company in fabricating the material was good, and the steel used was of good quality. The serious defects were fundamental errors in design.

M. No one connected with the general designing fully appreciated the magnitude of the work nor the insufficiency of the data upon which they were depending. The special experimental studies and investigations that were required to confirm the judgment of the designers were not made.

N. The professional knowledge of the present day concerning the action of steel columns under load is not sufficient to enable engineers to economically design such structures as the Quebec bridge. A bridge of the adopted span that will unquestionably be safe can be built, but in the present state of professional knowledge a considerably larger amount of metal would have to be used than might be required if our knowledge were more exact.

O. The professional record of Mr. Cooper was such that his selection for the authoritative position that he occupied was warranted, and the complete confidence that was placed in his judgment by the officials of the Dominion government and the Phœnix Bridge Company was deserved.

DIE SINKING AND ENGRAVING MACHINES.

The accompanying cuts, Figs. 1 and 2, show some interesting die-sinking and engraving machines, constructed by Messrs. Thomas Auty & Co., London, England. These machines are employed in a great variety of die-cutting work, and for engraving, and are used, to a great extent, in the British government shops for cutting the dies for various parts of rifles. The half-tone, Fig. 1, shows what is called the 42-inch Patent Die-sinking machine, which is the latest design brought out. The line cut, Fig. 2, shows exactly the same principle applied to a smaller machine, called the 27-inch die-sinking and engraving machine. The principle of these machines is that they copy from an enlarged former or model the form desired, reducing it by means of the pantograph arrangement shown.

The work to be operated upon is clamped to the table A under the head C. This head carries a milling cutter, constrained to follow the exact movement of the tracing-pin carried by head D along the form. The operating mechanism is carried on the table A, and consists of a pivoted arm B, the

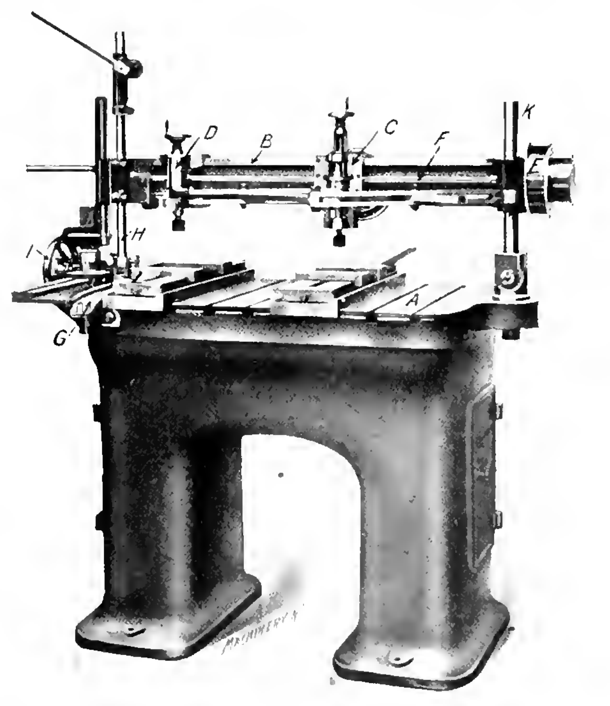


Fig. 1. Thomas Auty & Co.'s 42-inch Patent Die-sinking Machine.

end of which can be traversed in a horizontal plane around the axis of stud K. This arm is carried at its outer end by the roller L on the end of stud H, traveling along the circular path G of the machine table. The horizontal movement may be effected either directly by hand or mechanically through a pinion and rack, connecting with the hand-wheel I. As will be seen from the cut, at the right-hand end of the machine the arm B is carried by the stud K, which is, in turn, connected with the table by a universal joint, which permits the arm to rise and fall in a vertical plane, so as to accommodate itself to any irregular surfaces which there may be on the form, while, at the same time, the exact proportion between the cutter and the tracing-pin is maintained through the pantograph. By traversing the tracing head D longitudinally along the arm, a third movement is obtained, which imparts a relative, but reduced, motion to the cutting head C. The cutter spindle of head C is driven through a longitudinal shaft F, from the pulley E at the right-hand end of the machine. The drive in the head is through hardened steel helical gearing, carried in the slide itself. The arm B is secured to the stud K by means of a set-screw, the point of which

enters into a spline, as shown in the line cut, Fig. 2, so that the height of the arm may be varied according to the height of the work operated upon. The left-hand end of the arm is provided with a spring support on the end of rod H which takes the weight of the arm when vertical movements are required. This spring support is provided with the roller, as already mentioned. A thumb-screw is provided for preventing the spring from acting, thereby allowing the full weight of

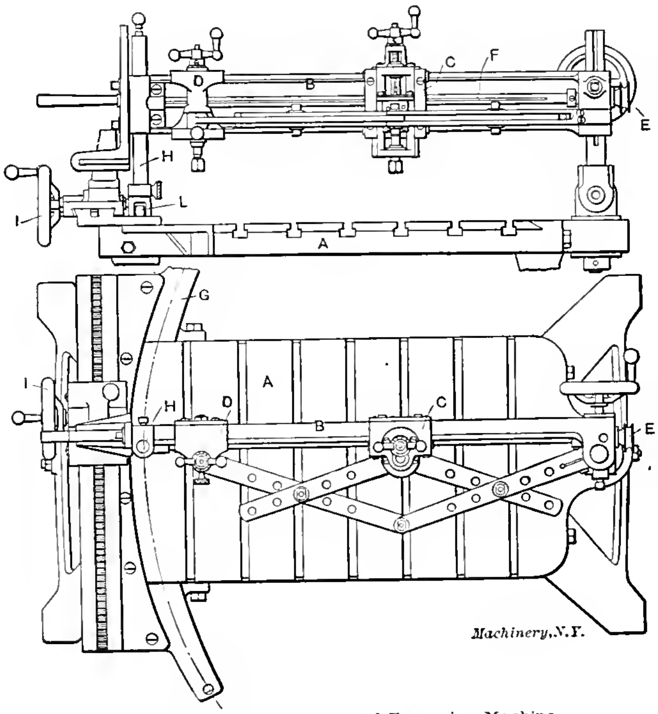

Fig. 2. 27-inch Die-sinking and Engraving Machine.

the arm to bear upon the work when necessary. In the machine in Fig. 1, reversible automatic feeds may be provided for both the longitudinal and transverse motion if required. The power is transmitted to the arm hand-wheel by a shaft in the back of the machine, driven through suitable gearing from the main shaft. The transverse movement is connected through a universal joint with the free end of the arm.

THE MANUFACTURE OF MACHINE TOOLS IN GERMANY.

Abstract of Report of Capt. Godfrey L. Carden, Special Agent of the Department of Commerce and Labor.

American manufacturers who have not heretofore attempted to analyze the European market, will find that German machine tool shops are turning out many machines that for practical shop work serve the purpose as well as the average American tool, and unless the German manufacturer can buy American machine tools cheaper than those made in his own country, he may be expected to patronize his own market. The majority of American manufacturers, however, can undersell the German tool manufacturers in German territory, despite the lower wages paid in Germany. This condition is due to the specializing and high standard of shop efficiency prevalent in America. Very few German establishments have attempted so far to confine themselves to a few lines of tools or to one type of machine, which specializing, of course, would greatly diminish the cost of production.

Many of the statements in the report are of a character that seems like the very rudiments of business requirements, but Capt. Carden says that he has been struck with the apparent ignorance on the part of many machine manufacturers in America, even men who are presidents of prominent concerns, of what constitutes the latest and most up-to-date practice in Europe. It is this very lack of knowledge which has probably had much to do with the failure of many American machine houses to accomplish more in the outside world. There is, however, some excuse for this, when we consider the great stress under which the home firms have been engaged during the last few years in the attempt to meet the enormous domestic demand. Under such conditions, there has been little incentive for many of our houses to study foreign markets.

The rate of wages has increased in German shops in recent years. The average wages paid at one large establishment is about 17 cents per man per hour. (In one large machine tool building firm in the United States the average wages paid per man per hour is 22 cents.—EDITOR.) The average working day is nine hours. The introduction of gages into Germany, as turned out by some of the best American firms, is serving as a potent factor in the development of the efficiency of the German workman. Measuring instruments are manufactured in Germany, but they are not recognized as equal to the best produced in America. There is very little competition in Germany on the part of English firms.

What concerns American manufacturers vitally is the fact that the Germans are putting more engineering thought into their designs than at any time in the history of tool construction. The mechanical skill still holds in favor of the Americans, and will probably remain to their credit in the case of those American firms which are paying close attention to the drafting-room. When tools from American firms are introduced into Germany, every feature of those tools will be the subject of close scrutiny, and if engineeering skill, backed up by careful mathematical deductions, make it possible to produce a better machine, the Germans will be among the first to discover the fact. The American firm need not, therefore, be surprised, if, in a very short time, there is found on the market a similar German tool, possibly American in its original idea, but essentially German in its improved form. It is therefore absolutely necessary for any American firm which proposes to hold its own in foreign competition, not to ignore technical education.

A visit to the A. Borsig plant, near Berlin, is referred to in the report. This plant employs about 5,000 men, and the managers have learned, to the highest degree, how to get the maximum work out of the machine tools. It would be surprising to many American manufacturers, says Capt. Carden, who believe that Americans alone understand shop efficiency, to take a walk through these shops, and he says that a glimpse of the workings of this particular plant would cause a realization of what there is ahead of America in foreign competition.

Practically one-half of the machinery production of Prussia is for export. The French have not been inclined for many years to patronize the German houses, but the merit of German production has forced itself even on the French buyer. On the whole, however, the Germans do not as yet understand in the great majority of cases how to operate the greatest number of machines with the least number of men, and the greatest improvement possible in German machine tool building is enhanced shop efficiency. The Germans, however, are learning fast in this respect, and if we propose to keep ahead in shop efficiency and in our ability to run a shop with the least possible number of men, there must be a thorough training of all those employed in the shop. In Germany, schools for apprentices are often established in the shops. These schools are presided over by men directly interested in the shop work. The apprentice works in the school-room either early in the morning, when he first comes to work, or at some other hour in the day, and the time devoted to the school-room is deducted from his wages. The education of the apprentice is carried along on carefully and well-thought-out lines, and always with the view of developing a highly skilled and technically trained man, developed, of course, particularly along the lines of work carried on by the firm employing him.

* * *

In a previous issue we referred, in a short note, to the tremendous volume of business done in the moving picture industry. The following additional information may be of interest, as indicating the proportions of the business. One of the largest French companies is employing about 1,000 people in its factories. For the production of moving pictures, two large theaters are in constant use, and a large park with artificial lakes, etc., is also included in the equipment. Outside of the employes in the factories, the company employs more than 300 actors for obtaining the scenes for the moving pictures.

MAXIMUM STRESSES—2.*

JOHN S. MYERS †

Moments in Two Planes; Crane and Telpher Girders.

In the design of crane, telpher, and similar runways, not housed, suitable provision should be made for lateral strength to resist wind loads. This, in conjunction with considerations of the buckling tendency of the compression flange, makes a single I-beam or a built-up girder of symmetrical section undesirable. The three types of section most commonly used for these purposes consist of: 1st, an I-beam for vertical strength with a channel riveted to the compression flange for lateral stiffness; 2d, the same construction with the addition of a smaller channel to the tension flange to increase the vertical strength; and, 3d, two I-beams, side by side, with a cover plate on the top flanges only. Tables V and VI in the supplement of the present issue give properties of these three varieties of built-up sections. Most of the combinations are made up of the minimum weight sections rolled, which are the most economic to use and most readily obtained.

For the purpose of illustrating the use of these two tables in conjunction with Table II and Diagram III in the supplement of the March issue, the following notation is assigned to the various quantities entering into the calculation of a girder acted upon by a moving load, dead load, and wind loads, the moving load being carried on two wheels equally loaded:

W_l = live load, *i. e.*, the sum of the two wheel loads.
W_d = dead load, *i. e.*, the weight of the girder.
W_w = wind load, one-half of which is carried by each wheel.
W_n = normal wind load on girder.
L = length of span in inches.
B = wheel-base (center to center of wheel).
Z_c = section modulus of upper chord about axis $a\ a$.
Z_t = section modulus of lower chord about axis $a\ a$.
Z_w = section modulus of upper chord about axis $b\ b$.

Z_c, Z_t, and Z_w are to be taken from Tables V and VI in the the supplement.

V_m = variable for determining the moment due to wheel loads. Use the maximum value given by Table II or diagram III in the March issue supplement.
V_{mu} = variable for determining the moment due to uniformly distributed loads. Use the value given by the top curve of diagram III, where the same vertical ordinate as used for V_m intersects. If using Table II, take the value given opposite $R = 1$ or over, and in the same vertical column from which the maximum value of V_m was taken.
M_l = moment due to live load W_l.
M_v = moment due to all vertical loads, W_l and W_d.
M_w = moment due to wind loads W_w and W_n.
S_t = tensile stress due to M_v.
S_c = compressive stress due to M_v.
S_w = stress in top chord due to M_w.
S_{mc} = maximum combined compressive stress.
S = assumed stress used for determining the size of a trial section.

Then $$M_l = W_l\ L\ V_m \tag{18}$$
$$M_v = L\ (W_l\ V_m + W_d\ V_{mu}) \tag{19}$$
$$M_w = L\ (W_w\ V_m + W_n\ V_{mu}) \tag{20}$$
$$Z_t = \frac{M_l}{S} \quad (21) \qquad S_t = \frac{M_v}{Z_t} \quad (22)$$
$$S_c = \frac{M_v}{Z_c} \quad (23) \qquad S_w = \frac{M_w}{Z_w} \quad (24)$$

If the structure is subjected to maximum wind while carrying full dead and live load, then

$$S_{mc} = S_c + S_w \tag{25}$$

but since unhoused cranes, telphers, etc., are not reasonably supposed to be in operation during a wind storm little short of a hurricane, it is more logical to assume but half the wind loads, when combining with the maximum stresses due to live and dead load; then

$$S_{mc} = S_c + \frac{S_w}{2} \tag{25a}$$

* Continued from the March issue.
† Address: 2456 Almond St., Philadelphia, Pa.

Example.—A girder, 30 feet span, supports 15,000 pounds on two wheels equally loaded. The wheel-base is 9 feet, the wind normal to the girder is taken at 30 pounds per square foot, and the area exposed to wind carried by the two wheels is 60 square feet. Find a suitable section, and state the maximum stress.

Solution.—L = 30 feet = 360 inches; B = 9 feet; $\frac{B}{L} = \frac{9}{30} = 0.3$; W_l = 15,000 pounds; $W_w = 60 \times 30 = 1800$ pounds.

From table II or diagram III (March issue supplement), the maximum value of $V_m = 0.1806$ for $\frac{B}{L} = 0.3$ or $B = 0.3\ L$, and for the uniformly distributed loads $V_{mu} = 0.1222$. For a trial section we have by formula (18) $M_l = W_l\ L\ V_m = 15{,}000 \times 360 \times 0.1806 = 975{,}240$ inch-pounds. Assuming the low fiber stress of 10,000 we have by formula (21)

$$Z_t = \frac{M_l}{S} = \frac{975{,}240}{10{,}000} = 97.5$$

From Table V, in the current supplement, the lightest weight girder having a section modulus Z_t in excess of this is seen to be composed of one 18 inch 55-pound I-beam with a 12-inch 20.5-pound channel on the top flange. For this section $Z_t = 99.11$, $Z_c = 161.57$, and $Z_w = 23.16$. The weight per foot is then $55 + 20.5 = 75.5$ and the total weight of girder is $W_d = 75.5 \times 30 = 2265$ pounds. By formula (19), $M_v = 360 \times (15{,}000 \times 0.1806 + 2265 \times 0.1222) = 1{,}074{,}882$ inch-pounds.

By formula (22)

$$S_t = \frac{M_v}{Z_t} = \frac{1{,}074{,}882}{99.11} = 10{,}820,$$

and by (23)

$$S_c = \frac{M_v}{Z_c} = \frac{1{,}074{,}882}{161.57} = 6660.$$

The depth of girder is 18 inches = 1.5 feet: the area exposed to wind is $1.5 \times 30 = 45$ square feet. Then

$$W_n = 45 \times 30 = 1350 \text{ pounds.}$$

By formula (20)

$$M_w = 360 \times (1800 \times 0.1806 + 1350 \times 0.1222) = 176{,}422.$$

Then by formula (24)

$$S_w = \frac{M_w}{Z_w} = \frac{176{,}422}{23.16} = 7610$$

The maximum stress is then, according to formula (25),

$$S_{mc} = 6660 + 7610 = 14{,}270 \text{ pounds per square inch,}$$

or, under the more logical assumptions of formula (25a),

$$S_{mc} = 6660 + \frac{7610}{2} = 10{,}465 \text{ pounds per square inch.}$$

Moments in Two Planes with Symmetrical Resisting Section.

The foregoing is an example of moments in planes at right angles to each other, but of such a special nature as to warrant classification under a specific heading. The most common case of moments in two places occurring in machine construction is that of shafting or pins supporting gears, drums, etc. In these cases the resisting section is round, and therefore symmetrical about any axis passing through the center of gravity. The stress in any particular plane is then proportional to the bending moment in that plane, and to find the maximum stress it is only necessary to find at what point the combined bending moment becomes a maximum, the moments in the various planes being susceptible of graphical combination in the same manner as forces. The point at which the combined moment is a maximum can generally be determined by an inspection of the problem, but when there is any doubt, the moments at the critical points should be calculated, and a scale diagram laid out for each plane in which moments occur. The ordinates of these diagrams can be combined for the various points where the maximum moment is liable to occur. To illustrate this method we will take an actual case.

Example.—The shaft shown in Fig. 4 is acted upon by the four forces P, P_1, P_2, and P_3, and by the two reactions. The forces P and P_1 are in the plane of line $E\ F$, and the moments they produce in this plane are represented by diagram A. The forces P_2 and P_3 are in the plane $G\ H$, their moments

being shown by diagram *B*. At *C* is shown the method of combining moments M_1 and M_5, producing the resultant moment M_{15}, which is the maximum moment occurring in the shaft at the point of application of the force P_1, the magnitude and direction of M_{15} being represented by the length and direction of the heavy line *c b*; *c a* is drawn parallel to *E F* and *a b* parallel to *G H*.

At *D* is shown the combination of M_2 and M_4 giving the resultant M_{24}, which is the maximum moment occurring at the point of application of force P_2. This resultant, M_{24}, exceeds in numerical value the moment at any other point of the shaft and is therefore the *maximum combined bending moment* for which it must be designed.

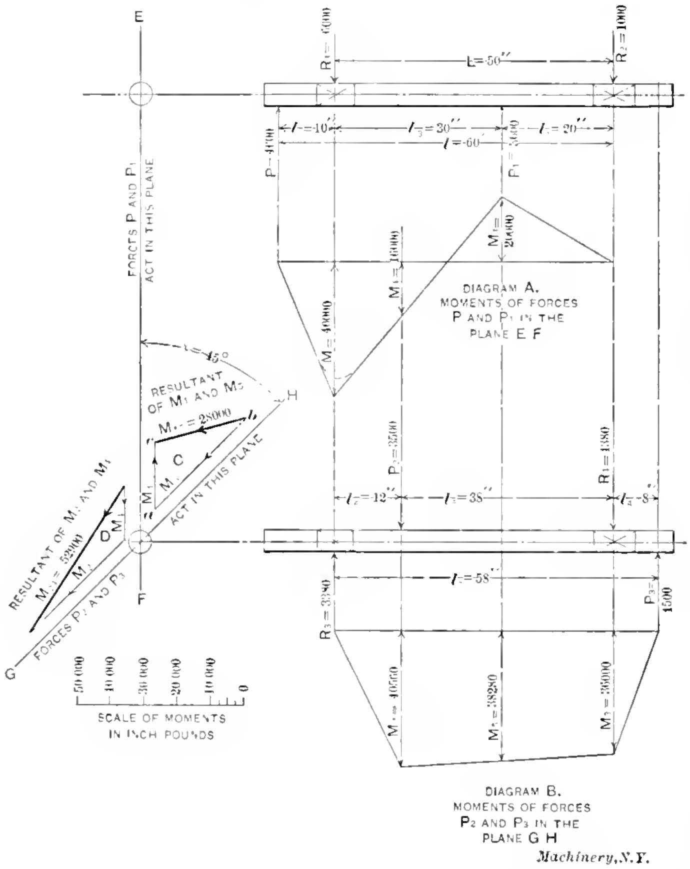

Fig. 4.

The method of calculating the reactions and moments at the various points used in making the diagrams of Fig. 4 is as follows:

$$R_1 = \frac{Pl + P_1 l_1}{L} = \frac{4000 \times 60 + 3000 \times 20}{50} = 6000 \text{ pounds.}$$

$$R_2 = \frac{P_1 l_3 - P l_2}{L} = \frac{3000 \times 30 - 4000 \times 10}{50} = 1000 \text{ pounds.}$$

$$M = Pl_2 = 4000 \times 10 = 40,000 \text{ inch-pounds.}$$

$$M_1 = R_2 l_1 = 1000 \times 20 = 20,000 \text{ inch-pounds.}$$

$$R_3 = \frac{P_3 l_4 + P_2 l_5}{L} = \frac{4500 \times 8 + 3500 \times 38}{50} = 3380 \text{ pounds.}$$

$$R_4 = \frac{P_3 l_7 - P_2 l_6}{L} = \frac{4500 \times 58 - 3500 \times 12}{50} = 4380 \text{ pounds.}$$

$$M_2 = R_3 l_6 = 3380 \times 12 = 40,560 \text{ inch-pounds.}$$

$$M_3 = P_3 l_4 = 4500 \times 8 = 36,000 \text{ inch-pounds.}$$

After laying out diagrams *A* and *B* from the above values, M_4 and M_5 may be scaled off, diagrams *C* and *D* constructed, and the final results M_{15} and M_{24} scaled off with sufficient accuracy for all practical purposes. If desired, they may be calculated. For this particular case

$$M_4 = M - \frac{M + M_1}{l_3} l_6 = 40,000 - \frac{40,000+20,000}{30} \times 12 = 16,000,$$

and

$$M_5 = \frac{M_2 + M_3}{2} = \frac{40,560 + 36,000}{2} = 38,280.$$

$$M_{24} = \sqrt{(M_4 \sin a)^2 + (M_2 + M_4 \cos a)^2} =$$
$$\sqrt{(16,000 \times 0.7)^2 + (40,560 + 16,000 \times 0.7)^2} = 52,900.$$

This latter is an unnecessary refinement which in practice would seldom, if ever, be resorted to, but is inserted here for purposes of illustration.

It will be noticed in the above solution that the forces were considered to be concentrated, no account being taken of the distributing action of the bearings. While this is quite customary, on account of simplifying the calculations, the error is sometimes considerable. In diagram *A* of Fig. 4, if the length of bearing *B* at the reaction R_1 is 7 inches, then the actual moment $M = P l_2 - \frac{R_1}{2} \times \frac{B}{4} = 34,750$. The diagram instead of coming to a sharp point should actually be rounded off as indicated by the dotted line.

Moments in Three Planes.

Fig. 5 is an illustration of moments in three planes, the proposition there presented being this: A shaft carries three drums, *A*, *A′* and *C*. *A* and *A′* are each acted upon by a rope whose load is represented by the force *F* at an angle of 30 degrees with the horizontal. An additional force F_1, due to the gears *B* and *B′*, acts at an angle of 90 degrees with the horizontal. Drum *C* carries a rope load F_2 on each side, and a gear load F_3 in the center, their direction being indicated by the dotted lines in the diagram.

The problem is to find the maximum combined bending moment.

Solution.—Force *F* is distributed over two bearings, their respective loads being *P* and P_1. $P = \frac{25,000 \times 7}{15} \cong 11,700$ and $P_1 = \frac{25,000 \times 8}{15} \cong 13,300$. The reaction due to *P* and P_1 is $R = 25,000$. The maximum moment in the plane of these forces is

$$M_0 = R\,(l + l_2) - P\,(l_1 + l_2) - P_1 l_2 = R\,l - P\,l_1 + l_2\,(R - P - P_1),$$

but since $R - P - P_1 = 0$, we have $M_0 = R\,l - P\,l_1$.

This shows that the moment for this case is the same in value as though the loads were concentrated at the center of the bearing, the only difference being that in the case of concentrated loads the moment would become maximum at point *H*, whereas with the load uniformly distributed over the bearing, the point of maximum moment shifts to *J* (see Fig. 5, diagram *D*). From the above may be stated the general principle that *for all cases of equal, symmetrically disposed loads acting in the same direction the maximum moment is the same in value whether the loads be concentrated at the center of bearings or distributed over their full length.* Then $M_0 = 25,000 \times 25 - 11,700 \times 15 \cong 449,500$ = maximum moment in the plane of *F*.

The force F_1, being central with a bearing, is all carried by that bearing. By the principle above stated its maximum moment is $M_1 = R_1 l = 18,100 \times 25 = 452,500$.

The forces F_2 and F_3 acting on drum *C* may be combined as in the diagram showing the direction of forces. This gives the resultant load $P_2 = 13,000$ pounds on each bearing of the drum. The maximum moment of P_2 in its plane is $M_2 = R_2 l_3 = 13,000 \times 35 = 455,000$.

Diagram *K* of Fig. 5 shows the combination of moments M_0, M_1 and M_2, giving the resultant *maximum combined bending moment* $M_{012} = 880,000$ inch-pounds, which is the moment for which the shaft must be designed.

Use of Table VII in the Supplement.

After the maximum moment to which a shaft is subjected has been found, the next step is to find what size must be used to withstand this and not exceed a safe fiber stress. By formula (8) in the March issue $Z = \frac{M}{S_b}$, where Z = section modulus, M = moment, and S_b = stress. Table VII in the supplement gives the value of *Z* for diameters ranging from 1/16 inch to 10 inches. It also gives the moment of inertia *I* for use when investigating for deflection. Formulas for

deflection covering various cases are given on data sheet No. 48 of the September, 1905 issue.

The values given in the supplement, Table VII, should be used for bending moments only. For torsional moments, the polar moment of inertia and section modulus should be used; but since these quantities are just double those for a rectangular axis, multiply the values in the table by 2.

The use of this table can best be illustrated by actual problems.

Example.—In the case shown by Fig. 4 the maximum combined bending moment was 52,900 inch-pounds. Using a fiber stress not exceeding 10,000 pounds per square inch, what size should the shaft be?

Solution.—By formula (8) the required section modulus is

$Z = \dfrac{52{,}900}{10{,}000} = 5.29.$ Referring to Table VII in the supplement, it is seen that for a 3 13/16-inch shaft $Z = 5.44$, which satisfies the conditions of the problem.

Example.—In the case illustrated by Fig. 5, the maximum moment was 880,000 inch-pounds. Allowing 25 per cent for

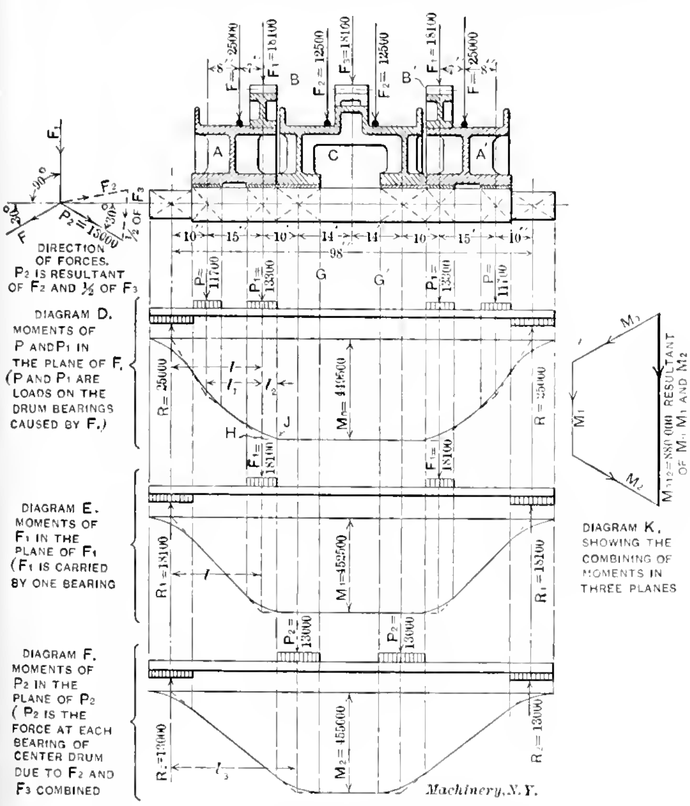

Fig. 5.

impact, what diameter of shaft may be used without exceeding a maximum stress of 15,000 pounds per square inch?

Solution.—25 per cent of 880,000 = 220,000.

$M = 880{,}000 + 220{,}000 = 1{,}100{,}000.$

$Z = \dfrac{1{,}100{,}000}{15{,}000} = 73.33.$ Referring to the supplement for 9-inch diameter. $Z = 71.57$ and for 9¼ inch diameter $Z = 77.7$; a 9⅛-inch shaft would then answer the purpose.

Example.—A shaft resists 50,000 inch-pounds torsional moment, what should be its diameter for a fiber stress of 8,000 pounds per square inch?

Solution.—Polar section modulus $= \dfrac{50{,}000}{8{,}000} = 6.25.$ Value in table $= \frac{1}{2} \times 6.25 = 3.125.$ For a 3⅛-inch shaft, the table gives $Z = 2.996$, and for 3 3/16-inch shaft $Z = 3.179$. Either of these sizes would be sufficiently near to satisfy the conditions.

Example.—What is the deflection of an 8¾-inch shaft loaded as shown in Fig. 6, taking the coefficient of elasticity at $E =$ 30,000,000?

Solution.—Referring to data sheet No. 18, September, 1905, deflection $f = \dfrac{W a}{24 E I}(3l^2 - 4a^2)$. For this problem $W = 26{,}000$, $l = 96$, $a = 34$.

From Table VII in the supplement of this issue $I = 287.7$ for an 8¾-inch shaft. Then the deflection $f =$

$$\frac{26{,}000 \times 34}{24 \times 30{,}000{,}000 \times 287.7} \times (3 \times 96^2 - 4 \times 34^2) = 0.098 \text{ inch.}$$

Example.—If in the last problem it is required to reduce the deflection to 1/16 = 0.0625 inch and use a coefficient of elasticity $E = 28{,}000{,}000$, what should be the shaft diameter?

Solution.—Let I, E and f be the values under the first condition, and I', E' and f' the corresponding values under the second condition. The deflection is inversely proportional to the moment of inertia and the coefficient of elasticity, then the required moment of inertia

$$I' = \frac{I f E}{f' E'} = \frac{287.7 \times 0.098 \times 30{,}000{,}000}{0.0625 \times 28{,}000{,}000} \cong 483.$$

Referring to the supplement, it is seen that for a 10-inch shaft $I = 490$. Ten inches is then the required size under these conditions.

Combining Shear with Tension or Compression. Table VIII.

The usual formulas given for the combination of shear with tension or compression are:

$$S_m = \sqrt{S^2 + \left(\frac{t}{2}\right)^2} \qquad (26)$$

and

$$t_m = \frac{t}{2} + \sqrt{S^2 + \left(\frac{t}{2}\right)^2} \qquad (27)$$

in which the letters have the following values:

S = unit shearing stress if acting alone.

t = unit tensile or compressive stress if acting alone.

S_m = maximum combined shear.

t_m = maximum combined tension or compression.

Both the above formulas, involving as they do the square and square root, are rather awkward to apply. Equation (26) may be expressed

$$S_m = S\sqrt{1 + \left(\frac{1}{2}\frac{t}{S}\right)^2} = S\,y \qquad (26a)$$

in which

$$y = \sqrt{1 + \left(\frac{1}{2}\frac{t}{S}\right)^2}$$

and formula (27) may be written

$$t_m = t\left[\frac{1}{2} + \frac{1}{2}\sqrt{\left(2\frac{S}{t}\right)^2 + 1}\right] = t\,x \qquad (27a)$$

in which

$$x = \frac{1}{2} + \frac{1}{2}\sqrt{\left(2\frac{S}{t}\right)^2 + 1}.$$

The value x then represents a factor by which to multiply the tension and arrive at the maximum combined tension, while y represents a similar factor by which to multiply the shear when the maximum combined shearing stress is desired. Table VIII in the supplement gives values of x and y for values of $\frac{S}{t}$ and $\frac{t}{S}$ ranging from 0.05 to 1.5.

To make the significance of these values clear, refer to the table, and note that for $\frac{S}{t} = 0.75$, $x = 1.40$, which means that if the shear is 75 per cent of the tension, the maximum combined tension is 1.40 times what it would be if there were no shear or an increase of 40 per cent. For the same value of $\frac{S}{t} = 0.75$, $y = 1.20$, which indicates that the maximum combined shear is 1.20 times what it would be if there were no tension or an increase of 20 per cent. Again, referring to the table for $\frac{t}{S} = 0.75$, $y = 1.07$ and $x = 1.92$ approximately, which shows that when the tension is 75 per cent of the shear the maximum combined shear is only 7 per cent greater than if there were no tension, but the maximum combined tension is 92 per cent in excess of what it would be if acting alone.

The combination of shearing stresses, produced by torsion, with tension or compression stresses due to bending, will be taken up in a later issue.

Stresses Due to Torsional Deformation.

When a machine element or member is subjected to a known torsional moment, an angular deformation occurs, or, if deformed torsionally a known amount a resultant shearing stress is produced. The following notation and formulas express the relations of the various quantities involved:

L = length of member in inches.

C_p = distance from polar axis of the section to the extreme fiber in inches.

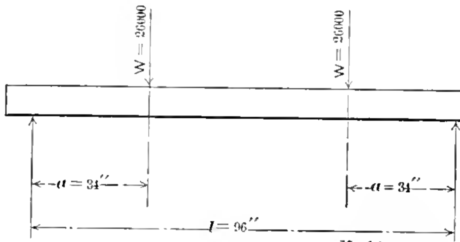

Fig. 6.

S = the shearing stress in pounds per square inch.

M_t = the torsional moment in inch pounds.

I_p = the polar moment of inertia.

E_s = the modulus of elasticity for shear (given by Reuleaux as 0.4 of that for tension).

ϕ = torsional angle in radians.

α = torsional angle in degrees.

$$\text{Then } \phi = \frac{M_t\, L}{I_p\, E_s} = \frac{S\, L}{E_s\, C_p} \qquad (28)$$

$$\alpha = 57.296\,\frac{M_t\, L}{I_p\, E_s} = 57.296\,\frac{S\, L}{E_s\, C_p} \qquad (29)$$

$$S = \frac{\phi\, E_s\, C_p}{L} = 0.01745\,\frac{\alpha\, E_s\, C_p}{L} \qquad (30)$$

Eye bars are sometimes used for supporting a load, while at the same time subjected to a torsional deformation. An example of this is seen in some bridge tramways where one end of the bridge is supported by a number of bars, permitting the bridge to slew through an angle of several degrees by twisting the bars.

Example.—A 4 × ¾-inch bar 24 feet long, sustaining a load of 21,000 pounds, is twisted through an angle of 5 degrees. What are the maximum stresses?

Solution.—$L = 24 \times 12 = 288$ inches.

$C_p = \sqrt{2^2 + 0.375^2} = 2.03$ inches. $\alpha = 5$ degrees.
$E_s\ 0.4 \times 27{,}000{,}000 = 10{,}800{,}000$. By formula (30)

$$S = \frac{0.01745 \times 5 \times 10{,}800{,}000 \times 2.03}{288} \cong 6650.$$

The direct tensiou is

$$\frac{\text{load}}{\text{area}} = \frac{21{,}000}{4 \times 0.75} = 7000. \qquad \frac{S}{t} = \frac{6650}{7000} = 0.95.$$

Referring to Table VIII in supplement, it is seen that the tension factor $x = 1.573$, and shear factor $y = 1.130$. Then by formula (27a) maximum tension $t_m = tx = 7{,}000 \times 1.573 \cong 11{,}010$. By formula (26a) the maximum shear $S_m = Sy = 6650 \times 1.130 \cong 7{,}510$.

As an example of bending, direct tension, and shear, also illustrating the method of determining moment of inertia of unsymmetrical sections, take the corner section on a C-frame, as illustrated in Fig. 7. This section is subjected to a bending moment equal to WL, where W equals 360,000 pounds, and L is the perpendicular distance from the line of action of the force to the center of gravity of the section. In addition to the bending moment, there is acting upon this section a force P, which is equal to $W \cos \alpha$ and is uniformly distributed over the section as tension; the other component P_1, which is equal to $W \sin \alpha$, is uniformly distributed over the section as shear.

In order to find the magnitude of the various stresses it is first necessary to find the area, center of gravity and moment of inertia of the section. Proceeding to find the center of gravity, take moments of the elementary areas of which the section is composed about some assumed line of reference, as $x\ x$, and divide the algebraic sum of the moments by the total area; the quotient is the distance from this line to the center of gravity. The operations are as follows:

	Areas.	Moments.
10×4	$= 40.000$	$\times\ 2.00 = 80.00$
1.25×13.5	$= 16.875$	$\times\ 10.75 = 181.41$
6×2.5	$= 15.000$	$\times\ 18.75 = 281.25$
A = total area	$= 71.875$	Sum of moments $= 542.66$

$$\frac{542.66}{71.875} \cong 7.55 \text{ inches to center of gravity of section} = C_t \text{ for}$$

tension flange; $20 - 7.55 = 12.45$ inches $= C_c$ for compression flange.

To get the moment of inertia, multiply each area by the square of its distance from the center of gravity of the entire section and add to each its moment of inertia about its own center of gravity. The moment of inertia of a rectangle being $\frac{b\,h^3}{12}$, the problem becomes:

$$40 \times 5.55^2 + \frac{10 \times 4^3}{12} = \begin{cases} 1232.10 \\ 53.33 \end{cases}$$

$$16.875 \times 3.2^2 + \frac{1.25 \times 13.5^3}{12} = \begin{cases} 172.80 \\ 256.29 \end{cases}$$

$$15 \times 11.2^2 + \frac{6 \times 2.5^3}{12} = \begin{cases} 1881.60 \\ 7.81 \end{cases}$$

$$I_r = 3603.93$$

The moment $M = WL = 360{,}000 \times 14.25 = 5{,}130{,}000$ inch-pounds. The tension is, $S_t = \frac{M\,C_t}{I}$ and the compression is

$$S_c = \frac{M\,C_c}{I}.$$

$$\text{Then } S_t = \frac{5{,}130{,}000 \times 7.55}{3603.93} = 10{,}747, \text{ and}$$

$$S_c = \frac{5{,}130{,}000 \times 12.45}{3603.93} = 17{,}722.$$

In this case the tension due to P and the shear due to P_1 are equal since sin 45 deg. = cos 45 deg. The value of these stresses is then

$$\frac{W \sin \alpha}{A} = \frac{360{,}000 \times 0.707}{71.875} = 3542.$$

Adding this to the stress in the tension flange, since this is also tension, and subtracting it from the stress in the compression flange we have: $10.747 + 3{,}542 = 14{,}289$ pounds per square inch tension, and $17{,}722 - 3{,}542 = 14{,}180$ pounds per square inch compression. Combining with the shear by formula (27) we have for the maximum combined tension

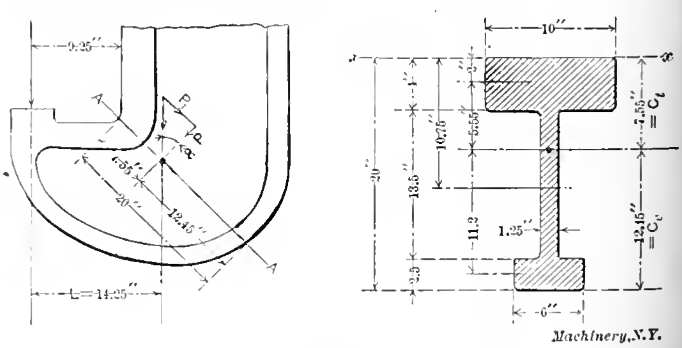

Fig. 7.

$$t_m = \frac{14{,}289}{2} + \sqrt{3542^2 + \left(\frac{14{,}289}{2}\right)^2} = 15{,}122 \text{ pounds per sq. in.}$$

The compression is so nearly the same value as the tension that it will be unnecessary to combine the shearing stresses in this case by separate calculation.

JIGS AND FIXTURES—2.

EINAR MORIN *

GUIDING THE DRILL.

The guides for the cutting tools in a drill jig take the form of concentric steel bushings, which are hardened and ground and placed in the jig body in proper positions. The bushings may be either stationary or removable, which latter, in the shop, are usually termed loose bushings. The most common, and the preferable form for the stationary bushing is shown in Fig. 5. This bushing is straight both on the inside and on the outside, excepting that the upper corners *A* on the inside are given a liberal radius, so as to allow the drill to enter the hole easily, while the corners *B* at the lower end of the outside are slightly rounded for the purpose of making it easier to drive the bushing into the hole, when making the jig, and also to prevent the sharp corner on the bushing from cutting the metal in the hole into which the bushing is driven.

When removable bushings are used, they should never be placed directly in the jig body except if the jig be used only a few times, but this should always be provided with a lining bushing. This lining bushing is always made of the form shown in Fig. 5. If the hole bored in the jig body receives the loose or removable bushing directly, the inserting and removing the bushing, if the jig is frequently used, would soon wear the walls of the hole in the jig body, and after a while the jig would have to be replaced, or at least the hole would have to be bored out, and a new removable bushing made to fit the larger-sized hole resulting. In order to overcome this, the hole in the jig body is bored out large enough to receive the lining bushing referred to, which is driven in place. This

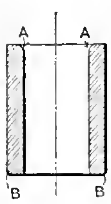

Fig. 5.

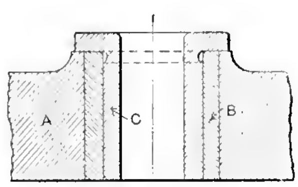

Fig. 6.

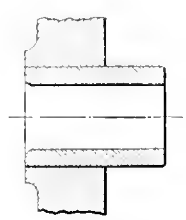

Machinery,N.Y.
Fig. 7.

Guide and Lining Bushings for Drill Jigs.

lining bushing then, in turn, receives the loose bushings, the outside diameter of which closely fits the inside diameter of the lining bushing, as shown in Fig. 6, in which *A* is the jig body, *B* the lining bushing, and *C* the loose bushing. Both of these bushings are hardened and ground so that they will stand constant use and wear for some length of time. When no removable bushings are required, the lining bushing itself becomes the drill bushing or reamer bushing, and the inside diameter of the lining bushing will then fit the cutting tool used. The bushing shown in Fig. 5 is cheaper to make, and will work fully as well when driven in place in the hole receiving it, as do bushings having a shoulder at the upper end, as has the loose bushing shown in Fig. 6. It was the practice some years ago to make all bushings with a shoulder, but this is entirely unnecessary, and simply increases the cost of making the bushing.

Dimensions of Jig Bushings.

It is rather difficult to give any standard dimensions for jig bushings as these depend, in most cases, on the different conditions of the various classes of jigs in which the bushings are inserted. As a rule the common practice is to make the length of the bushing twice the inside diameter of the hole in the bushing for stationary drill bushings. On very small bushings, however, say 1/4 inch diameter hole and less, the length of the bushing will have to be made longer than twice the diameter, while on very large bushings the length may be made somewhat less than twice the diameter. The accompanying Table I gives proportions of stationary drill bushings. The dimensions, as here given, will be found suitable in all cases where no special conditions demand deviation from ordinary practice. If the jig wall is thin, the bushing may project out as shown in Fig. 7, so as to give the cutting tool the proper guiding and support as close to the work as possible. In Table II are given dimensions for lining bushings, not intended to directly guide the drill, but to hold removable bushings, which in turn, guide the cutting tools. The dimensions given in Tables I and II are for bushings made from tool steel or machine steel.

While it may be, in some cases, difficult to draw a distinct line between stationary drill bushings and lining bushings, it may be said in general, that the bushings in Table I are

TABLE I. DIMENSIONS OF STATIONARY DRILL BUSHINGS.

used for guiding the drills when drilling holes directly, either with a full-sized drill, when the hole is not required to be very smooth or accurate, or, if greater accuracy is required, for guiding a spotting drill which fits the bushing exactly, after which the hole is drilled out with a so-called reamer drill which is 0.010 inch or less under the size of the finished hole, and finally reamed out with a reamer fitting exactly the hole in the bushing. These bushings are thus, in general, used when no tapping or counterboring would be required. The lining bushing in Table II again may guide one of the tools for the holes to be finished directly, and then removable bushings are inserted to guide the other tools used.

Miscellaneous Types of Drill Bushings.

As already mentioned, it was, some years ago, always the practice to provide even stationary bushings with a shoulder or head, as shown in bushing *C*, Fig. 6. This will prevent

TABLE II. DIMENSIONS OF LINING BUSHINGS.

the bushing from being pushed through the jig by the cutting tool, but this seldom occurs if the bushings are made to fit the tool correctly. Sometimes the shoulder is used to take the thrust of a stop collar, which is clamped on the drill, to allow it to go down to a certain depth, as shown in Fig. 8, in which *C* is the stop collar, *D* the wall of the jig, and *E* the stationary bushing, *F* being the piece worked upon. In such a case, a shoulder on the bushing may be in place.

* Address: 833 W. Sixth St., Plainfield, N. J.

If the work to be drilled is located against a finished seat or boss on the wall of the jig, and the wall is not thick enough to take a bushing of standard length, then it is common practice to make a bushing having a long head, as shown in Fig. 9. The length A of the head can be extended as far as necessary to get the proper bearing. As the bushing is driven in place, and the shoulder of the head bears

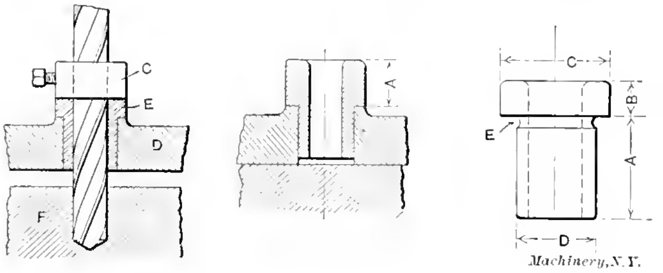

Fig. 8. Fig. 9. Fig. 10.
Types of Drill Jig Bushings for Different Purposes.

against the finished surface of a boss on the jig, it will give the cutting tool almost as rigid a bearing as if the jig metal surrounded the bushing all the way up.

Stationary or fixed drill bushings are almost invariably made from tool steel, but machine steel bushings, case-hardened and ground, give good service and wherever it seems necessary to save in the expense of the jig, machine steel will serve the purpose well enough for any jig that is not in constant use. For large bushings in particular, the difference becomes quite considerable, and, therefore, a great many prominent firms have made it a rule to make all larger bushings and, in particular, all lining bushings of machine steel.

Removable bushings are frequently used for work which must be drilled, reamed, and tapped, there then being one bushing for each of the cuttting tools. They are also used when different parts of the same hole are to be drilled out to different diameters, or when the upper portion of the hole is counterbored, or when a lug has to be faced off. In this case, each tool, of course, has its own guiding bushing. The common design of removable bushing is as shown in Fig. 10. The outside is made to fit the inside of the lining bushing with a nice, sliding fit, so that it can be gently pressed into the lining bushing by the hand. The distance A under the head of the bushing should be the same length or longer than the guiding bushing; in the latter case for the purpose of getting close to the work. The thickness B of the head varies, of course, according to the size of the bushing. The diameter C of the head should be from 1/4 to 1/2 inch larger than the diameter D of the bushing. A groove E, 1/8 to 1/4 inch wide, is cut immediately under the head, so that the emery wheel can pass clear over the part being ground.

Means for Preventing Loose Bushings from Turning.

In order to prevent the bushings from turning, in some shops a collar, with a projecting tail, as shown in Fig. 11, is forced over the head of the bushing. This arrangement also

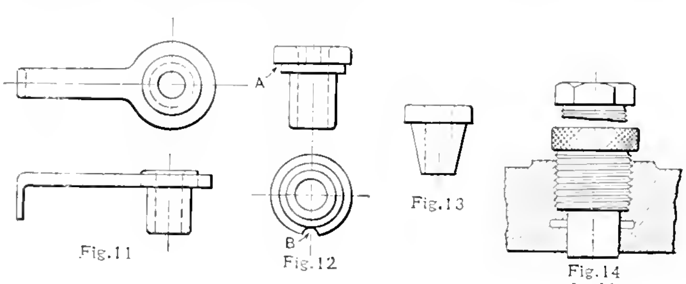

Fig. 11 Fig. 12 Fig. 13 Fig. 14
Means for Preventing Drill Bushings from Turning, Taper Bushing, and Screw Bushing.

makes it easy to remove the bushing. The dog, as it is commonly called, is usually bent at the end of the tail, as shown in the cut, one end resting against some part of the jig, the proportions of which the dog must suit. Sometimes the bent end is left straight, if there is a possibility for the tail to strike against some lug in the same plane. The making of such dogs involves some extra expense, but it is very effective in avoiding troubles with bushings turning and working their way out of the holes. In some cases simply a hole is drilled in the shoulder of the bushing at the edge, and a corresponding pin is driven into the jig body. This serves the same purpose as the dog. It is probably cheaper, but it does not add the convenient means for removing the bushing as does the dog. To make such a bushing more easily removable, the arrangement shown in Fig. 12 is probably the most common. A step A is turned down on the head, which, in this case, will have to be a trifle larger in diameter. This step permits some kind of a tool—a screw driver, for instance—to be put underneath, and with a jerk the bushing may be lifted enough to get a good hold on it. The half-round slot at B is milled or filed in the periphery of the head, and fits over a pin or screw which is fastened in the jig body, as mentioned before. There are, of course, a number of other devices for preventing drill bushings from turning, but the ones shown will serve the purpose of plainly exhibiting the principles.

In Table III are given dimensions for removable bushings of the type shown in Fig. 12. As will be seen in the engraving above the table, dotted lines have been shown, indicating a

* When using dogs as illustrated in Fig. 11, the dimensions in these columns are omitted.

shoulder without any recess of the kind shown at A, Fig. 12. The dimensions for such a shoulder as would be the result if the head of the bushings were made to the dotted lines apply to such bushings as are used with a dog, as shown in Fig. 11. In this case the dimensions in columns I and K in the table are omitted.

Table IV gives dimensions for bushings for holes which are reamed with a rose chucking reamer, after having first been drilled with a drill 1/16 inch smaller than the diameter of the reamer with which the hole is finally reamed out. The bushing to the extreme right, over the table, is the lining bushing, which is made of machine steel, case-hardened and ground. The bushing to the extreme left is the bushing for the rose

chucking reamer. It is made of cast iron and ground. The bushing in the center is the drill bushing which is made from tool steel, hardened and ground, or in cases where it does not seem warranted to make the bushing of tool steel, of machine steel, case-hardened and ground

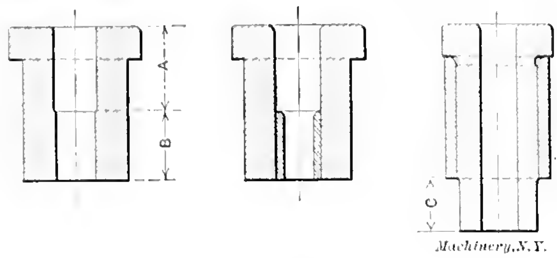

Fig. 15 Fig. 16 Fig. 17
Special Types of Drill Jig Bushings.

The tapered removable bushing shown in Fig. 13 is objectionable on account of being expensive to make, and also on account of its liability to be thrown out of true by chips, etc., getting in between the outside of the bushing and the hole.

Screw Bushings.

Sometimes removable bushings are threaded on the outside and made to fit a tapped hole in the jig, as shown in Fig. 14. The lower part of the bushing is usually turned straight, and ground, in order to center the bushing perfectly in the hole in the jig. The head of the bushing is either knurled, or milled hexagon for a wrench. When these bushings are used they are, as a rule, not used for the single purpose of guiding the cutting tool, but combine with this the purposes of

* When dogs illustrated in Fig. 11 are used, dimensions in these columns are omitted.

locating and clamping the work. For such purposes they are quite frequently used. These bushings are not commonly used as removable bushings, as it would take considerable time to unscrew, and to again insert a bushing of this type into the jig body.

Sometimes bushings for guiding the tools may be made of cast iron, but only in such cases when the cutting tool is of such a design that it does not have any cutting edges in the bushing itself, as, for instance, in the case of guiding the smooth surface of a boring-bar, or the shank of a reamer or a rose reamer, but hardened steel bushings must always be used when the cutting tool is liable to cut the bushing, as, for instance, in the case of drills and reamers, guided on their flutes, taps, etc.

Special Designs of Guide Bushings.

When the guide bushings are very long, and consequently would cause unnecessary friction in their contact with the cutting tools, they may be recessed, as shown in Fig. 15. The distance *A*, of the hole in the bushing, is recessed enough wider than the diameter of the tool, so as not to bear on it. The length *B*, being about twice the diameter of the hole, gives sufficiently long guiding surfaces for the cutting tool, to prevent its running out. If the outside diameter of the bushing is very large, as compared with the diameter of the cutting tool, as indicated in Fig. 16, the expense of making the bushings may be reduced by making the outside bushing of cast iron, inserting into this a hardened tool steel bushing, driven in place. The steel bushing is then given dimensions according to Table I for stationary bushings. The reason why there may be a necessity of a bushing having so large an outside diameter and so small a hole, may be that the bushing is required to be removed for counterboring part of the small hole being drilled, by a counterbore of large diameter, in which case the hole in the jig body has to be large enough to accommodate the larger sized counterbore.

If a loose or removable bushing is longer than the lining bushing, as illustrated in Fig. 17, it will prove advantageous to have the diameter of the projecting portion of the bushing about 1/32 inch smaller in diameter than the part of the loose bushing which fits the lining bushing. This lessens the amount of surface which has to be ground, and, at the same time, makes it easier to insert the bushing, giving it, so to say, a point, which will first enter the lining bushing, and it interferes in no way with the proper qualities of the bushing as a guide for the cutting tool.

In some cases, the holes in the piece to be drilled are so close to one another that it is impossible to find space for lining bushings in the jig. In such a case, it will be necessary to make a leaf, or a loose wall, or the whole jig of machine steel or tool steel, hardening a portion or the whole jig thus made.

* * *

MACHINE SHOP PRACTICE.

MACHINING A FIXTURE CASTING.*

MACHINERY'S articles on shop practice aim to supply, in a comprehensive way, definite, practical information about the various methods and operations chiefly comprising the work of the machinist; and while such instructions are always necessarily more or less elementary in character, and intended primarily for the apprentice, they are invariably interesting and valuable to the more advanced workman. We select, as examples, those operations which are general in character and best serve to teach the methods employed in actual practice, and the underlying principles of machine shop work; and in following this policy the information is of the greatest value to the largest number.

In Fig. 1 is shown a drawing of a milling machine fixture casting which is to be machined as indicated by the finish marks *f*. In this article we shall only discuss the planing operations, the boring and milling work being reserved for the next installment. In the Shop Operation Supplement accompanying this issue we have given condensed instructions for performing the planing operations, together with diagrams showing how the work is set up on the machine. Before setting this casting up on the table of the machine, it is first necessary to determine which of these surfaces shall be machined first. In general, when there are several surfaces on a piece of work to be machined, the shape of the work, and the relation of the finished surfaces to each other, must be considered in determining which part of the work is to be machined first. The fixture casting which we have selected as an example of

* With Shop Operation Sheet Supplement.

planing, boring, and milling work, is to have the bearing planed, which includes facing the top, planing the pillow-block cap fitting and facing the ends; the base with its tongue-piece, which is to be at right angles to the pillow-block cap fitting, planed; the top surface of the arm *H* planed; a T-slot milled in it, and the bearing bored. The T-slot *C* is to be parallel with the tongue-piece *B*, and the finished surface of the arm parallel with the base. Either the bearing or the base might be planed first in this case, but it is preferable to begin with the bearing, as the casting can be supported better on the rough base than on the unplaned bearing end. The first illustration on the Shop Operation Supplement shows the work set up for the first planing operation. Small parallel pieces were inserted beneath each corner of the base, as shown, in order to get a better bearing by preventing the casting from bearing on any high spot. If the base of the casting, because of its roughness, does not rest on all four parallels, liners of brass or tin should be inserted. In order that the base be of uniform thickness, its top surface should be set parallel with the table by using a surface gage. As the first planing operation consists of facing the top of the bearing and planing the fitting *G* for the pillow-block cap, and as this bearing is to be at right angles to the long side of the base and the T-slot *C* in the arm *H*, it will be necessary to set the casting with reference to these points. Inasmuch as the arm *H* is

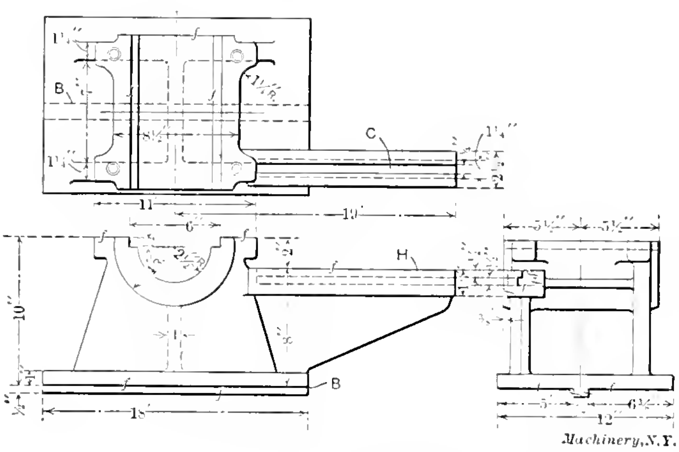

Fig. 1. Elevations and Plan of Milling Machine Fixture Casting.

considerably above the base, a straight-edge *A* is first set at right angles to the side of the table, as shown in the Supplement, and clamped in position. When the base is set parallel with the straight-edge, the cored slot in the arm may be tested by placing a square against the straight-edge and measuring from the blade of the square to the T-slot *C* at two points as far apart as possible. If the T-slot is not parallel, the casting should be shifted slightly so that both T-slot and base are as near parallel with the straight-edge as possible. The tongue-piece *B*, which is to be at right angles to the bearing, should also be approximately parallel with the straight-edge, so that when the casting is turned over and the base planed, the tongue-piece will true up. It is well to remember that in setting up any piece of work having a number of surfaces to be machined, that it should be so set that all surfaces can be finished in their proper relation to one another. After the casting is set it should be clamped firmly to the table, and set-screw plugs or other suitable stops set against it to prevent it from shifting when taking a cut. When planing the top surface *F* of the casting, the amount of metal to be removed will depend upon the distance between this surface and the base, and the required thickness of the base.

By locating the center *c* of the boss and the arcs *d*, and then working to these lines when planing the cap fitting, the fitting is made central with the boss. Obviously, the projection on the cap should also be planed central with its boss, so that when the cap is bolted in place the bosses and lugs on both castings will match each other.

When planing the base, the casting is inverted, as shown in Operation Sheet No. 62. As the tongue-piece *B* and the cap fitting are to be at right angles to each other, set the cap fitting at right angles to the side of the planer table by using a square as shown. As it is somewhat difficult to see the square blade when it is against the fitting, a piece of paper inserted between the square blade and fitting at each end of the fitting will aid in determining when the work is correctly set, as then both paper strips will be pinched by the square blade. When planing the base, roughing and finishing tools, similar to those shown at *A* and *B*, Fig. 2, may be used. The importance of removing the right amount of metal when plan-

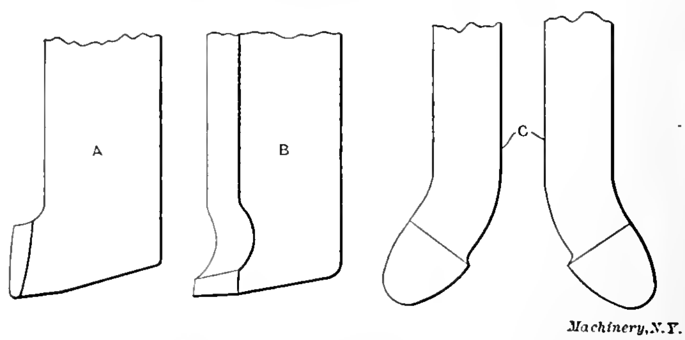

Fig. 2. Roughing, Finishing, and Right- and Left-hand Tools for Vertical Cuts.

ing the top of the bearing, will now be understood; if too much metal be removed, the casting will not finish to the dimension *H*, while if too little be removed, the flange of the base will be made too thin when the casting is machined to this dimension.

Before planing the ends of the bearing, the drilling and tapping for the cap bolts should be done, and the cap bolted in place. The casting is then set up on the planer table, as shown in Operation Sheet No. 63, with the tongue-piece ***B*** against one side of a T-slot. In this way the casting is set so that the finished ends of the bearing will be parallel with the tongue-piece. Before taking a vertical cut on a planer, the nuts *D* (Fig. 3) should be loosened, and the top of the apron *E* swung away from the plane of the surface to be planed, so that when the tool rises on the return stroke, instead of rubbing against the surface of the work, it will swing away from it or in a plane indicated by the line *F*—*G*. Of course, when planing the opposite end of the bearing, the apron must be swung in the opposite direction. Right and left round-nose tools for facing the ends of the bearing are shown at *C*, Fig. 3. When clamping the tools in place for these vertical cuts, they should be set so that a continuous cut can be taken over the entire surface to be planed.

When it is desired to plane surfaces at an angle to a line perpendicular to the platen, the bolts *H* are loosened, and the planer head *J*, which is mounted on a swiveling base *K*, is set

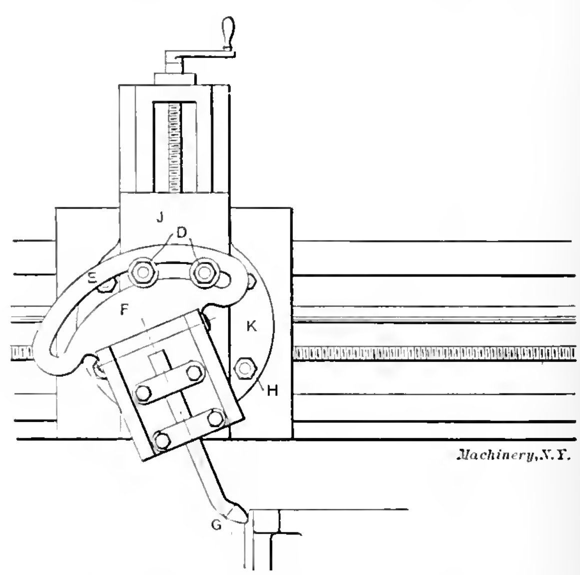

Fig. 3. The Planer Tool-block set for Taking Vertical Cuts.

to the required angle by the graduations provided. In this case, as the ends of the bearing are to be at right angles to the base, the head is set to the zero mark. If the planer has been in use for a considerable time the zero mark may not be absolutely correct, and it is advisable to test the accuracy of the work by the use of a square.

LETTERS UPON PRACTICAL SUBJECTS.

TWO-JAWED LATHE CHUCKS.

The accompanying engravings illustrate the best two-jawed chuck for general use that the writer has ever seen. It has been made by the Mueller Mfg. Co. Decatur, Ill., exclusively for this company's own use. The chuck was designed by Edward Mareille and patented as long ago as January, 1889, but as the original patent has now run out, and as the Mueller Mfg. Co. does not make these chucks for the market but simply for shop use, a description of them and the manner in which they are made, may be of interest and value to the readers of MACHINERY. About fifty of these chucks

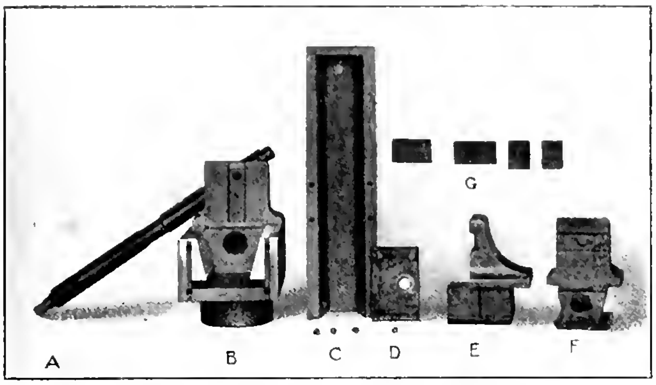

Fig. 1. Details of the Two-jawed Lathe Chuck.

are in use in the factory mentioned. Ten are used in the tool-room and about forty in the brass working shop. As a tool-room chuck, this design is unsurpassed for many jobs which formerly were done on the face-plate or on an angle plate. This is especially true in the case of core box work, where small metal core boxes are made for brass valve cores.

Some of these chucks, which have been continually in use for seven years, were recently overhauled, and showed very

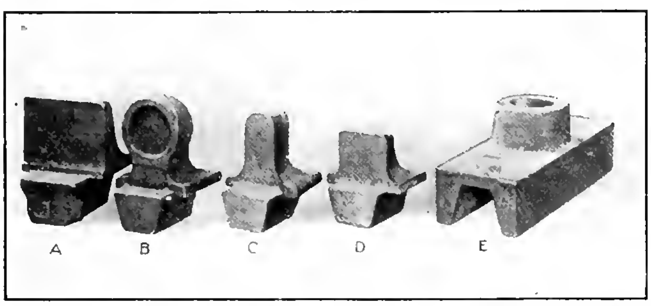

Fig. 2. Rough Castings used in making the Two-jawed Chuck.

little indication of the rough usage to which they had been subjected. The details of the chucks taken apart are shown in Fig. 1, in which *A* represents the chuck screw, threaded right- and left-hand, as usual. At *B* is shown an end view of the chuck, with the end-plate removed and one jaw in place. The part shown at *C* is a front view of the chuck body with everything removed, excepting one end-plate, the other end-plate being shown at *D*. A side view of the chuck jaws is

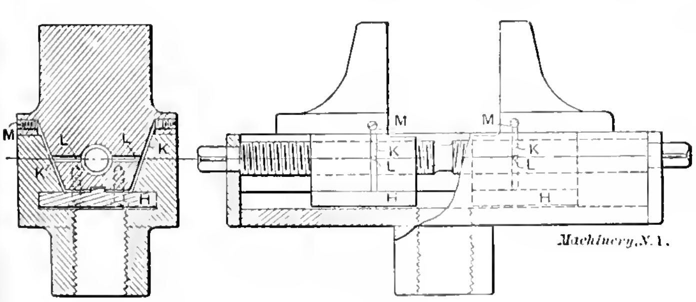

Fig. 3. Section and Side Elevation of the Chuck

shown at *E*, and a front view is shown at *F*. It will be noted that these two jaws are grooved on their faces differently from the one shown at *B*. This is done in order to permit the holding of special false jaws, but most of the chuck jaws are grooved lengthwise of the jaw face. Finally, at *G* are shown small metal plates used to protect the chuck screw from chips and dirt.

In Fig. 2 is shown a group of the rough castings used for making these chucks. The castings shown at *A* and *D* are for regular jaws of different sizes while those shown at *B*

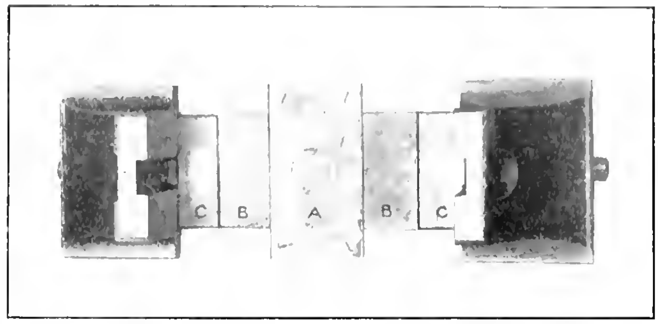

Fig. 4. View of Chuck with Jaws opened to Maximum Capacity.

and *C* are for special chucks. The casting for the chuck body itself is shown at *E*. The engraving Fig. 3 shows a section and a side elevation of the chuck. The section is taken at such a place as to illustrate the way in which the chuck is oiled, and the manner in which the jaws are set into the body and held. A plate *H* is screwed to the bottom of the

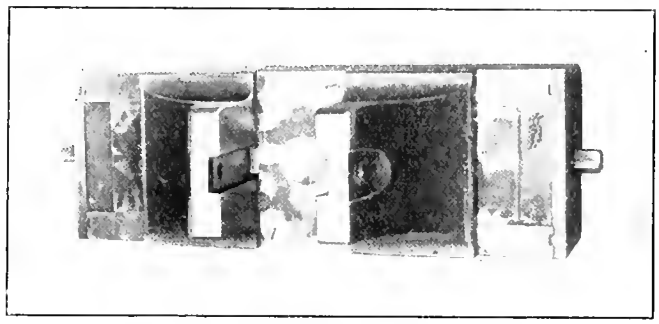

Fig. 5. View of Chuck with Jaws closed.

jaw, and fits into slots in the chuck body as shown. In regard to the oiling arrangement, oil grooves leading down the sides of the jaw are shown at *K*, while oil holes running in to the chuck screw nut are shown at *L*. At *M* are shown small screws for plugging up the oil holes. In the side elevation, part of the chuck is shown in section, to show the oiling arrangement. The half-tone Fig. 4 shows the chuck with the jaws open to their maximum capacity, and illustrates the

Fig. 6. Several Forms of Cast False Jaws used with the Chuck.

way in which the plates shown at *G* in Fig. 1 slide in and out and thus keep the chuck screw covered, excluding chips in a most effective manner. The plate *A* is stationary, and is held in place by screws. The plates *B* are made to slide in small grooves cut in the sides of the chuck body, and telescope in and out with the movement of the jaws by means of small pins working in the slots. The circular spot in the middle of plate *A* is an "accident." The parts *C* are projections of the jaws. In Fig. 5 the jaws are shown closed, and it is seen how the sliding plates at the back of the jaws are working, covering up the chuck screw in the same manner as the sliding plates in the front of the jaws.

As will be readily seen, these chucks are all intended to be used with false jaws, and an inspection of the construction will show how simple the chuck is, and how easy it is to take up the wear, on account of the beveled slot in the body,

and how rigid the long bearing of the jaws permits them to be. The location of the oil holes and grooves keep the working parts thoroughly oiled, being so placed that it is only necessary to take out the plug set-screws and inject some oil, the centrifugal force taking care of the rest. In the toolroom, flat false jaws are usually employed, but in the factory

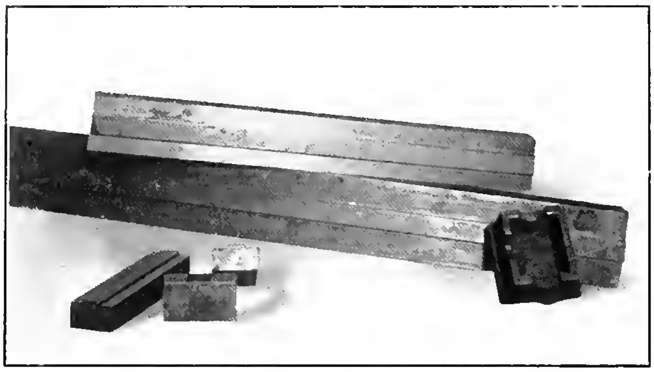

Fig. 7. Steel Bars from which Pieces are cut for making False Jaws.

special shapes are made for holding the different forms and sizes of valves being machined. The false jaws are made to fit the groove in the chuck jaws, and are held by a strong screw, and are interchangeable for any chuck of a given size. In Fig. 6 are shown groups of castings for several forms of false jaws, but most of the false jaws are made from machine steel bars and case-hardened. The bars are planed in long

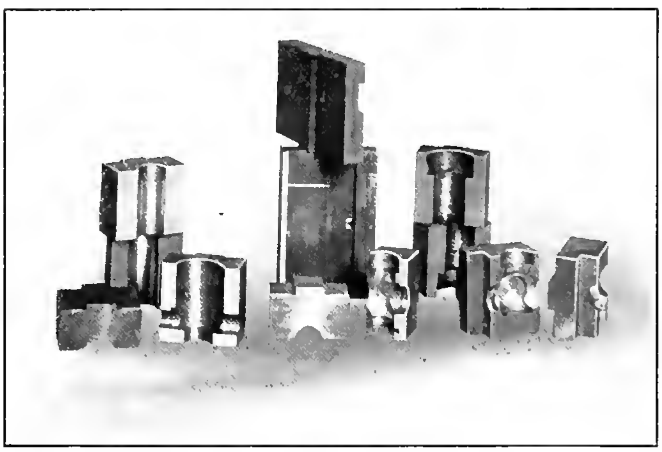

Fig 8. Partly Finished False Jaws which were cut from the Pieces shown in Fig. 7.

sections, as shown in Fig. 7, and the pieces are cut off when needed and machined to whatever shape is required. In Fig. 8 some of these false jaws made from machine steel, and partly finished, are shown.

Special angle plate clamps, which are used to hold the chuck jaws when performing the various operations through which they pass on the shaper, are shown in Fig. 9. These

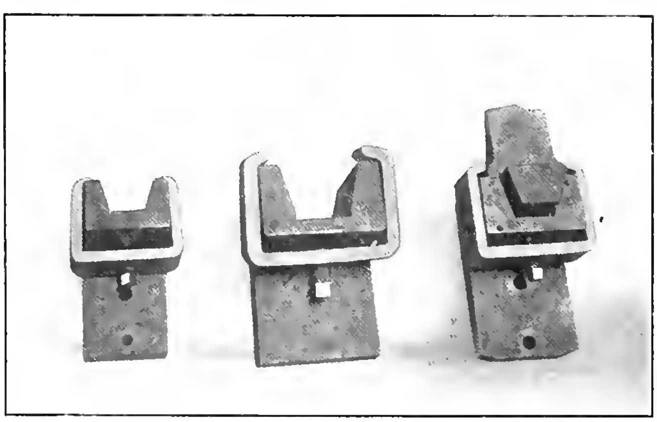

Fig. 9 Special Angle Plate Clamps used for Holding the Chuck Jaws when machining them.

appliances are also used on the lathe face-plate, to hold the jaw while the thread is being cut for the chuck screw. Finally, in Fig. 10 is shown a square block screwed onto the lathe spindle, and the chuck jaws screwed up to it. After the chuck jaws and all working parts have been carefully scraped and fitted into place, the assembled chuck is clamped by means of its jaws onto this block, and the threads in the body cut and the boss finished. These angle plates and the block mentioned are the only jigs or special tools used for making these chucks. ETHAN VIALL.

Decatur, Ill.

TO MAKE ACCURATE ARBORS.

An arbor, to be an efficient tool, should have a true cylindrical surface, and have center holes that are exactly coincident with the axis, round, true as to angle, and perfectly smooth. The most important of these requirements is the center hole, as it is easily deranged. An arbor can be very easily ruined in a few seconds by letting one of the center holes get dry and roughen. The shape or design of a center hole is a

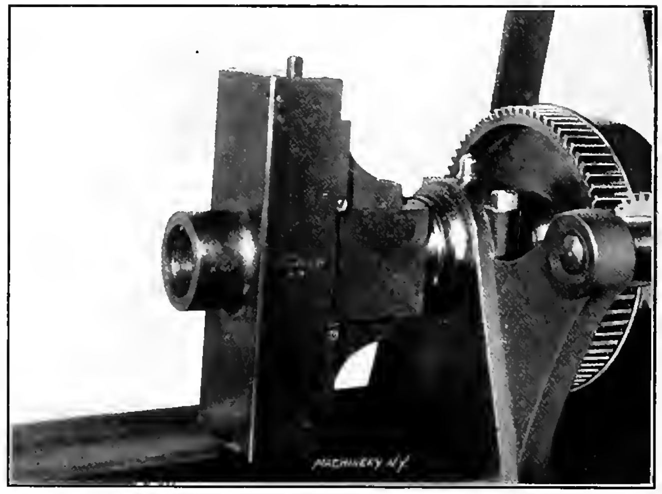

Fig. 10. The Way in which the Chuck is held when cutting the Thread and finishing the Boss.

factor that must not be looked upon as unimportant, though it is largely a matter of choice. The center shown in Fig. 1 is reamed to standard angle and the corner is rounded off at the mouth, while the center illustrated in Fig. 2 is reamed to standard angle and the end of the arbor counterbored. The advantages claimed for the latter are, protection of the center hole, and that it will stand considerable driving without spoiling the center hole, but then, driving is rather a barbaric practice. If by chance the arbor shown in Fig. 2 should get caught by the lathe center near the center hole, the point of the center is liable to raise a small burr, or chip out a small piece at the edge of the center hole. With the center shown in Fig. 1, this is prevented by the center striking the curved edge of the hole, and sliding into place. If the point strikes back of the curve it will be too far from the center hole to do any damage.

When making arbors the stock is cut first to length, and then carefully centered so that there will be a uniform amount of stock removed from all sides of the piece. This is important because of the difference of density caused by the rolling operations. After taking a roughing cut over the pieces, it is advisable to pack anneal them. This is to give any internal strains which were caused by the stock being straightened cold after being rolled, a chance to adjust themselves. After annealing they may be turned down, leaving the part *A* (Fig. 1) large enough to allow for grinding. This allowance will depend upon the length and size of the arbor. The possible spring of the stock in hardening must also be considered. The part *B*, with the curved edge *C*, may be turned to size and polished. Hold one end of the arbor in a true universal chuck, and run the other end in a steady rest. The curved edge of the center hole is now finished with a hand graver, and the end polished. The arbor is now ready for milling the flat places on the part *B* upon which the lathe dog is to be clamped. Procure a drill the size of the teat of the center drill used, and drill the center hole to the depth of about $\frac{1}{2}$ inch. This is to make a reservoir for the storage of oil to lubricate the center when in use.

We are now ready to ream the center holes. This is a very important operation, and one that cannot be rushed, for much

depends upon this part of the work. We will need a 60-degree center reamer, one having several flutes preferred. These flutes should be honed so that they have smooth, keen edges. Grip the center reamer in a chuck so that it runs absolutely true and block the lathe spindle. Now flood one center hole of the arbor with lard oil, and support the other end on the tail center which has been carefully lined up with the live spindle. Ream out the center hole by slowly turning the

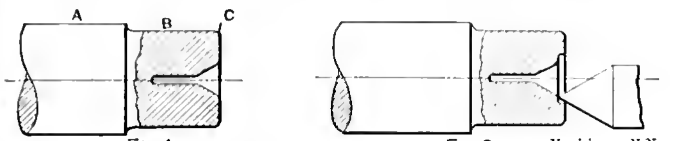

Fig.1 Fig.2

Figs. 1 and 2. Common Forms of Arbor Center Holes.

arbor by hand and tightening up on the tail center enough to make the reamer cut. Right here is the place to go slow. Take very light cuts at a slow speed and use plenty of oil. Ream sufficiently to clean up the center hole from the center to the edge of the curved mouth. After carefully reaming all the arbors, inspect them to see that the burrs caused by the milling have all been removed, and that all the other operations have been done properly. The arbors are now ready to be hardened. If the hardening is done with care, the majority of them will be fairly straight. Large arbors may be left hard, but arbors below ¾ inch should be drawn, so that they will not be so liable to break.

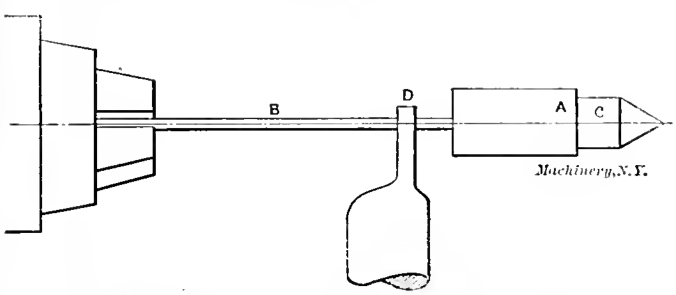

Fig. 3. Lap used for Polishing Arbor Center Holes

The first operation after hardening is to pickle off the scale, after which the center holes are lapped. An accurate center hole is the most important part of an arbor, and to get this, it must be carefully finished. Brass laps seem to work very well, and as the lap has to be of correct shape to get a true hole, it is advisable to make up a quantity of them, so that the temptation to continue using a lap which is worn out of shape will be removed. The lap should be gripped in a small chuck or holder, and run at a very high speed. A speed lathe with a lever feed is excellent. If the lathe is not provided with a lever feed, remove the tail-stock cap so that the spindle can be moved in and out very easily by taking hold of the tail-stock screw. For the rough lapping use coarse emery. Drop a little coal oil in the center hole, and then sprinkle in a small amount of the emery. Support the other end of the arbor on a center in the tail-spindle and gently feed the arbor onto the revolving lap, removing it as soon as it touches the lap. Repeat the operation, and keep turning the arbor to neutralize any error that may exist in the alignment of the machine. It is important to do the lapping by instantaneous contacts with the lap to prevent the emery getting caught and ringing the center hole. It is much easier to keep the hole smooth, than to smooth it up after it is scored. Lap just enough to correct any distortion that may have been caused by the hardening. After rough lapping, change the lap, and with a finer grade of emery, re-lap the center holes to get them smoother, and to correct any errors that may have occurred in the roughing out.

To get the required polish, we will proceed as follows: Make a small brass cup *A* (Fig. 3) with a flexible steel shaft *B* about 4 inches long and 3/32 inch in diameter. With sealing wax, embed a small piece of oilstone *C* in the cup. Then rig up a small rest with a short bearing at *D*, about ½ inch back of the cup. The oilstone can be trued up with a diamond or piece of emery wheel, to the correct 60-degree angle. The object of the flexible shaft is to neutralize any chatter that may be caused by entering the lap in the center hole. This chatter, if not provided for, will cause the point of the oilstone to chip off. The rest is to keep the lap revolving in one plane. If this is not done, the lap revolving at a high speed is liable to go down through the shop if it by chance gets a little off center. Clean out all the center holes with gasoline to remove all emery, and insert the lap, using plenty of lard oil. Bear lightly on the lap to prevent it from getting dry and sticking, which would cause the point to break off. The oil stone will require truing up for every fifteen or twenty holes lapped, but considering the quality of work done, and the rapidity, it is a refinement well worth while. The lapping done, carefully test all the holes with a standard 60-degree plug, and mark all that will need to be lapped again to correct errors.

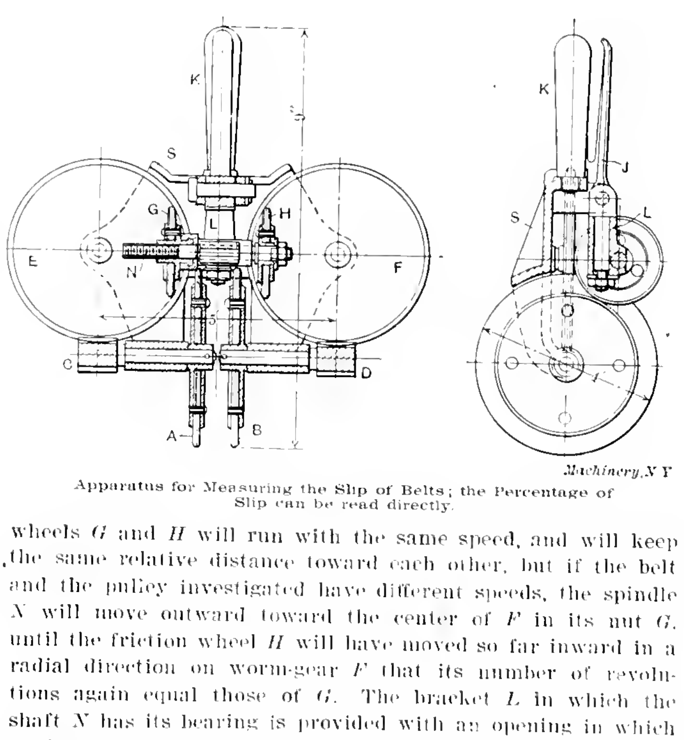
The last operation is to grind the cylindrical part. Because of the strains caused by the hardening, it is advisable to let the arbors season between the roughing and the finishing cuts. It will be found in some cases that they change shape after the roughing cut is taken. The arbor, if tapered, should have the number on the large end, and the amount of taper is governed by the length and the use to which it is to be put.

Lafayette, Ind. FOSTER HILLIX.

APPARATUS FOR MEASURING THE SLIP OF BELTS.

Belts slip under load a great deal more than is ordinarily supposed, and, for this reason, they are worn out much faster than is necessary, and at the same time the slip effects a great loss of driving power, so that a device which, under all circumstances, shows the amount of loss through slip, is of interest not only from a theoretical point of view, but also for its practical value. A simple and handy device for measuring belt slip is shown in the accompanying engraving. The device is held by the handle *K*, and applied in such a manner to the pulley on which the belt slip is to be measured that one of the two friction wheels *A* and *B* rests on the belt, while the other presses against the face of the pulley which projects outside of the width of the belt. The motion of wheels *A* and *B* is transmitted to the worm-wheels *E* and *F* by means of the worms *C* and *D*, of which one is right- and the other left-handed. From the worm-wheels *E* and *F* the motion is finally transmitted to the friction wheels *G* and *H*.

The hub of the wheel *G* is threaded on the inside so as to act as a nut on the threaded spindle *N*, which carries the other friction wheel *H*. When the belt is not slipping, the



Apparatus for Measuring the Slip of Belts; the Percentage of Slip can be read directly.

wheels *G* and *H* will run with the same speed, and will keep the same relative distance toward each other, but if the belt and the pulley investigated have different speeds, the spindle *N* will move outward toward the center of *F* in its nut *G*, until the friction wheel *H* will have moved so far inward in a radial direction on worm-gear *F* that its number of revolutions again equal those of *G*. The bracket *L* in which the shaft *N* has its bearing is provided with an opening in which a piece of glass is inserted. On this piece of glass a scale is provided, and the spindle *N* has a line cut at one place on its circumference, so that when the spindle moves in an inward direction the percentage of the loss through slipping

can be directly read off on the scale. The body L is connected with a lever J, which is mounted on a stud in the frame of the device, so that by pulling the lever towards the handle K, the friction wheels G and H may be disconnected from contact with the worm-wheels E and F at any time.

The appliance may be used for belts moving in either direction, and will show the correct result on the driven as well as the driving pulley, provided the device is applied correctly. It is, of course, necessary to always place the friction disk B against the part which is expected to run fastest, that is, in the case of driven pulleys against the belt, and in the case of driving pulleys, against the pulley. When correctly applied, the friction roller H and the spindle N on which it is mounted will, in the case of slip, move towards the center of F. If this is not the case, then the apparatus is not applied correctly, and should be turned around so that the proper friction disk works against the belt. The apparatus will also sometimes have to be put on the one side and sometimes on the other side of the pulley for which the belt slip is measured, in order that the scale on which the percentage of slip is read off may always be turned toward the operator of the device.

Pilsen, Austria-Hungary. MORITZ KROLL.

[The ingenious device shown and described above was designed by Prof. Kroll himself. His short and concise description hardly gives full justice to the ingenuity of this interesting device, but our readers will, no doubt, appreciate the simplicity of the mechanism by means of which the object sought is attained.—EDITOR.]

DIRECT FRACTIONAL-READING MICROMETER.

The direct fractional-reading micrometer, herein illustrated, is the result of talks with many mechanics in which all agreed that such a feature added to a micrometer would, by making it directly a fractional and decimal gage, more than double its practical value. While approximate readings in

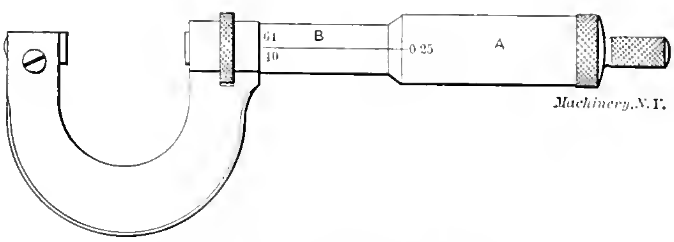


Fig 1. Direct Fractional-reading Micrometer.

64ths, etc., may be obtained by the graduations on the hub B (Fig. 1) as on an ordinary inch scale, the exact readings of 64ths, etc., may be obtained only by reference to graduations on the movable thimble A. There are but eight places on A which coincide with the long graduation line on B when any 64th, 32d, 16th, or 8th, is being measured, and each of these eight places is marked with a line, and the 64th, 32d, 16th, or

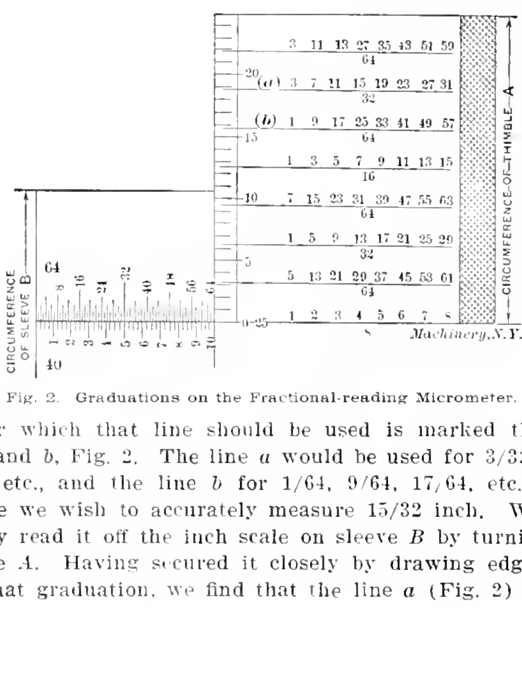

Fig. 2. Graduations on the Fractional-reading Micrometer.

8th for which that line should be used is marked thereon. See a and b, Fig. 2. The line a would be used for 3/32, 7/32, 11/32, etc., and the line b for 1/64, 9/64, 17/64, etc. Now suppose we wish to accurately measure 15/32 inch. We first roughly read it off the inch scale on sleeve B by turning out thimble A. Having secured it closely by drawing edge of A over that graduation, we find that the line a (Fig. 2) on the movable thimble very nearly or exactly coincides with the long graduation line on B. When these lines coincide, we have the exact measurement of 15/32 inch without reference to how many thousandths may be contained in the fraction. And so on through the scale any fraction may be found instantly. There is no mental arithmetic, use of tables, or memory work in using the tool. The new graduations are independent of the old, and may be used equally well with or without them.

Tools of various makes and sizes, which have been graduated, and are being graduated, differ from this in two re-

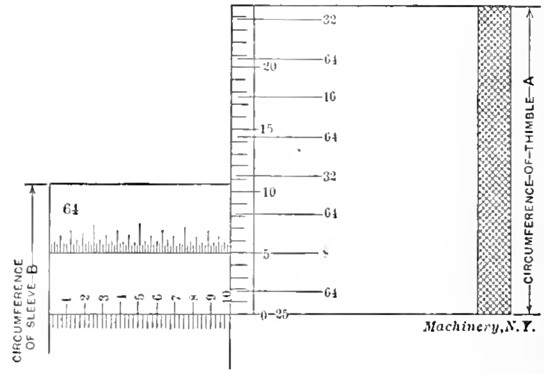

Fig. 3. Another Method of Graduating for Fractional Reading.

spects. Instead of using the zero line on A as a base line, a point is taken one-fifth of a turn around A, and the graduated scale on B is placed to correspond, as shown in Fig. 3; also, instead of making lines a, b, etc., on A full length, they are made about half an inch long, and the numerators are entirely omitted and the denominators placed at the end instead of under the line. To the ordinary user of the tool, this is all that is necessary for a perfectly clear reading of the fractions.

That this method of graduating is entirely new in principle and application, is proved by the very thorough search that was made in the patent office prior to the application, and further, by the fact that a broad patent has been allowed. To anyone having learned the use of micrometers, the new graduation appears, after one or two trials, perfectly simple, and they do away with all confusion as formerly experienced in reading fractions. CHARLES A. KELLEY.

Spring Lake, Mich.

THE CONFIDENCES OF A WORKMAN.

In the November, 1907, issue of MACHINERY there is an article on The Confidences of a Manufacturer which brings to my mind a little experience I had once, and incidentally I have learned that there is more than one kind of confidence. My title, which I received through promotion, was master mechanic. The place employed from 50 to 60 men, and some of the duties I performed were to look over the drawings that were made, and, as we did not employ a pattern-maker steady, take the drawings to an outside pattern-maker, and sometimes go personally and get the patterns and examine them. As our foundry deliveries were not regular, I sometimes carried the patterns to the foundry. (It might be well to mention here that the pattern-shop was about three miles in one direction, and the foundry about 4½ miles in another direction, by trolley.) I ordered all castings, and, as our patterns were returned each time they were used, I was obliged to get out the patterns, and when they were returned, check them all off, assort the castings, and place them in their proper bins. I also gave out the work to the men, looked after it, and often, with a new man, personally broke him in. I looked after all finished stock, and if a man was off a machine tool for a day, I was welcome to make use of it.

There was a constant cry from the management for better ways of doing the work, but if even a simple jig was suggested, it was stated that it would cost too much; if a fixture for some machine tool was suggested, the reply was, "Well, we haven't the time to make it," or "We cannot spare the machine as the machine has all it can do;" so, of course, the part would have to go back to the bench and be finished by hand. But even at that, when I did manage to make some

devices that were tried and liked, I would hear the old story repeated again. Then, in addition, when we made any new improvements in the machines we were building, of which I did a number, if it was a case for a patent, I made an assignment without any reward whatever. I also looked after all shafting and belting, motors, etc., made outside repairs to the buildings, looked after all the men's time cards, saw that they kept them straight, and I suppose did a number of other things that I do not recall just now—but I was supposed to enjoy the confidence of the management. When I went away, they called me "superintendent," but I didn't know it before. MARS.

EXPANSION BORING-BARS.

There still seems to be room for the improvement of boring-bars. There are shown in the accompanying engravings two different types of bars, which I do not claim to be past improving upon, but nevertheless they have proved to be very satisfactory in many respects. About ten months ago I made the bar shown in Fig. 1, and gave it to the foreman of the boring mill department of the Colburn Machine Tool Company,

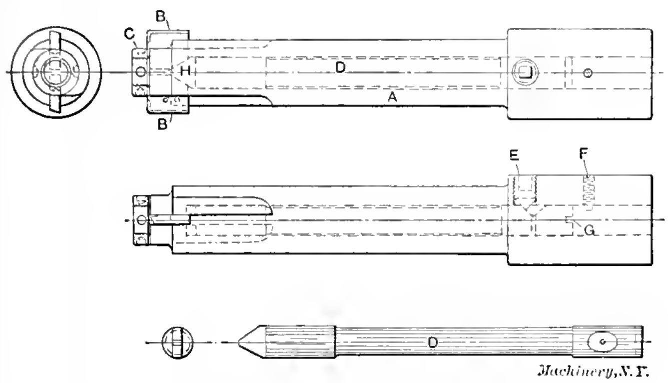

Fig. 1. Boring-bar with Adjustable Cutters.

by whom I was employed at the time as head tool-maker. He was very much pleased with it, and had me make up different sizes of cutters at once. The bar is still in good working order and does not show any great wear. A bar of somewhat similar construction, which was designed by one of the men under me, is shown in Fig. 2. This bar is a great deal cheaper and easier to make than the bar shown in Fig. 1, but does not prove so satisfactory in some respects. Referring to Fig. 1, bar *A* is made from a piece of machine steel. A hole for plunger *D* is drilled and reamed, the hole being bottomed out with a square-nosed drill. This may not seem practical, as in drilling long holes the drill is very liable to run off,

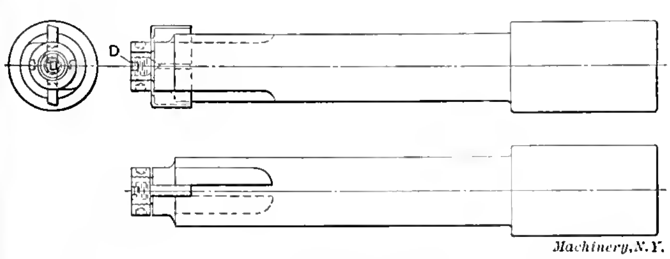

Fig. 2. Bar with Cutter Adjustment, but of Simpler Construction than the One shown in Fig. 1.

but in this case that does not make any material difference, as plunger *D* is all fitted in place before the cutters *B* are turned. Binder collar *C* is screwed firmly against the cutters *B*, and the bar is then put in the lathe and the cutters turned to size while in position in the bar. One cutter should be marked, so that each cutter can be placed back in the bar in the same position, making it impossible for them to be out of true, regardless of the location of the plunger hole. Binder collar *C* is made from machine steel, and case-hardened. The included angle of plunger *D* at *H* is 60 degrees. The maximum adjustment of the cutters is about 3/16 of an inch. This adjustment is accomplished by screwing the plug *E* against the conical surface of the plunger *D*, which forces the plunger against the cutters *B*, spreading them apart. Screw *F* is merely to keep the plunger from dropping out of place, in case screw *E* should be backed out too far. Screw-driver slot *G* is merely put in to aid in the assembling of plunger *D*. In setting cutters *B*, binder collar *C* should be tightened slightly by means of a spanner wrench, until after the cutters have been set to the proper size. One of the advantages that this bar has over the bar shown in Fig. 2, is that the adjustment screw *E* is always out of the way of the work and can easily be adjusted whether cutters be in the bore or out. The cutters of the bar shown in Fig. 2, are held in the same manner as in Fig. 1, but they are adjusted by means of the adjustment screw *D*, which is screwed in or out with a suitable wrench. One bad feature in connection with the bar shown in Fig. 2 is that the adjustment screw *D* sometimes jars loose and works out, but even then the binder collar *C* holds the cutters so firmly that I have never known them to move. These bars have both been in use on a 34-inch Colburn boring mill where there is lots of power to give them a hard test. The cutters used are made of high speed steel. B. M. WELLER.

Franklin, Pa.

MAKING PISTON RINGS.

The method here described of making piston rings is used with good results in a shop building first class gas engines. A common ring blank having three lugs on one end is jig drilled, and secured with three cap-screws to a turning plate which has a number of tapped holes for the different size ring blanks. This turning plate is clamped to the chuck face with three clamps, and after the blank is turned outside, the plate is given one-half turn on a chuck bushing the plate end of which is turned 1/32 inch eccentric to chuck end. A stop-pin hole is drilled in the plate, which is used when the plate is revolved one-half turn after turning blank. The blank is then in position for boring. The bushing on which the plate turns is a driving fit in the bore of the chuck of a turret lathe (in this case a "Gisholt"), and this bushing is bored to take a stiff cutter bar. Two cutters are used in boring, one for roughing, and the other for finishing the bore of the blank to size. The bushing and chuck are marked plainly so that the bushing will always be driven in the chuck with the eccentric in the same relation with the stop pin hole in the turning plate.

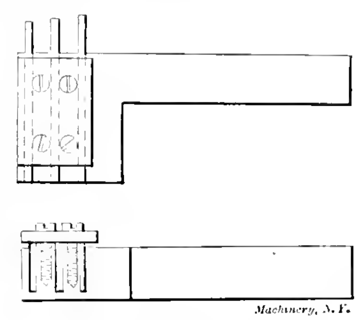

Fig. 1. Gang Tool for Cutting Off the Rings.

A gang cut-off tool is made, as shown in Fig. 1, and the rings are cut off 1/32 inch wide to allow for side finish. An expanding arbor (Fig. 2) and a straddle tool (Fig. 3) are used in facing the rings to size. A standard snap gage is used to keep the rings to a standard width. A straddle tool for each width of ring should be made so that readjusting on

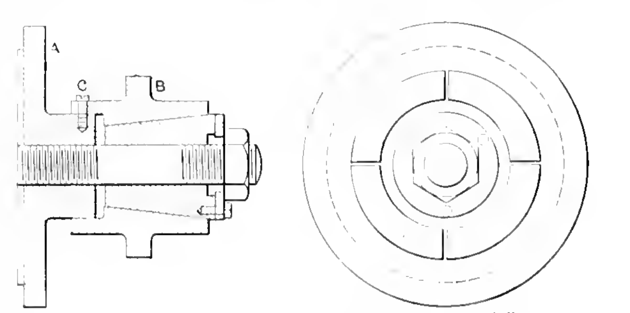

Fig. 2. Expanding Arbor for Holding the Rings while Facing them.

each size of ring will not be necessary. An almost incredible number of rings can be faced without regrinding when high speed steel bits are used. The expanding arbor plate *A* is secured to the face-plate of an engine lathe with three screws. The expanding sleeve *B* is held loosely to hub of plate by three screws *C*. These hold the expanding sleeve while drawing out the taper plug, and they also keep the bushing in the same position so that the ring to be faced will always

be central with the straddle tool. The sleeve is made in the usual way, one side being milled through with a milling saw, and a number of other slots being milled from both ends to within about ⅜ inch of the opposite ends. Almost any size sleeve can be made for this plate and arbor.

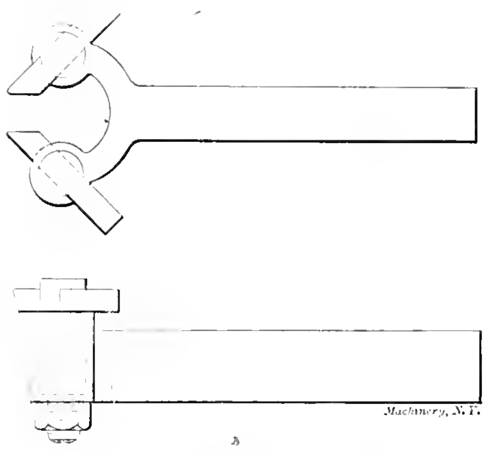

Fig. 3. Straddle Tool for Facing the Rings.

In Fig. 4 is shown the fixture used in milling the lap joint. The block *A* and clamp *B* are made to correspond with the outer and inner curvatures of the ring, the clamp having a flange to clamp down on the edge of the ring. The other end of the clamp is beveled to fit the block *C*. When the eccentric

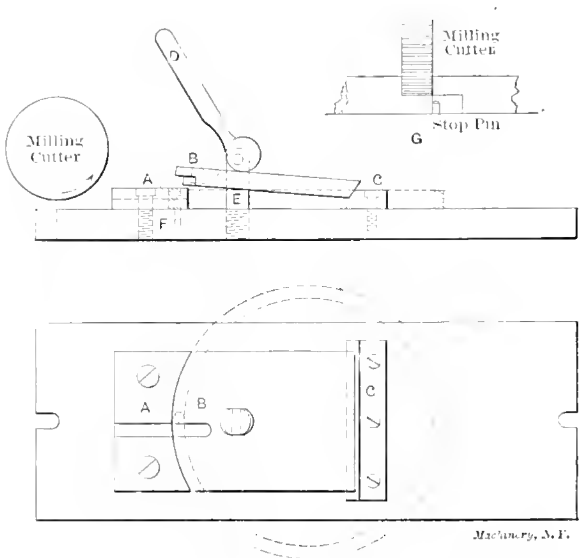

Fig. 4. Fixture for Holding the Rings when Milling the Lap Joints.

lever *D* is forced down, the clamp will hold the ring down and against the block *A*. The position of the ring is shown in Fig. 4 by the dotted lines. A coiled spring under the clamp *B*, and around the stud *E*, will raise the clamp so that the ring can be removed easily. After the rings are milled on

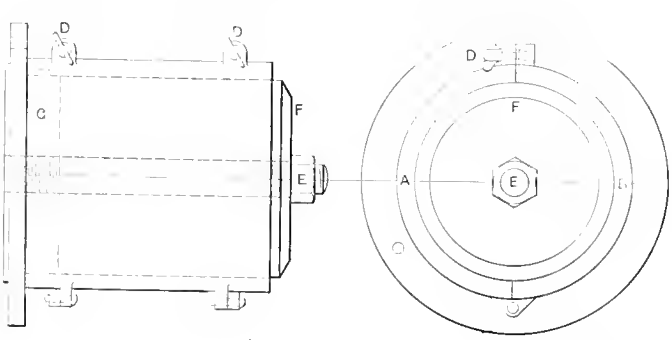

Fig. 5 Fixture for Holding the Rings when Finishing the Outside.

one side they are turned over, and the milled slot is set against a stop pin *F* which is inserted in the bottom plate. This stop pin sets the ring so that the cuts are taken as indicated at *G*, and a lap joint is formed when the rings spring together. A number of blocks and clamps can be made to use with rings of different sizes. The rings are now ready to be finished on the outside. The device shown in Fig. 5 is used in connection with this operation, and it is also secured to the face-plate. This device consists of a sleeve having two parts, *A* and *B*, these being connected with a hinged joint. The rings are placed inside this sleeve, and it is clamped to the plate *C* by the thumb screws *D*. The rings are then clamped to the plate by the nut *E* and plate *F*. The hinged sleeve is removed and the rings are turned to size.

Y. Ziegler.

TECHNICAL EDUCATION FOR MACHINISTS.

In this age of intellectual progress, one cannot help wondering at the comparative backwardness of the rank and file, engaged in mechanical arts, in acquiring technical knowledge pertaining to their vocations. Although technical knowledge is a rather broad term, it is generally applied to such knowledge as involves the fundamental and derived principles of any branch of industry, and upon which principles the evolution of any industry must be based. It can no longer be argued that the general lack of technical knowledge among machinists is due to absence of opportunity. Every large industrial center has institutions which offer every facility for technical education; and such facilities are in almost all cases available for persons for the mere asking, or at a minimum nominal cost.

It is manifestly impossible for every machinist to have had the benefits of a course of study in a technical school. Nearly every machinist starts to learn the trade at the average age of sixteen years. The knowledge he starts out with is rarely more than that acquired in the grammar school. Indeed, a canvass among the apprentices of any large plant would very likely show that not more than one-half have even graduated from the public grammar school or its equivalent. It is only in rare cases that a young machinist is found who is steadily pursuing a systematic course of technical study. Investigation will generally prove that those who do, have had the early advantage of better education, probably a few years in high school, which, no doubt, has given them the impulse to learn more.

In Greater New York, as well as in all larger cities, the Board of Education maintains a splendid system of evening schools of all grades. Here anyone can make up any deficiency in education due to lack of early opportunity. Instruction in these schools is absolutely free, including even the free use of text-books and supplies. The instructors are very often men who during the day teach in the best engineering and trade schools, and also men who hold important and responsible positions in the engineering professions. The correspondence schools also offer splendid opportunities for acquiring knowledge, although the scope of the knowledge they impart is necessarily somewhat limited on account of the impossibility of personal association between instructor and pupil. There are also the free public libraries whose shelves hold the best books on technical science. The Pratt Institute free library of Brooklyn has a splendid science reference room in which are kept current numbers of numerous industrial and technical periodicals, as well as complete reference libraries of every science and industry. This department could easily accommodate many times the number of persons who now regularly make use of it. It seems as though young men were needlessly starving in the midst of plenty. Although the democracy of education has been made practicable, how few there are who have thus far taken advantage of it. What valuable suggestions for mechanical improvement might come from machinists who can think with the precision acquired by a systematic course of technical training, and who have developed the capacity for keen observation during their daily work. Many large concerns have recognized the value of such training in their employes by maintaining regular schools, in which every apprentice receives, as far as practicable, a thorough technical training, aside from his regular shop instruction. In many cases these apprentices advance to responsible positions in these concerns. While it is true that the technical schools are graduating large numbers of young men as mechanical and electrical engineers, it is

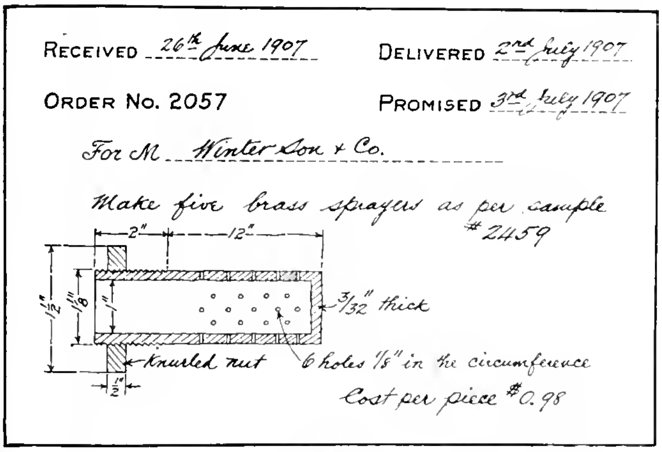
equally true that these men are more or less handicapped by a lack of thorough shop training. The ambitious mechanic need not therefore fear much from the competition of college graduates if he is himself well equipped in technical knowledge. Of course, one cannot expect every machinist apprentice to become an expert mechanical or electrical engineer. There are, however, many men engaged in the trade who, if they followed their natural bent, and took advantage of some of the many educational opportunities, would develop into men who would eventually play an important part in the progress of the machine industries. F. WALSLEBEN.

Brooklyn Hills, L. I.

SIMPLE COST SYSTEM FOR SMALL SHOPS.

A great number of small shops, especially jobbing shops, use no cost system. It is then, very often, a part of the foreman's task to keep the record of the time and the materials needed to carry out the work. This may be easy to do when many of the same kind of pieces are required, but, when thirty men are working on several jobs, repair jobs for instance, the foreman's task may prove to be too heavy. It is obvious that under such conditions the exact cost and profit of a job are seldom known. The writer has had many occasions to note the big differences between the apparent and the real costs, and these differences indicated the necessity of a cost system even in the smallest shop. The one here illustrated was devised for, and has been for several years in use in, a jobbing shop employing about fifty men.

An order, Fig. 1, is sent from the office to the foreman for every job. Full details of the work to be done are given,



RECEIVED 26th June 1907 DELIVERED 2nd July 1907
ORDER No. 2057 PROMISED 3rd July 1907
For M. Winter Son + Co.
Make five brass sprayers as per sample #2459

Fig. 1. Order for Foreman, giving Details of the Work to be Done.

indicating numbers of drawings, sketches or samples, if there are any, in short, everything that will furnish a ready reference in the future. The foreman notes in a special book the date order is received and the name and address of the customer. When the work is ready, he notes on the same line in his book the date of delivery. Every day the new orders are recorded, and the finished cancelled. Once in a month the whole is rewritten. Patterns, castings or special materials are ordered by the office according to the foreman's directions.

A shop order, Fig. 2, is given by the foreman to the workman for every piece or series of pieces to be made in the shop. All material wanted is applied for in the store-room. The storekeeper notes on the back side of the shop-card the kind and quantities of the materials used. When the work is finished the workman writes down, as shown in Fig. 2, his name, shop number, and the time devoted to the work.

The shop card, Fig. 2, was issued for the office order, Fig. 1, and a glance at both will show nearly everything in regard to the system. As will be seen, the work was first handled by the turner and then by the fitter. Finally a boy polished the finished sprayers, and delivered the work and the card to the foreman, who saw thus at a glance everything concerning the cost of the job. The net weight of material is marked upon the card which is then sent with the office order to the office, where special expenses and general charges are added. Finally, the cost and the date of delivery are marked upon the orders and they are filed.

Some orders require more than one shop card; for instance, to bore a 22-inch cylinder true, put new spring rings in the piston, true up the piston rod, and put new bronze bushing on the stuffing box. Four shop cards are then made, one for every part of the job, so that the cost of every detail is known. Nothing in the shop is done without an order, and not an hour is spent at a job without a shop card.

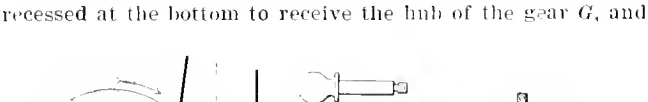
BALL GRINDING FIXTURE.

Once, when employed by a firm engaged in the manufacture of printing presses, an occasion arose for making certain details, having a ball point as shown in Fig. 1 in the accompanying engraving. These balls had formerly been turned and then lapped with emery, but it was concluded that, by a proper fixture, these balls could be produced in a simpler way by grinding to the finished shape, after rough turning. The device shown was used on a Brown & Sharpe universal grinding machine.

Referring to Fig. 2, the frame A is made of cast iron, provided with a hole bored to receive the bolt B. The frame is recessed at the bottom to receive the hub of the gear G, and a



Figs. 1 and 2. Sample of the Work, and Fixture for Grinding the Ball Point on a Universal Grinder

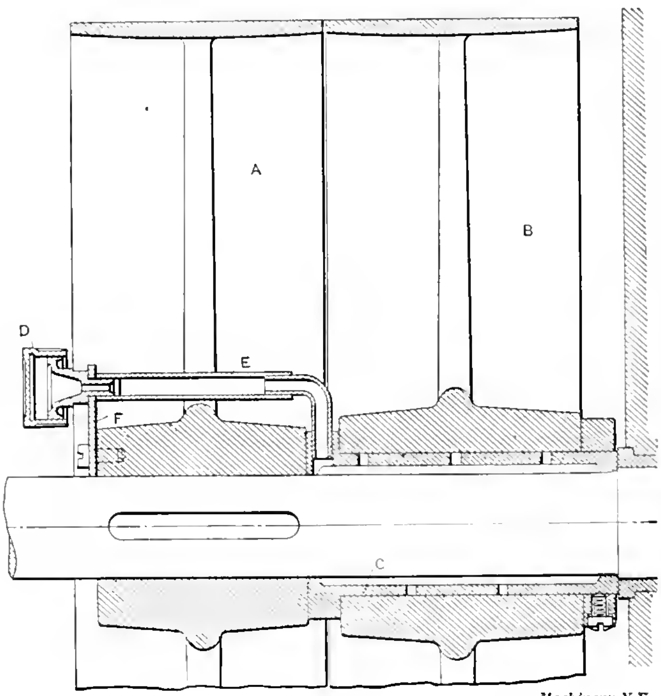
projection on the bottom of A is turned to a running fit in the cast iron plate P, upon which the fixture is mounted. A hole forming a bearing for the sleeve S is bored in A in the same plane as, and exactly at right angles to, the bolt hole B. A pulley R is mounted on the sleeve S, and keyed to it. This pulley is driven by a belt from an overhead pulley, causing the ball to revolve on its longitudinal axis. The wrought iron brackets or straps E are forged and support the fixture. They

are bolted to the sides of the bed, and are set so as to allow a slight clearance between the spur gear G and the table of the grinder. The rack M is fastened to the table, and is in the right position to engage with the spur gear G, and as the table is driven back and forth it carries the rack with it, which drives the spur gear, producing a rotating motion for the frame A, causing the ball to rotate on its perpendicular axis. Now, as the ball rotates on the perpendicular axis and has a revolving motion on its longitudinal axis, it is plainly seen how the ball is ground. This fixture gave good satisfaction in the shop where it was used. W. A. SAWYER.

Athol, Mass.

DEVICE FOR OILING LOOSE PULLEYS WHICH ARE INACCESSIBLE FOR ORDINARY OILING DEVICES.

When a loose pulley is placed very close to the frame of the machine, as is the case with the loose pulley shown in the accompanying engraving, the question of oiling the loose pulley may offer difficulties, and in dusty places sometimes cause disturbances in the running of the machine.



Section through Tight and Loose Pulleys showing Method of Oiling.

The oiling of loose pulleys mounted in this way, however, can easily be accomplished by the use of the device shown in the engraving. The loose pulley B is mounted on a bushing, which in turn is keyed to the shaft. In this bushing an oil reservoir is provided which is connected with the inside surface of the bore of the loose pulley by a number of small perforations. The oil cup is fastened to the tight pulley on the side where there is no difficulty of access. The oil cup is then connected with the oil chamber in the bushing by a small bent pipe as indicated in the engraving. By arranging this oiling device on the drive of a vertical gang saw, the disturbances in operation, on account of the bearing of the loose pulley running warm, were entirely eliminated.

Pilsen, Austria-Hungary. MORITZ KROLL.

PUZZLING ARITHMETICAL EXPRESSIONS.

It seems as if the mathematical rules for simplifying an expression like $10 + 4 \times 5$ are not well known among mechanics. The general idea is to solve in succession, instead of regarding the manner in which the expression is connected by the signs, $+$, $-$, $\times$, and $\div$. Mistakes are therefore commonly made. It surprised the writer to find that in a shop of about 300 men there were only two men who were sure that the correct answer to the expression $10 + 4 \times 5$ is 30, and this was in a shop with men of average intelligence. Most of the men got the result 70. The reason why the result of this expression is 30 instead of 70 is that the signs $\times$ and $\div$ take precedence over $+$ and $-$ in mathematical calculations. However, in no text-books that the writer has been able to obtain has this rule been given in plain words, although all the examples have been worked out according to this rule.

New Britain, Conn. D. W. JAMES

[In order to make the expression containing the numbers and signs mentioned in our correspondent's example equal 70, it would be necessary to put a parenthesis around the expression $10 + 4$; that is, $(10 + 4) \times 5 = 70$. Otherwise, the multiplication should be carried out before the addition, and the result will be 30. If, instead of treating this little problem as an arithmetical one, we transform it into algebraic form, the reason for this rule is very obvious. If we substitute a for 10, b for 4, and c for 5, we have $a + b \times c$, or, as it is commonly written, $a + bc$. A glance at this expression shows at once that b is to be multiplied by c before the result of the multiplication is added to a. If it is required to add a to b, and then multiply by c, the expression would have to take the form $(a + b)c$. If we insert the mathematical values for a, b and c in these two expressions, we get 30 and 70 respectively, as before, and we have a valid mathematical proof, as well, for our rule.—EDITOR.]

LOCKING DEVICE FOR JIGS.

Quite often drill jigs have a bushing plate in the form of a leaf which swings on a hinge out of the way so that the piece to be drilled can be put in place in the jig. This requires a locking device which can be depended upon to hold the bushing plate exactly in place while drilling. The locking device shown in Fig. 1, and also shown applied to a jig

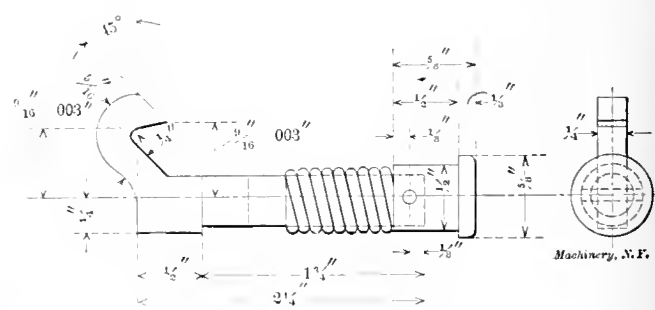


Fig. 1. Detail of Locking Device.

in Fig. 2, answers this purpose admirably, and after using a number of different designs I find the one shown here to be by far the best I have ever seen. To open the jig so as to put in the piece to be drilled, all that is necessary to do is to push the button on the end of the lock trigger and lift the leaf up. When the piece is in place in the jig, the leaf is again pressed down into place. The pressure springs the locking device, and the trigger grips the pin shown. The part

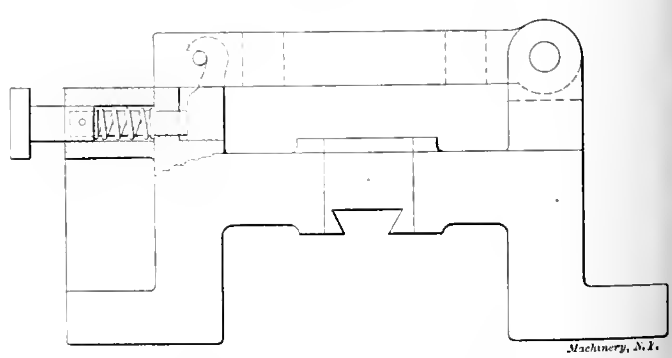

Fig. 2. The Locking Device applied to a Jig.

of the trigger which fits against the pin should taper slightly. This makes it hold much more tightly, and also takes up what little wear there may be on it. The device can be fitted to a great variety of jigs and fixtures. It is very simple and inexpensive to make, and above all, it is quick and simple to operate, positive in its action, and will last the lifetime of any jig without repairs. TOOL DESIGNER.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

SUBSTITUTE FOR STEADY-REST.

Under the head of "Shop Kinks" in MACHINERY I have a suggestion to make. A very good substitute for a follow-rest or steady-rest, and one which can be used in a great many cases where a steady-rest is troublesome, for instance on small shafts which are too long to turn without chattering unless a steady- or follow-rest is used, consists of a wooden block, say 4 inches square and of sufficient length to reach from the back side of the carriage to the shaft being turned. The block should bear on the shaft a little ahead of the cutting tool and its weight will prevent chattering to a very great extent. JOHN MCLEOD.

Birmingham, Ala.

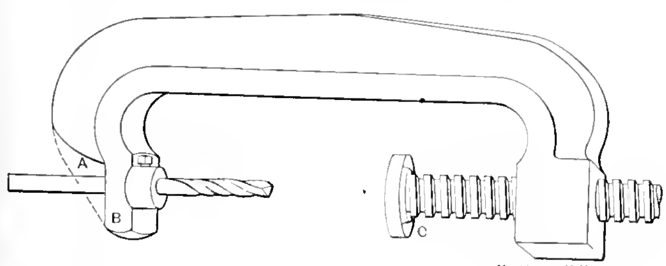
KINK FOR LINING.

I have seen several devices for section lining, but find the following very satisfactory: Take a bow pencil and set the needle point about one-sixteenth short of the pencil point, which should be sharpened to a chisel point; then set the bow pencil to the correct distance between the section lines wanted. Draw your first line with the pencil point next your triangle; your needle point will gage the width of lines and should not touch the paper but simply act as a guide for the eye. The bow pen can be used in the same manner. I do not claim this to be original, and some of the readers of MACHINERY may already be familiar with this method, but I have worked in some of the largest drawing-rooms in the country and have not known of this method being used.

TRIANGLE.

SIMPLE PORTABLE DRILL.

The quickest and simplest method of constructing a portable drill is by taking a large clamp, cutting out a part of the web, as shown at *A* in the accompanying engraving, and then drilling a half-inch hole through the upper jaw *B*, through which hole the drill may be passed. Then a collar with a set-screw is made, which is placed on the tool shank, the collar bearing against the inside of the upper jaw. For turning the



drill a chuck may be used with a bit stock, or a crank may be made provided with a set-screw for clamping the drill, which will serve the purpose equally well. The feeding is done by the clamp screw *C*. This style of drill may be used in numerous places where no other device could be applied; and if the clamp is wanted for clamping purposes, it may still be available for that purpose. G. M.

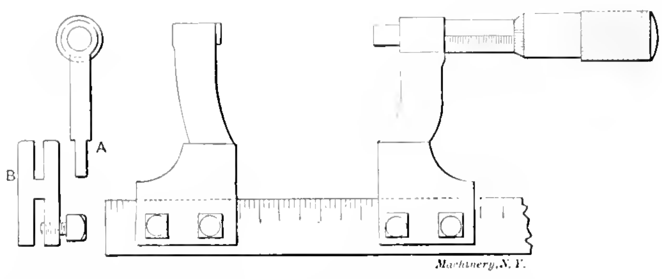
APPLYING LEATHER FILLETS TO PATTERNS.

It is very common to see a notice on the tags, attached to bundles of leather fillets, "Use plenty of good glue." Glue, however, is a bad thing to use for applying leather fillets to patterns, because the moisture from the wet sand penetrates the thin edges of the leather and makes them curl away from the patterns when glue is used. The best adhesive to use for leather fillets is the regular orange shellac used in varnishing patterns, excepting that the shellac used should be quite thick. A sufficient amount of fillet for the work in hand is given a coat of shellac on the inside, and the same is done with the corners of the patterns which are to receive the fillets. Repeat this operation about three times, allowing two or three minutes between the coats, so that the varnish may soak in. After applying the last coat, place the leather fillet in position and rub it into place with a round stick of suitable size to correspond to the radius of the fillet. Proceeding in this way, the result will be far more satisfactory than when using glue, and the fillet will be practically water-proof. J. W. WOLFENDEN.

Nashville, Tenn.

MICROMETER SCALE.

I have been using the micrometer, mounted as seen in the illustration, for some time, and I don't see how I could get along without it now. I use the micrometer on a 4, 6, 9, or 12-inch scale. It can be adjusted on standard plugs. I have made a set of gages up to 12 inches, out of 3/16-inch round tool steel wire. In mounting the micrometer, before cutting

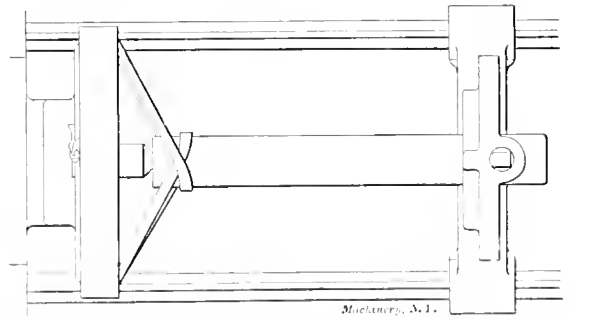


it apart, I milled the shoulders shown at *A*, and in milling the bottom pieces *B* used a piece of machine steel long enough for both, cutting the piece in halves after milling the slots. In this way I was sure of perfect alignment. In a shop where they do not keep a set of micrometers, this arrangement is very handy. WM. AINSCOUGH.

Plainfield, N. J.

USE OF THE STEADY-REST.

I have noticed that some men who claim to be tool-makers do not know how to make the best use of a steady-rest, and others seem to have very crude ideas about using it. A great many men use a chuck for holding one end of the work, even when it has centers in it. Of course, the work has to be trued up in the chuck, and this is a very difficult operation, although a very common one. A test indicator is almost indispensable for a job that requires accuracy. I never use a chuck unless the work is without centers. I always strap my work to the face-plate with a strip of belt lacing, and this method has proved very satisfactory. Two 3/4-inch holes are drilled in the face-place at right angles to the driving-slot, and opposite each other. Then the work is placed between the centers, and the jaws of the steady-rest adjusted to it. The face-plate is then unscrewed a few turns, and the leather strap is wrapped around the work from one side, and the two ends of the strap passed through one of the holes in the



face-plate. One end of the strap is then passed back through the opposite hole in the face-plate and around the work from the other side. The ends are then tied together, and the face-plate is screwed onto the spindle, which causes the strap to tighten and draw the work against the center as shown in the engraving. Work can be done in this way accurately and quickly. I never use wooden or fiber jaws unless a steady-rest is equipped with them. If the work has a finish, a strip of emery cloth with the cloth side next to the work will protect it, and keep it from being marred. J. J. VOFTEKER.

Decatur, Ill.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

DRILLING DEEP HOLES.

A. L. B.—What is the average time required for drilling small deep holes, say, from ¼- to ½-inch diameter and 20 to 30 inches deep, where special appliances are provided?

A.—The only drilling of this nature of which we have any record is gun barrel drilling, and the figures given below were taken from the records of a large concern, three or four years ago. Since then we understand the speed has been considerably accelerated, especially on 22-caliber barrels.

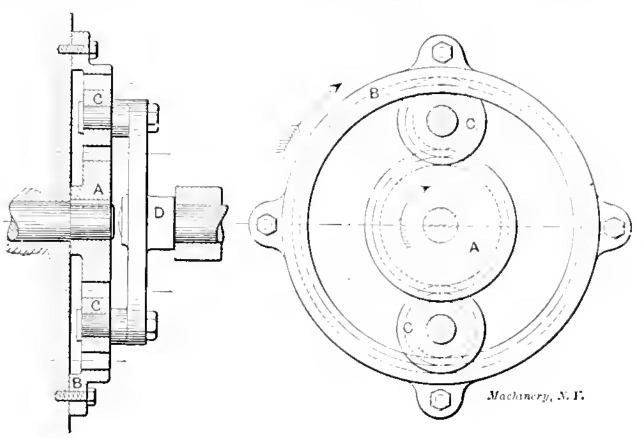
Caliber, inch.	Length, inches.	Time, minutes.	Driller's Daily Production.
0.22	24	48	120
0.32	24	34	130
0.38	24	24	140
0.44	24	24	140

The above figures are for low carbon steel. Nickel steel barrels require from 5 to 7 minutes longer.

EPICYCLIC GEARS.

L. A. F.—I desire to construct an epicyclic mechanism of the kind illustrated in the accompanying sketch. *B* is a stationary internal gear, *A* is the driving spur gear, and *C* two intermediates connecting *A* and *B*. These intermediates are mounted on pivots carried by disk *D*, which is keyed to the driven shaft. *A*, driving, makes 1,140 revolutions per minute; internal gear *B* has 62 teeth; how many teeth should gears *A* and *C* have to give *D* 690 revolutions per minute?

A.—A simple way to analyze a case of epicyclic gearing like this is to find, by the following method, how many revolutions *A* makes to one of *D*. In the sketch, *B* is shown held to the frame of the machine by cap screws. Remove these cap screws, and revolve the whole mechanism (with gears *A*, *B*



and *C* locked so that they do not turn on each other) in the direction of the arrow, for one revolution. This, of course, will revolve both *D* and *A* one revolution each. If the gears be now unlocked, and *D* be held stationary while internal gear *B* is revolved back again (in the direction opposite to the arrow) to the position it originally occupied, this movement will still further revolve *A* in the direction of the arrow, and will leave the mechanism in the same condition it would have been in had *B* remained fixed to the frame of the machine, and while *D* was revolved once in the direction of the arrow. If we can find, then, how many revolutions *A* makes in the operation we have just been through, we will know how many revolutions it makes for each revolution of *D* while the mechanism is in operation.

In the following analysis, these reference letters are used:

N_a = number of teeth in *A*
N_b = number of teeth in *B*
M_a = revolutions per minute of *A*
M_d = revolutions per minute of *D*

In revolving *B* in the direction of the arrow for one revolution with the gears locked, *A* evidently makes one revolution. In returning *B* to its original position with *D* locked, the number of revolutions *A* makes is evidently found by dividing the number of teeth in *B* by the number of teeth in *A*, since *C* acts merely as an idler under these conditions and does not affect the ratio. The sum of the two movements thus effected, gives the number of revolutions of *A* to one revolution of *B* when the mechanism is working. We have then

$$\text{revolutions of } A\text{, mechanism locked} = 1$$

$$\text{revolutions of } A\text{, returning } B \text{ to position} = \frac{N_b}{N_a}$$

$$\text{revolutions of } A \text{ to 1 revolution of } D = 1 + \frac{N_b}{N_a} \qquad (1)$$

The desired number of revolutions of *A* to one revolution of *D* is evidently found thus:

$$\text{revolutions of } A \text{ to 1 revolution of } D = \frac{M_a}{M_d} \qquad (2)$$

Making (1) and (2) equal to each other, we have the following equation:

$$\frac{M_a}{M_d} = 1 + \frac{N_b}{N_a}$$

This solved for N_a gives us $N_a\left(\frac{M_a}{M_d} - 1\right) = N_b$

$$N_a = \frac{N_b \times M_d}{M_a - M_d} \qquad (3)$$

which is the formula for finding the number of teeth in gear *A*, under the conditions proposed by our problem. Solving this formula for the figures given, we have

$$N_a = \frac{62 \times 690}{1140 - 690} = \frac{42,780}{450} = 95 +$$

which is evidently absurd, since it is impossible for *A* to have more teeth than *B*, the internal gear which surrounds it, both being of the same pitch. No mechanism of this sort will give *D* as much as half the number of revolutions per minute that *A* makes. The larger gear *A* is, and the smaller intermediate gear *C* is, the nearer 2 to 1 will the ratio be. It can be done by using compound gearing in place of *C*, but very likely you would not care to go to that extent of complication; otherwise the problem is impossible. In solving problems by this formula it should be noticed that the difference between the number of teeth in *A* and the number of teeth in *B* must be an even number: and that half this difference will be the number of teeth for each of the intermediate gears *C*.

JIB CRANES.

H. E. R. How should the stresses and sizes of the members for the crane shown in Fig. 1 be figured? The load is 5 tons. Members are to be built up of two channel irons each side, back to back.

A.—The calculation of the size of the channels is one of trial and error largely, and would occupy too much space to give here in detail, so we will simply give calculations showing the maximum stresses in the members we have selected as suitable for use in the case in question, after having tried various sizes. As shown in Fig. 2, it seems best to use 15-inch 33-pound channels for the yard arm, and 12-inch 20½-pound channels for the mast and brace. The channels forming the mast should be latticed. The calculations given below do not consider any of the minor factors which enter into the problem, such as the weight of the beams themselves, the weight of the trolley, and the pull of the ropes. These factors would appear to be amply taken care of in the margin of strength given by the channels selected. The designer, however, should always make sure of this.

The following table gives the properties of the shapes we will consider in our calculations:

Depth of channel in inches........	15	12	10
Weight per foot in pounds........	33.0	20.5	15.0
A = area of section in square inches	9.90	6.03	4.46
r = least radius of gyration........	0.912	0.805	0.718
Z = section modulus, axis perpendicular to web..............	41.7	21.4	13.4

In addition to the reference letters given in the table above and in Fig. 2, the following will be used:

M = bending moment.
S_b = maximum fiber stress due to bending.
S_t = maximum fiber stress due to tension.
S = maximum fiber stress.

First find the maximum fiber stress due to bending at D in the yard-arm, when the load is at the extreme outer position E in Fig. 2.

$$M = Wc = 5,000 \times 60 = 300,000 \text{ inch pounds.}$$

$$S_b = \frac{M}{Z} = \frac{300,000}{41.7} = 7,200 \text{ pounds per square inch} \quad (1)$$

Note that W is only half the total load, since each member of the structure is composed of two channels, one on each side. The bending moment at D when the load is at B is found thus:

$$M = \frac{Wl}{4} = \frac{5,000 \times 96}{4} = 120,000 \text{ inch-pounds} \quad (2)$$

This being much smaller than in the previous case, it will give less than half the fiber stress. Unless there is some good reason for the design of framework adopted, it should be well to make ED about one-fourth of the length of DH. If this is done, the bending moment will be the same whether the load is at E or B, and, will in either case, be less than the maximum moment we have just found, so that a smaller section could be used.

The vertical reaction at D is found thus:

$$R_1 = W \times \frac{a}{l} = 5,000 \times \frac{13}{8} = 8,125 \text{ pounds} \quad (3)$$

This produces a tensile stress in DH which may be found by the parallelogram of forces shown in Fig. 2, or by the following calculation:

$$R_3 = R_1 \times \frac{l}{g} = 8,125 \times \frac{8}{12} = 5,420 \text{ pounds} \quad (4)$$

The stress per square inch in DH due to this force is:

$$S_t = \frac{R_3}{A} = \frac{5,420}{9.9} = 550 \text{ pounds per square inch} \quad (5)$$

Adding this to the stress found in (1) we have the total stress in DH:

$$S = S_t + S_b = 550 + 7,200 = 7,750 \text{ pounds per sq. in.} \quad (6)$$

which is the maximum fiber stress in the yard-arm, occurring just to the right of point D. This is well within the limit of safety, which may be taken as about 13,000 pounds per square inch.

The allowable fiber stress in the brace may be calculated from the following formula based on Rankin's formula for columns:

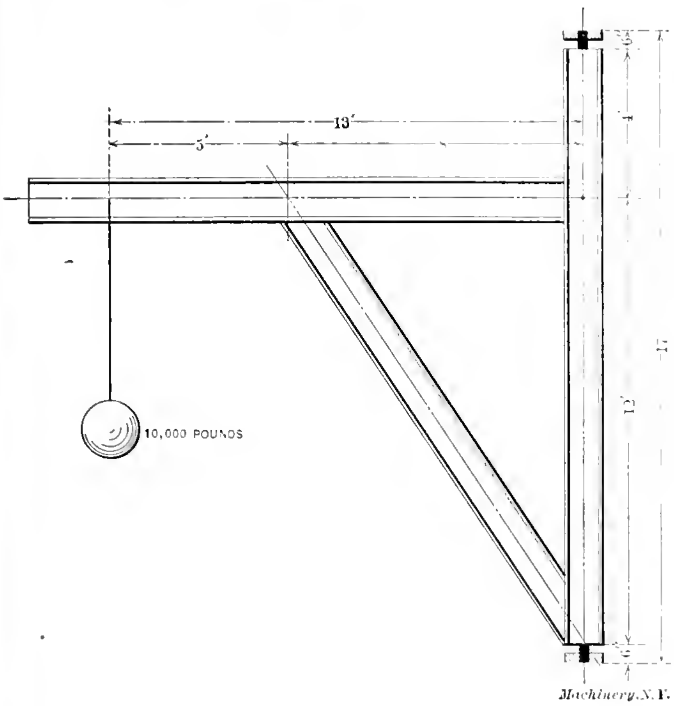


Fig. 1.

$$S = \frac{15,000}{1 + \frac{e^2}{13,500 \times r^2}} = \frac{15,000}{1 + \frac{173^2}{13,500 \times 0.805^2}}$$

$$= 3,395 \text{ pounds per square inch.} \quad (7)$$

The reaction producing compression in CD is found by the force diagram in Fig. 2, or by the following calculation:

$$R_2 = R_1 \times \frac{e}{g} = 8,125 \times \frac{173}{144} = 9,760 \text{ pounds} \quad (8)$$

The compressive stress per square inch in the brace is, then,

$$S = \frac{R_2}{A} = \frac{9,760}{6.03} = 1,620 \text{ pounds per square inch} \quad (9)$$

which is, as may be seen, not quite one-half the allowable amount. The ratio of the length to the radius of gyration ($e \div r$) in this strut is so great, being about 215, that it is wise to keep the unit compressive stress down to a very low point.

The mast is most liable to fail by bending at H when the load is at E. To find the bending moment at H, we must first find the horizontal reaction at G:

$$R_4 = W \times \frac{a}{k} = 5,000 \times \frac{13}{17} = 3,825 \text{ pounds} \quad (10)$$

The bending moment at H is then:

$$M = R_4 \times f = 3,825 \times 54 = 206,550 \text{ inch-pounds} \quad (11)$$

and the maximum fiber stress due to bending at this point is

$$S_b = \frac{M}{Z} = \frac{206,550}{21.4} = 9,650 \text{ pounds per square inch} \quad (12)$$

which is well within the limit of safety.

If the next size smaller standard channels had been used for these members, the results would have been as follows: A 12-inch $20\frac{1}{2}$-pound channel for the yard-arm would give a

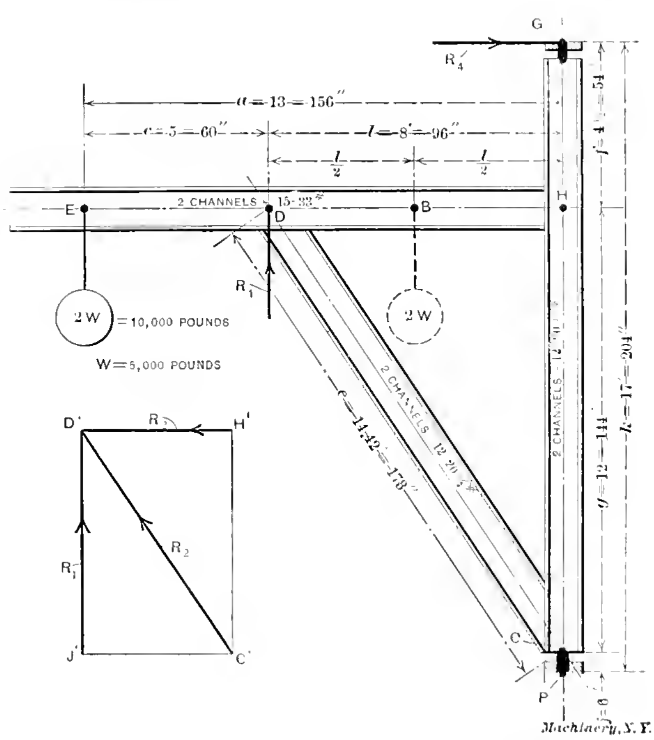

Fig. 2.

maximum stress at D of about 14,000 pounds, which is too much. The unit compressive stress in the brace, if made of 10-inch 15-pound channels, would be about 2,190 pounds. Rankin's formula for this would allow 2,830 pounds, but there is not enough margin of safety with the high ratio of e to r, which is here about 240. The maximum stress in the mast at H would be 15,400 pounds per square inch. It will thus be seen that the sizes we have selected are the commercial sizes best suited for the case in hand.

We expect to publish in a forthcoming issue of MACHINERY an exhaustive article dealing with jib cranes of this type, in which the matter will be taken up more thoroughly.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

QUICK CHANGE GEAR DRIVE FOR THE QUEEN CITY SHAPER.

The Queen City Machine Tool Co., Cincinnati, Ohio, has recently designed a positive speed changing mechanism for their 20-inch back-geared shaper, to take the place of the four-step cone previously used. This device has been designed with especial care, so that it will be simple, durable, effective and easily operated. The builders believe that they have so far accomplished their purpose, that the purchaser who desires to avail himself of the manifest advantages of the geared drive, may obtain them without running the risk of meeting the deficiencies which are found in many mechanisms of this kind.

The mechanism will be understood by reference to Figs. 2 and 3, which show in detail the mechanism seen applied to the shaper in Fig. 1. The single speed driving pulley at the left of Fig. 2 is keyed to the gear box shaft, which runs clear through the column to the gear box attached to the frame on the opposite side. At the right-hand end it carries a friction clutch, operated by the handle shown. The operation

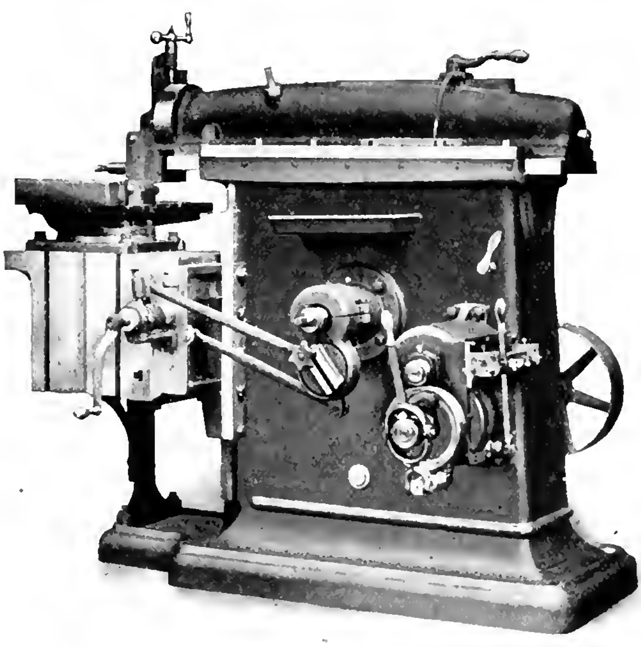

Fig. 1 Quick Change Gear Drive for Queen City Shaper.

of this clutch connects the shaft with a sleeve loosely mounted on it. It may thus be used for starting and stopping the machine, an overhead counter-shaft not being necessary.

The sleeve carries keyed to it a series of four gears of 21, 27, 32, and 38 teeth, respectively. On the driving shaft above the gear box shaft are keyed two sets of double gears, of 38 and 32, and 27 and 21 teeth, respectively. Though keyed to the shaft, these double gears are free to be shifted longitudinally, so that either one of the four gears in the sleeve may be engaged to its corresponding gear on the driving shaft, giving the latter the speed appropriate to the ratios of the driving gears in use at the time.

The mechanism for shifting the gears on the driving shaft is best seen in Fig. 3. The gear shifter lever is pivoted at the bottom on a universal joint, so that it may be moved in and out, or forward and back. Brackets attached to the rear of the gear box support the two sliding rods and the two fixed rods shown in the top view. When the gear shifter lever is tipped in toward the gear box, it lies between gear shifter No. 1 and the dog shown, both of which are fastened to sliding rod No. 1. The shifter lever may now be thrown toward the column or away from it, so that the 27- and 32-tooth gears may be engaged (see Fig. 2), or the 21- and 38-tooth pair. To engage the other set of gears, sliding rod No. 1 has to be brought to the central position shown, where it is held by a spring locking plunger; the shifter lever may then be swung past the fixed rods to operate sliding rod No. 2. The function of the fixed rods is thus to prevent the possibility of throwing two sets of sliding gears at once, by making it impossible to operate one set until the other has been moved to the neutral position. When the lever has

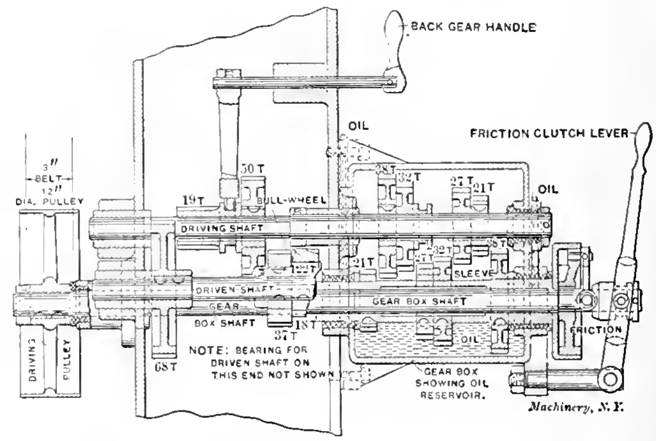

Fig. 2. Longitudinal Section through Driving Mechanism, showing Arrangement of Gearing.

been swung over to lie between the dogs on sliding rod No. 2, the gear shifter may be operated to bring either the 38- and 21-, or the 32- and 27-tooth combinations of Fig. 2 into action. The yoke shown, attached to a sliding rod No. 1, simply serves the purpose of preventing the rotation of that member, thus keeping gear shifter No. 1 in position, the yoke sliding freely on No. 2 for that purpose. Gear shifter No. 2 is kept in position from the fact that sliding rod No. 1 passes loosely through a hole in it, and thus supports it.

The four speeds obtained by the gear box are multiplied by two, giving eight in all, by the double sliding gear on the driving shaft inside the column, whose 19-tooth and 50-tooth members engage respectively with 68-tooth and 37-tooth gears, keyed to driven shaft shown, which also has keyed to it an 18-tooth pinion, engaging the bull wheel from which the ram

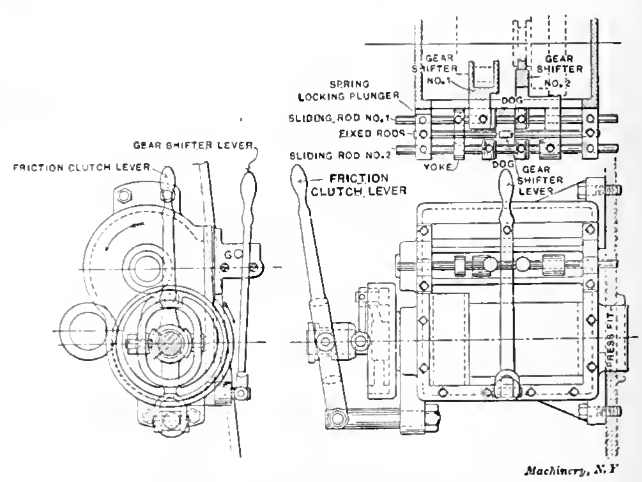

Fig. 3. The Arrangement of the Gear Box, and the Levere by which the Drive is Controlled.

is operated. This double gear is shifted, as plainly shown, by the back gear handle projecting through the side of the column.

The handles for stopping and starting the machines and making the eight speed changes are all located close together, as shown in Fig. 1, and the changes may be made almost instantaneously. The four gear box changes may be made in as many seconds. The clutch is disconnected for this purpose, so that the sleeve is free from the gear box shaft being driven by it only by the slight frictional contact of the bearings. The "selective" control, operated by the gear shifter lever, may then be used to obtain instantly any one of the

four speeds provided without going through the intermediate changes. The slow revolving of the telescopic sleeve permits the meshing of the gears at once, and since the load is off, no shock occurs, so that the change is as smoothly effected as with the cone pulley and the belt, although the power of the drive is very much greater than with the older arrangement.

The use in this mechanism of the principles which have become the standard for the automobile speed change devices will at once be recognized. The changes are made without the use of insecurely supported tumbler gears, or a multiplicity of clutches and levers. In the drawings, the clutches and all the gears are shown disengaged, and it will be noted that the length inside of the box is but slightly greater than the sum of the gear faces, so that the floor space required does not exceed that of a cone driven machine. The positive shifting of the gears and the arrangement of the rods, prevent the possibility of interference and insure safety and reliability. The gear box itself is a press fit in the column besides being firmly bolted to it. All parts are easily accessible for inspection without taking the box from the column. The gears all run in oil so that an efficient and durable action is assured.

When using a constant speed motor (for which this drive is especially suited) the changes can be made without stopping it. When the shaper pulley is belted to the line shaft, it should run at about 350 revolutions per minute on this size of machine. This gives cutting strokes of 7.2, 10.96, 15.4, 23.5, 34.8, 53.1, 74.7, and 114 per minute. An index plate aids in selecting the proper speeds.

EBERHARDT BROS. SMALL AUTOMATIC GEAR-CUTTING MACHINE.

Fig. 1 shows a front view, and Fig. 2 the rear elevation, of the smallest of the line of automatic gear-cutting machines made by Eberhardt Bros. Machine Co., 66 Union St., Newark, N. J. This newly designed tool resembles somewhat its

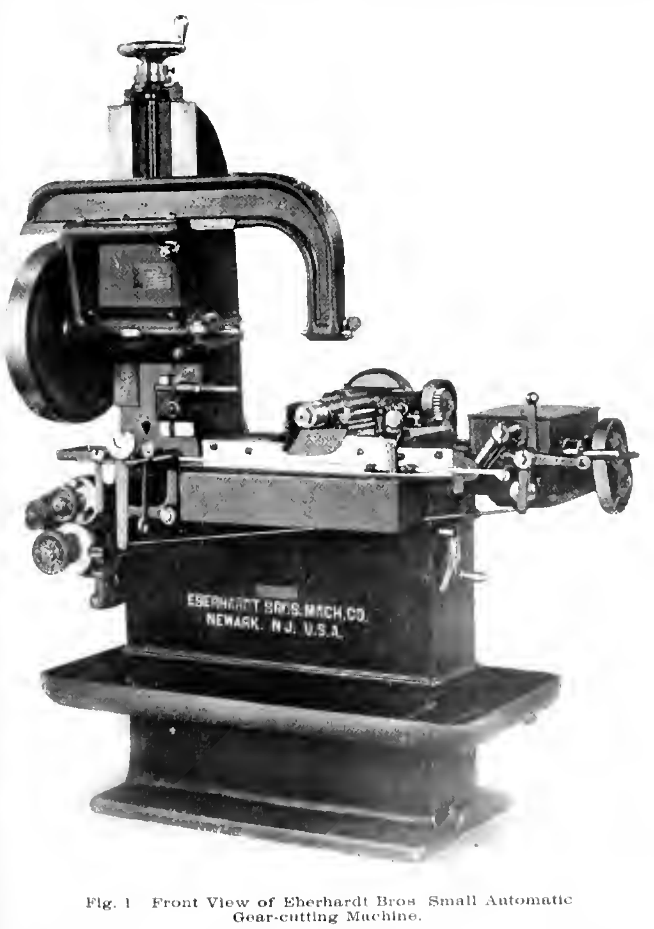

Fig. 1. Front View of Eberhardt Bros. Small Automatic Gear-cutting Machine.

predecessor, the combined spur and bevel gear cutting machine shown in "New Machinery and Tools" for July, 1907. The machine has the distinctive features of simplicity of construction and convenience of arrangement. These features are shown most prominently in the ribbed frame (see Fig. 2), doing away with the use of cores in the molding, and in the overhanging arm support provided for the work arbor. The result of these and similar provisions is an inexpensive and convenient machine for small work.

The machine is driven directly from the counter-shaft to the single speed tight and loose pulley shown in Fig. 2. This makes the use of a counter-shaft unnecessary. The indexing

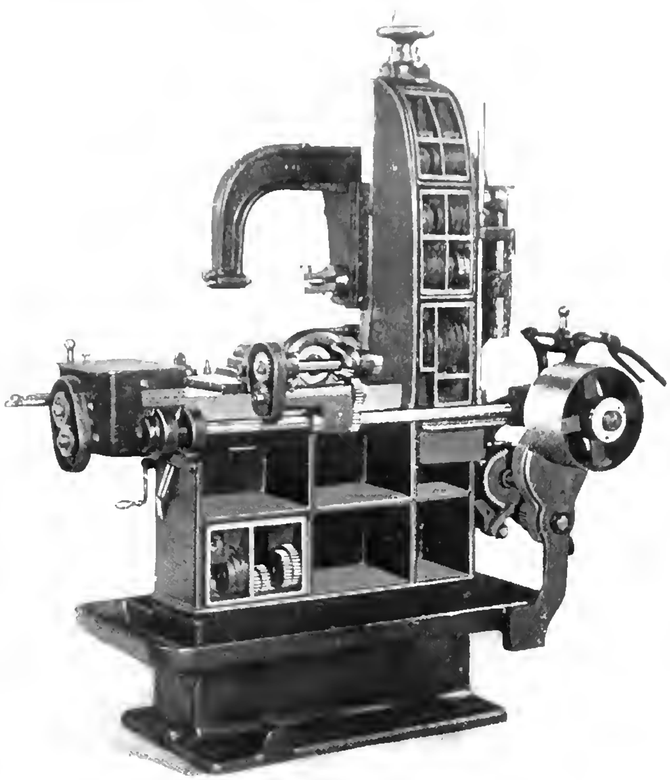

Fig. 2. Rear View of Machine, showing Spindle Drive, etc.

mechanism is connected to the shaft for this pulley by the gearing shown, while the cutter slide is driven through bevel gears and the long splined shaft running lengthwise of the bed. This splined shaft is geared to an intermediate shaft which is connected by change gearing (giving six rates of spindle speed) with the main bevel driving gear keyed to the spindle. This driving gear is of large diameter compared with the cutter, giving a strong, steady action to the latter.

The splined shaft from which the spindle movement is derived is continued forward to the feed box at the front of the bed, where is located the proper mechanism for automatically feeding the slide forward at a rate determined by the change gears provided (giving 8 changes) and quickly returning it at high speed to allow the work to be indexed and to commence a new cut. All these movements, as well as the control of the indexing, are positive.

The work arbors have tapered shanks, which fit the tapered hole in the steel work spindle. A bolt is provided at the rear of the work spindle for drawing in and forcing out the arbors without hammering. On most work, the overhanging arm shown is used to support the outer end of the work arbor. For work over 17 inches in diameter, for which the arm cannot be used, it is easily removed. A pair of centers and a dog driver are supplied, to be used for work similar to that of cutting a gear blank on a lathe mandrel, or the teeth of a pinion solid with a shaft.

This machine will cut gears as coarse as 8 diametral pitch in steel, or 6 diametral pitch in cast iron. It will thus be seen to be especially adapted to the cutting of change gears, and is used on this work in the shops of its builders, one machine being kept in continuous operation on change gears from 20 up to 6 diametral pitch. The machine is capable of being used for many odd jobs as well as for manufacturing, and has been especially designed to allow it to be quickly set up for work of various kinds. The operator can easily set the machine for any ordinary work in 15 minutes, and usually in much less time.

CINCINNATI AUTOMATIC GEAR-CUTTING MACHINE.

A new automatic gear-cutting machine of the orthodox type (such as shown in Figs. 21 to 28, in article entitled "Gear Cutting Machinery," engineering edition), has been placed on the market by the Cincinnati Shaper Co., Cincinnati, Ohio. Aside from the interesting points in the design and construction of this tool, which we will mention later, it is noteworthy from the fact that it is the first machine of its kind built in Cincinnati—a city which can claim to produce pretty nearly everything else required in the line of machine tools.

The main features in the design of this machine as may be seen in Figs. 1 to 4, are its simplicity and compactness, together with its rigid construction and the case with which it may be adjusted. The bed has been considerably shortened without decreasing the length of the cutter slide bearing, this being made possible by extending the cutter slide forward of the cutter spindle, so that it extends past the face of the column when at the forward extreme of its travel. It is gibbed with rectangular guiding surfaces instead of the usual dove-tail bearings, and has a long taper gib for taking up the wear. The same form of bearing and gib is used for holding the work saddle to the face of the column. In the case of both the work saddle and the cutter slide, the length of the guiding surface is much greater than its width, thus making any binding action impossible. This is particularly important in the case of the work saddle, since it prevents the work spindle and blank from dropping out of parallelism when the clamps are loosened for adjusting the work for the tooth depth. This fault, found in many gear-cutting machines, makes the micrometer reading of the screw practically worthless.

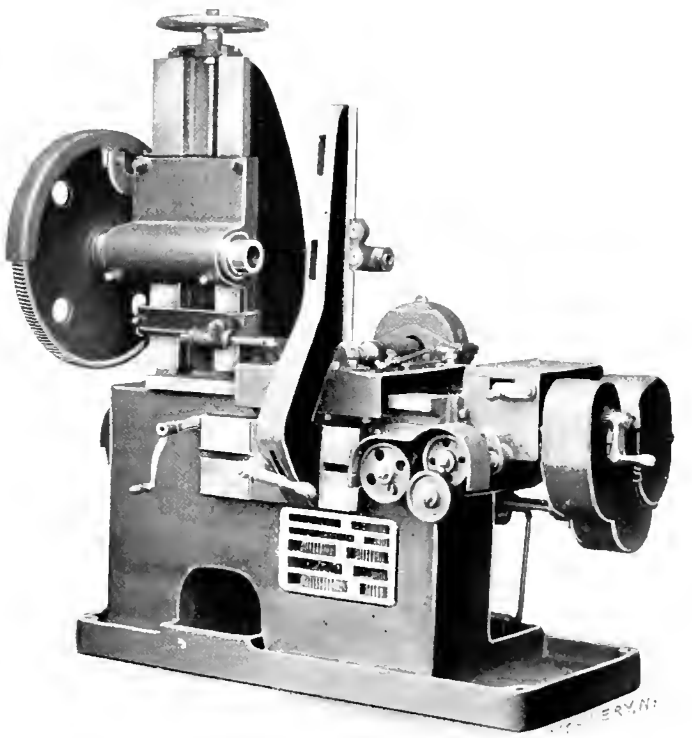

Fig. 1. Automatic Gear-cutting Machine made by Cincinnati Shaper Co

Both cutter and work spindles are of large diameter, are accurately ground, and are journaled in bronze bushings with provisions for taking up wear. The journal of the cutter spindle is adjustable endwise for centering the cutter to a gage furnished with the machine. The cutter spindle is driven by worm gearing provided with means for taking up the end thrust wear of the worm. The cutter end of the spindle has a No. 10 Brown & Sharpe hole for the cutter arbor, which is keyed to the spindle, and is drawn in or forced out by a threaded bolt. A removable bearing is provided for supporting the outer end of the cutter arbor.

All of the mechanism is driven from one single speed pulley *N* (see Figs. 3 and 4), the various changes for the feeds and spindle speeds, as well as the indexing, being obtained by change gears. Great care has been taken to provide short stiff shafts for the connections between the driving pulley and the spindle, so as to avoid torsional vibration in the members to which they transmit power. The driving pulley is connected by bevel gearing with a short shaft extending into gear box *O*. The swinging door, shown at the end of the gear box, in Fig. 2, covers the change gearing by which the desired spindle speeds are obtained. This change gearing gives six rates, ranging from 28 to 146 revolutions per minute. A splined shaft *P* leads from the change gearing through the worm carried by the cutter slide, thus driving the spindle. The drive, it will be seen, is simple and direct.

The gears for altering the feeds are mounted underneath the guard at the front of the machine in Fig. 1. They provide for ten changes, ranging from 1 to 7¼ inches per minute. Change gears for faster feeds can be furnished if desired. The feed of the cutter slide is effected by a screw, whose motion is controlled by positive clutches, operated by reverse lever *K*. The clutch for the quick return is cushioned to prevent undue shock. The feed motion and the indexing mechanism are so interlocked that it is impossible for the cutter to be fed forward until it has been indexed fully to its new position. All the movements have to take place in proper sequence, it being impossible for any one of them to begin until the succeeding ones have been completed.

An ingenious feature of the machine is best shown in Figs. 3 and 4. This is the arrangement for adjusting the dogs by which the movement of the cutter slide is limited and reversed. At the front of the bed are two shafts *A*, with ends squared for cranks. These are carried through to the rear of the machine where they are keyed to spiral gears *B* engaging mating gears *C* on screws *D*. These gears are keyed to the screws which thus turn with them, while still being allowed to move endwise through a limited distance. Stops *F*, *G*, and *H* are carried by screws *D*. Stop *F* is fixed as to longitudinal position on outer screw *D*, but allows the latter to revolve freely in it. Its inner end is supported by a slide screwed to the base of the machine, so that it thus helps to support both of screws *D*. Stop *G* is threaded on the inner screw, and slides loosely on the outer one, while stop *H* is threaded on the outer screw and slides on the inner one, as best shown in the upper detail view in Fig. 4. By this means the revolving of the left-hand shaft *A* adjusts stop *G*, while the revolving of the other adjusts stop *H*.

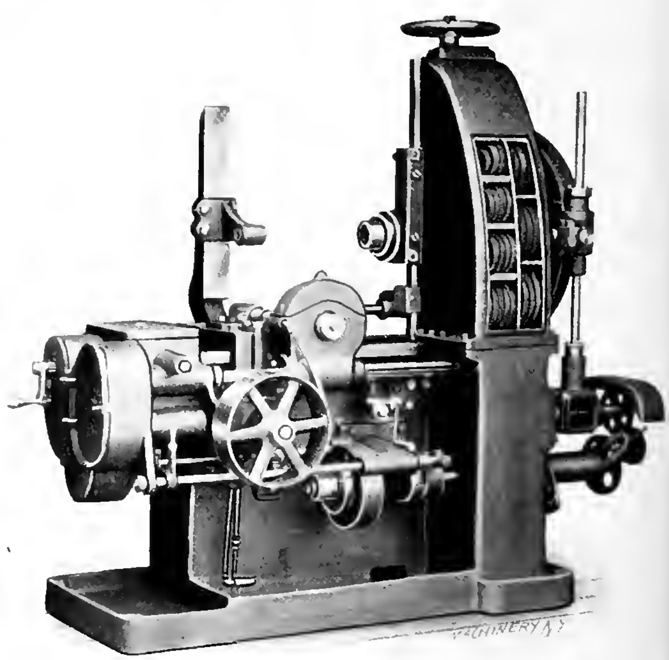

Fig. 2. Rear View of Cincinnati Gear-cutter, showing Driving Mechanism.

Tappet *E*, in the cutter slide, normally acts on stops *G* and *H* to reverse the motion of the cutter slide when it has reached either extreme of its travel. When striking *H* on its forward movement, it forces screws *D* to the left, thus moving spool *J*, which throws reversing lever *K*, returning the slide to its

forward position. Here the tappet strikes dog G which throws the spool J, and with it the reversing lever K in the other direction, starting the slide forward again on the feeding cut, though this is not allowed to take place until the indexing movement has been completed, as previously explained. By withdrawing pin E out of the reach of stop G, the return of the slide may be allowed to continue until E strikes fixed stop F, which is the extreme limit of the table movement in the backward direction. It is thus unnecessary to alter the adjustment when it is desired to run the slide clear back.

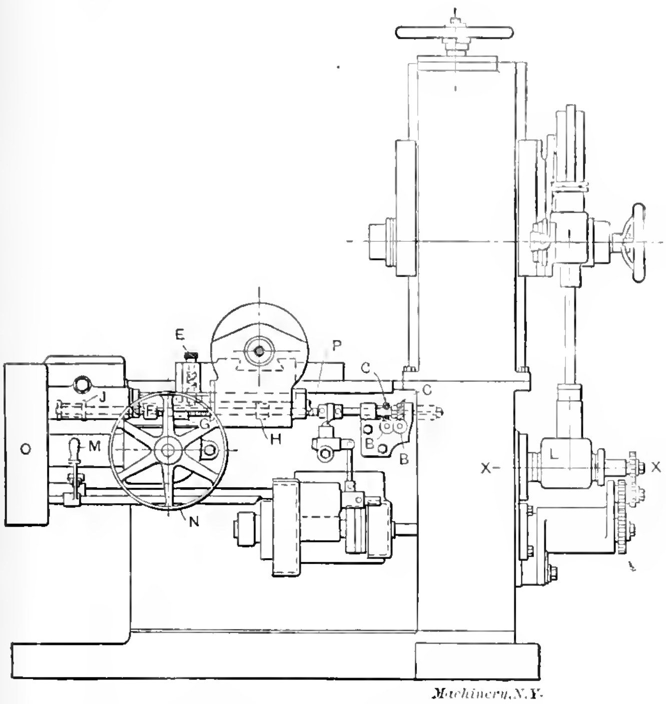

Fig. 3. Diagram of Rear Elevation of Machine.

This arrangement makes the setting of the stops possible from the front of the machine, and it is easily effected before the machine is started, by proceeding as follows: The cutter slide is run to the extreme forward position desired and then, by means of the crank, dog H is run against the tappet E until the reverse lever throws the clutch over to engage the reverse side. Then the cutter slide is run back by hand until the desired back position is reached, when dog G is run against the tappet until the clutch is thrown over to engage

Fig. 4. Plan of Gear-cutter, with Detail of Stop Adjusting Mechanism.

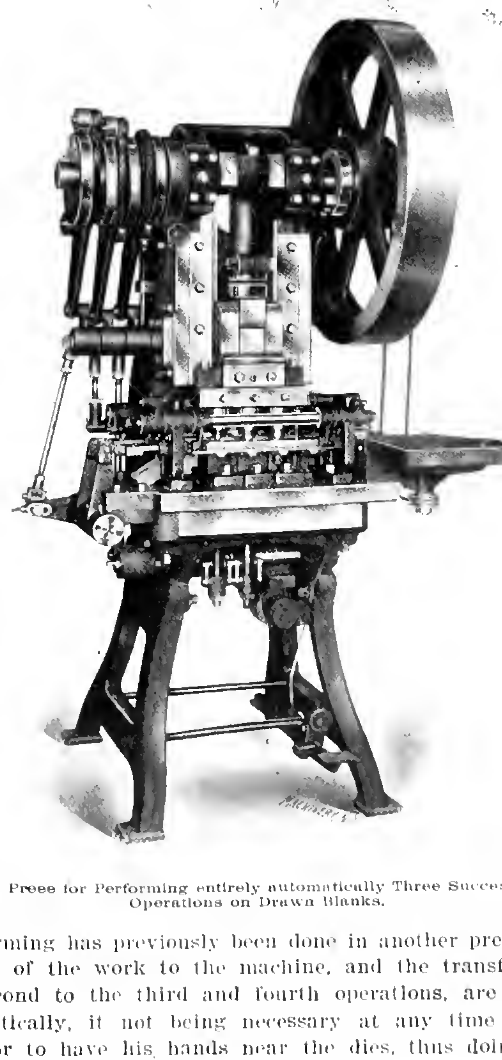
the feeding movement. Then, as is easily seen from the above description, the cutter slide will reverse at these positions. The crank for operating the cutter slide feed-screw is permanently mounted in place, but disconnects itself automatically when not being manually operated, so that it does not give trouble from its balance wheel effect as it rapidly revolves, or from catching in the clothing of the operator.

The indexing mechanism is effective, yet free from trappy, complicated parts. It operates without shock and is easily accessible. As has been mentioned, it is so interlocked with the feed-screw that the cutter cannot enter the work until the indexing has been completed. The number of gears in the indexing train has been reduced by the novel means provided for disengaging the index worm from the wheel. This is shown in Fig. 3. The vertical index worm-shaft is driven by bevel gearing in box L, which may be swung about axis X X. In throwing the worm out of connection with the index worm-wheel, the worm-shaft is simply rocked about its axis, suitable provision being made in the mounting of the worm for guiding it and bringing it back to its proper relation with the wheel. The index wheel is made in two parts, by the method commonly followed in such cases to insure the required degree of accuracy. The work spindle may be made to space once or to revolve continuously, by the operation of the indexing lever shown near the gear casing at the left of Fig. 2. Index gears are furnished to cut all numbers of teeth from 12 to 100 and, with the exception of prime numbers and their multiples, from 100 to 450. Special gears for cutting other numbers of teeth are furnished at an additional cost, if desired.

This machine is at present made in two sizes for cutting gears of 36 and 48 inches diameter, respectively, up to 10 inches width of face. It will cut 3 diametral pitch in cast iron, and 4 diametral pitch in steel. An outer support is provided for the work arbor, as well as a roller support for the rim of the gear blank. The net weight of the machine and counter-shaft is 4,000 pounds. The machine may be very easily arranged for motor drive, a constant-speed motor being secured to an extension of the base, and connected with the constant-speed driving shaft by spur or chain gearing.

BLISS AUTOMATIC GANG PRESS.

The E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., has recently built the automatic gang press we herewith illustrate and describe. It was designed and built for performing at each stroke, simultaneously, the second, third and fourth operations on shells on which the first operation of cutting



Bliss Press for Performing entirely automatically Three Successive Operations on Drawn Blanks.

and forming has previously been done in another press. The feeding of the work to the machine, and the transfer from the second to the third and fourth operations, are effected automatically, it not being necessary at any time for the operator to have his hands near the dies, thus doing away with all possible danger from accident.

The drawn shells on which the die operations are to be performed, are laid on a revolving friction dial which forms the bottom of the hopper or tray at the right of the machine. This disk, which is driven by a round belt from a groove cut in the hub of the fly-wheel, carries the shells up to a stop, from which they are automatically released one at a time, and gripped by a reciprocating lateral feeding movement, operated by the bell crank lever seen at the extreme left of the bed of the machine. This movement carries the shell from the feeding position through the subsequent operations, finally discharging it into a chute, from which it falls into a receptacle conveniently placed to receive the finished article. After the first three revolutions of the press, a finished blank is produced at each revolution.

Of the three cam movements at the left end of the crank-shaft, the first one operates the reciprocating movement for the feed, through the bell crank levers just mentioned; the second one opens and closes the reciprocating guides for feeding the work forward; and the third one operates a positive knock-out motion, seen beneath the bed of the machine.

The main slide is adjustable, allowing the use of dies for a great variety of articles, and provided for different heights of dies, as well as allowing for the wear to which they are subjected. The lateral feed is also adjustable for different kinds of work. As may be seen, the press is of the inclinable type, adjusted by a worm and worm segment beneath the bed. For the work being performed in the case shown, however, the vertical position is the most suitable one.

The press runs at the rate of from 75 to 100 strokes per minute, the rate depending on the size and shape of the shell on which the operations are to be done. From 225 to 300 operations per minute are thus performed, entirely eliminating the intermediate handling between the operations, saving much time, labor and shop room.

SPECIAL REAMING AND TAPPING MACHINE.

With the present specialization in manufacturing, it becomes more and more desirable to have special machines built for carrying out, in the shortest time and with the simplest means, the various operations required on interchangeable work which is produced in large quantities. The accompanying halftones illustrate a special machine which is designed primarily for performing a few reaming and tapping operations on sections used for hot water heaters. Such a section is shown most plainly on the table of the machine in Fig. 2. These sections have, in the first place, three holes, one at the extreme top, and one each at the lower ends of the two legs, which must be bored and reamed to a nice fit. In these holes taper bushings, tapering both ways so that one end enters one section, and the other, the next, are inserted. These bushings then form the joint between two sections. The work is required to be very accurate, so that the sections can be drawn up together closely at the three points forming the joint. In Fig. 1 is shown the machine when carrying out this operation, together with the work placed on the machine table, the hole previously referred to at the top of the section being reamed. The sections are clamped on a circular revolving table as shown, and are located by a stud in the center of the table, which enters the center hole. The three holes to be bored and reamed are placed equidistant from the center, so that all that is necessary after the work has been properly located on the revolving table, and placed in proper position in relation to the machine spindle, is to revolve the table to

Fig. 1. Baker Bros. Reaming and Tapping Machine for Hot Water Heater Sections.

Fig. 2. Machine with Revolving Table Removed, and Work Mounted on Lower Rectangular Bed.

the successive positions. It will be noticed that an indexing arrangement is provided, with slots in the side of the revolving table, so that when rotating the table and indexing, the holes will be located exactly alike on the different sections. The table is mounted on ball bearings so that it can very easily be swung around from one position to the other. As soon as all three holes are bored, the boring-bar is removed, and the holes taper reamed. The reaming operations are first performed on one side of a great number of sections, and then taper bushings, which are to fit the reamed taper

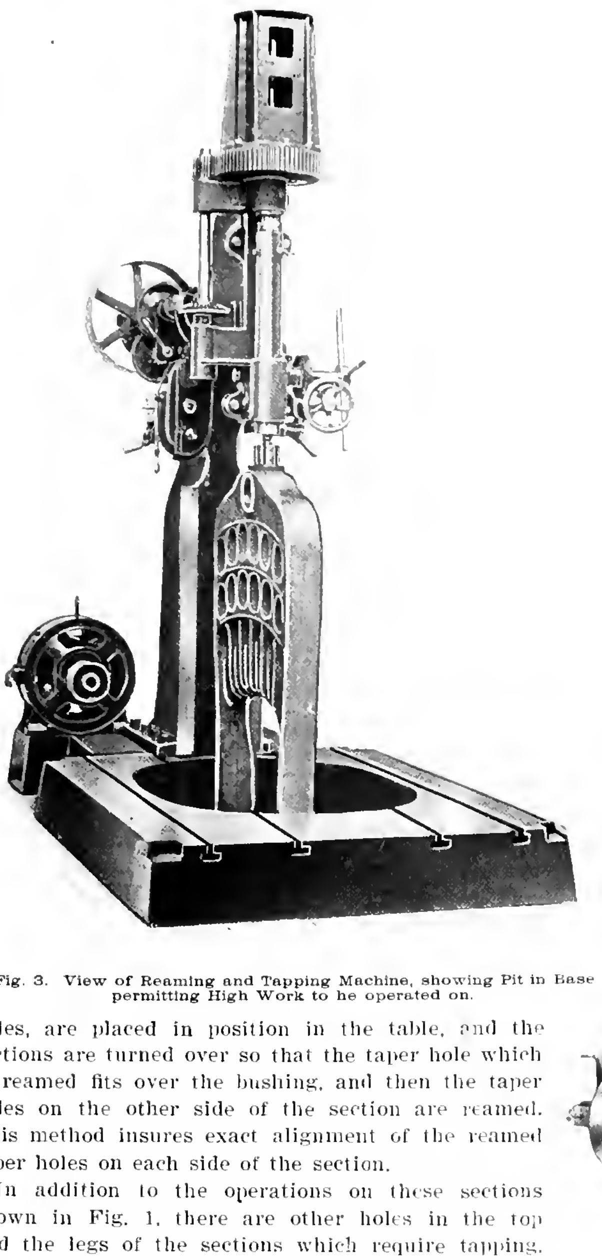


Fig. 3. View of Reaming and Tapping Machine, showing Pit in Base permitting High Work to be operated on.

holes, are placed in position in the table, and the sections are turned over so that the taper hole which is reamed fits over the bushing, and then the taper holes on the other side of the section are reamed. This method insures exact alignment of the reamed taper holes on each side of the section.

In addition to the operations on these sections shown in Fig. 1, there are other holes in the top and the legs of the sections which require tapping. The tapping of the hole in one of the legs is shown in Fig. 2, and the tapping of the hole in the top of the section is shown in Fig. 3. The last of these photographs shows only the work in position, without showing the jigs for holding it. It will be noticed that in Fig. 3 a novel feature of the construction of these special machines is shown. The base of the machine contains a large pit 40 x 56 inches, which permits high work to be operated upon. This opening is covered with the rectangular table shown in Fig. 2, on which, finally, the circular table shown in Fig. 1 is placed, when it is in use.

Referring to Fig. 2, it will be noticed that this machine is provided with individual motor drive, and that the speed changes are accomplished through the gear box shown on the side of the machine. The machine is built in two sizes, the one shown in Figs. 1, 2, and 3 respresenting the smaller size. In Fig. 4 is shown the larger size which here is shown belt driven; but either of these sizes may be belt or motor driven.

The belt driven machine shown is of exceptionally heavy design, and has a capacity for tapping holes up to 10 inches pipe tap size. As will be seen from the engraving, this machine is provided with triple back gearing and four different belt speeds, giving a large variation of spindle speeds.

A special feature of all the tapping machines built by Baker Brothers, Toledo, Ohio, who are the manufacturers of these machines, is the spindle drive, the design of which is shown in all the accompanying halftones. Instead of driving the spindle by means of a simple key and keyway, the motion is transmitted by means of a strongly designed driving head at the upper end of the spindle. This permits far greater power to be safely transmitted to the sliding spindle than is possible by commonly used driving arrangements.

SLOAN & CHACE PRECISION BENCH MILLING MACHINE.

The bench milling machine shown herewith is built by the Sloan & Chace Mfg. Co., Ltd., Newark, N. J. It is intended especially for tool-room use and experimental work, although it is adapted to some classes of precision manufacturing. It is built along the lines of the full-sized standard milling machine, with such alterations in design as to fit it for the more minute and accurate work it has to do.

One provision incorporated in the machine, which may be employed where extreme accuracy is required, is that for holding the head-stock of a bench lathe on the table of the miller. It is possible, owing to this provision, after setting up a piece of work on the face-plate or chuck of the lathe, and

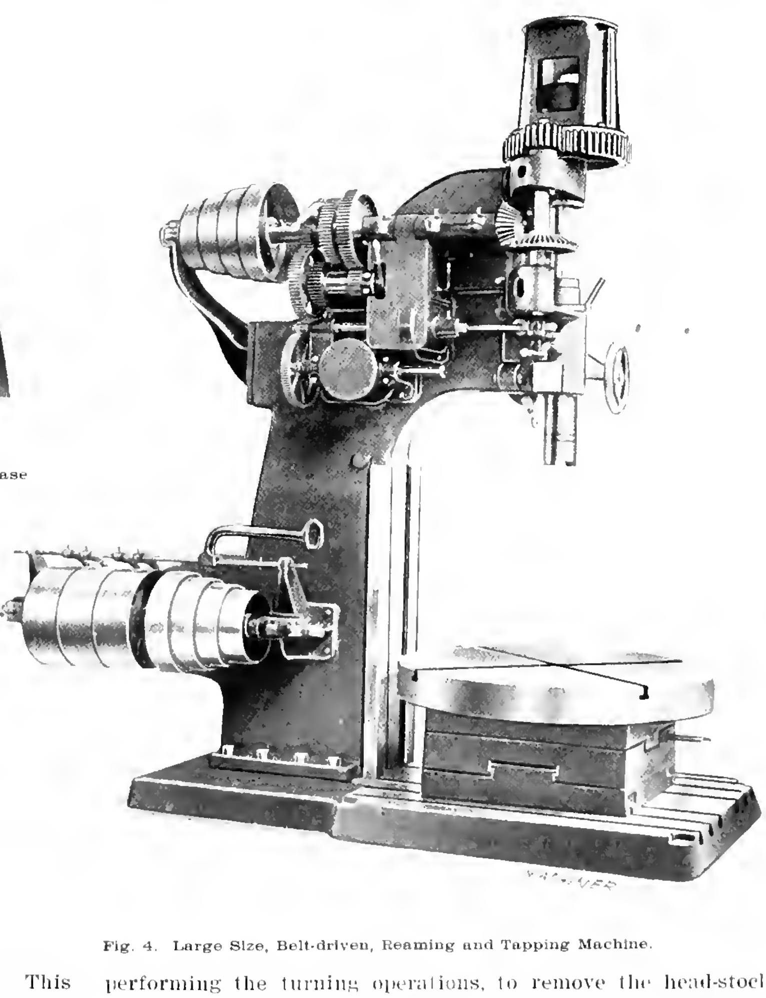

Fig. 4. Large Size, Belt-driven, Reaming and Tapping Machine.

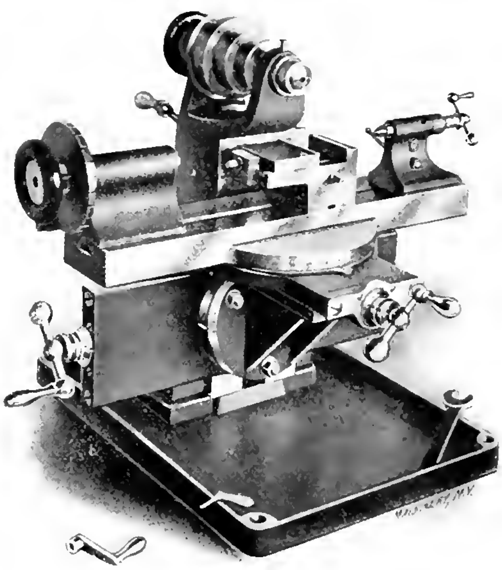
performing the turning operations, to remove the head-stock of the lathe to the milling machine table, and clamp it there in place of the regular index head provided with the machine, using an adapter furnished for the purpose. Another respect in which it differs from the larger machine is in the arrangement of the slides. Instead of having the table longitudinally adjustable on the saddle, the knee is attached to a slide which is longitudinally adjustable on a saddle, which is in turn vertically adjustable on the face of the column. This change of construction is made to allow the most convenient use of an extra angular adjustment provided, by means of which

the work table may be set in any desired angular position about a horizontal axis parallel with the spindle. This angular adjustment, which is made by swiveling the knee on the longitudinal slide to which it is attached largely increases the usefulness of the machine. In combination with the table swivel and the index head, it permits angular settings in three planes.

The index head carries a hardened and ground spindle of the same diameter and chuck capacity as the cutter spindle,



Sloan & Chace Bench Milling Machine for Precision Work.

which is, in turn, similar in the same respects to the spindle of the maker's regular No. 5½ lathe. The tail-stock is accurately fitted to the table, and is bored in special fixtures which insure accurate alignment. The table has a working surface 22 inches long, allowing a maximum of 11½ inches between the index head and tail-stock centers. When the head and tail-stock of the No. 5½ lathe are mounted on the table, there is a distance of 6½ inches between centers. The feed-screws of both cross and longitudinal slides have adjustable dials, graduated to read to thousandths of an inch, and provided with adjustments for taking up wear. The elevating screw is operated by a bevel gear shaft having a hand crank at the back of the column, and is capable of easy and accurate adjustment by means of adjustable graduations.

The vise provided has jaws 3½ inches long by ¾ inch deep, and will open to take in 2⅛ inches. It may be used in either a horizontal or a vertical position. The vertical travel of the machine is 7 inches, the longitudinal movement is 10 inches, and the transverse movement is 4¾ inches. The counter-shaft provided has two speeds. The net weight, including the counter-shaft, is 308 pounds.

CLEVELAND DOUBLE TANG DRILL SOCKET.

We show herewith a new drill socket made by the Cleveland Twist Drill Co., Cleveland, O., embodying a special feature calculated to overcome the troubles incident to the driving of taper shank drills of the usual construction. As may be seen, a double tang is provided—one of the usual size, and

A Drill Socket with Double Driving Tangs.

an additional one of greater thickness. If the smaller one should break off, there is still the larger and stronger one to hold and drive the drill.

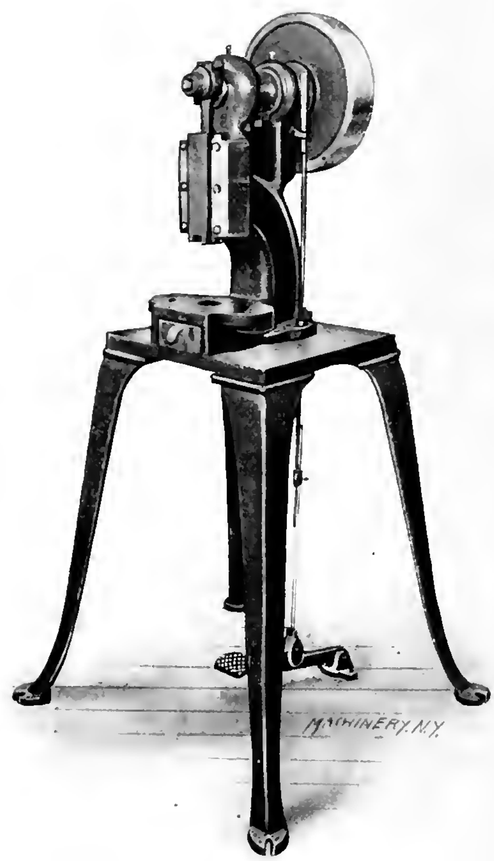
Not only does this device hold taper shank tools so that tangs cannot be twisted off, but old tools with tangs broken off can be ground or milled with new tangs to fit these sockets, so as to renew their life to the full extent of their usefulness. Most shops have an accumulation of drills that would still be serviceable except for their broken tangs. No turning down or key-way milling is required to fit these tools for use with this style of socket.

Any taper shank tool can be easily fitted to this line of sockets by grinding or milling a second tang below the original one. This second and stronger tang fits in the secondary opening of the "Perfect" socket, as the makers call this device. The shank is thus held by two bearing surfaces which cannot be twisted off under the severest strains. In contrast with some previous attempts at improved sockets, which have been complicated and high priced, this arrangement is both simple and inexpensive. It has no parts to get out of order or to wear out, and it fits any spindle having a regular taper hole.

STANDARD MACHINERY COMPANY'S LIGHT POWER PRESS.

The small power press shown herewith is being placed on the market by the Standard Machinery Co., 7 Beverly St., Providence, R. I. It is designed especially for light optical, hardware and jewelers' work, but is well adapted for all light operations requiring press work of any kind.

One of the features of the press is the clutch used. This is the Horton patented roller friction clutch, which engages instantly, there being less than 1/32 inch travel of the periphery of the fly-wheel from the time the treadle is pressed until the clutch takes hold. This clutch is of exceptional



A Power Press for Optical, Jewelers' and other Light Work.

strength, as well as being quick in its action, since there are several positive engagement points which connect simultaneously, giving a very rigid connection between the fly-wheel and the crank-shaft. A positive safety stop is provided which prevents the possibility of a second stopping in case the treadle is released and again depressed. When it is desired to run the machine continuously, the stop may be removed from the clutch, this being done by simply sliding it out of position.

All bearings are adjustable for wear, the slide having particularly long bearings with adjustable side gibs providing an accurate and easy means of alignment. The adjustment

of the plunger for vertical position is made by operating an eccentric bushing with a clamping collar, surrounding the crank-pin; this does not affect the length of the stroke. The base of the press is made with an opening of any size ranging from ½ to 1½ inches, and may be provided with a small drawer, shown in the engraving, to catch finished work. The table may be used, or the tool may be used as a bench press. Punches with round shanks or dove-tails may be used; both methods of fastening have been provided for in the design.

The regular stroke of the machine is 1 inch; when desired it may be made as large as 1½ inch. The adjustment for the stroke is ¾ inch, and the distance from the slide to the bolster with stroke up and adjustment down is 5½ inches. The total weight of the machine with table is 300 pounds. The normal speed of the press is 300 revolutions per minute.

SPRINGFIELD AUTOMATIC RING WHEEL EDGE GRINDER.

The accompanying half-tones show front and rear views of an automatic edge grinding machine, built by the Safety Emery Wheel Co., Columbus Ave., Springfield, Ohio. This machine is intended for grinding from the rough, flat edges and surfaces in iron, steel, brass, bronze, etc. The grinding process for this work not only removes the stock very rapidly, but leaves a fine finish as well—finer than can be obtained by any other means practicable for heavy work.

The machine is very heavily built. The base is in one solid casting of T-form, on the front portion of which is located the table support, while the rear is provided with ways to which is gibbed the heavy column on which the wheel spindle head is carried. The table is reciprocated auto-

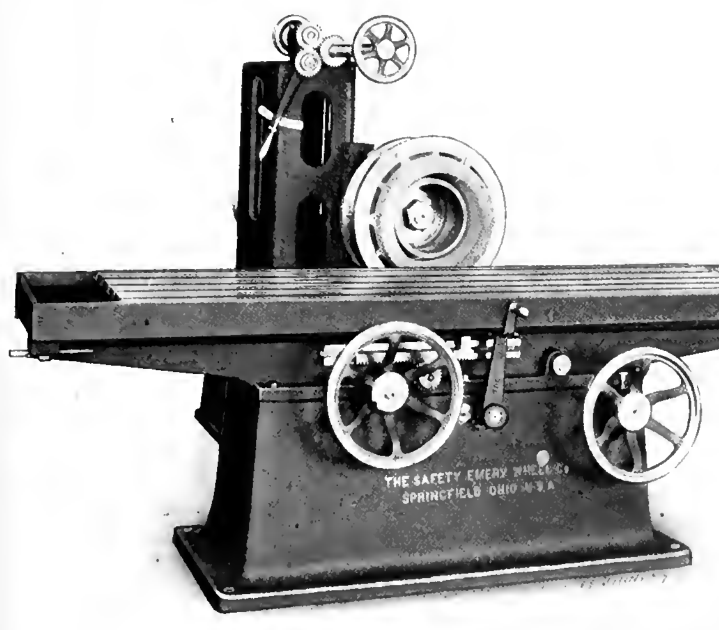


Fig. 1. Front View of Springfield Edge Grinder, note the Safety Chuck for the Ring Emery Wheel.

matically, suitable stops being provided for limiting its movement, as may be desired. The wheel column is fed automatically toward the work at any rate of feed required.

The spindle is driven from a drum on the counter-shaft by a flying belt arrangement, whose tension is maintained, whatever the vertical adjustment of the spindle may be. The tension is kept to the proper amount by shifting the lower idler pulley, which is attached to a bracket sliding in ways on the rear of the column, being adjusted by the screw shown. The wheel slide has a vertical adjustment of 12 inches on the column, which may be obtained by hand or by power. In the latter case, it is operated by the small pulley at the top of the column, and controlled by the tumbler gearing and hand lever shown. The grinding wheel is of the ring or cylinder shape, firmly held in the patent chuck made by this firm. It permits with perfect safety the high speed which is essential to fast cutting. The wheel spindle is supported in very heavy boxes, with suitable thrust bearings to take up end play.

An extra long bed supports the carriage, which travels on one flat and one V-way. The working surface of the table is provided with T-slots for clamping work or jigs and fixtures required for holding it. The carriage movement is triple back-geared, all gears and racks being cut from the solid. The motion of the carriage is easily controlled by the oper-

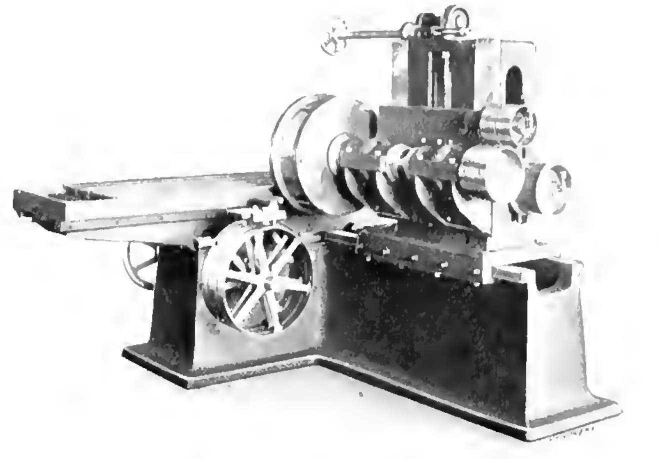

Fig. 2. Rear View of Edge Grinder showing Spindle Drive and Table Reversing Mechanism.

ator, being stopped at any desired point by centering the vertical reverse lever on the front of the bed, when it may be moved by hand, by means of the large hand-wheel at the right in Fig. 1. The reverse dogs which actuate this lever are provided with threaded contact points, which may be adjusted to give at each end of the table motion a greater or less movement to the sliding rack, seen beneath the edge of the table in Fig. 2. This rack operates a pinion, which, through a ratchet movement, operates the cross feed screw by means of which the wheel column is fed forward on the bed toward the work. Any feed, from 0.001 inch to ⅛ inch or more may be given to the column. All the operating mechanism is on the front of the machine, within easy reach of the operator in his working position.

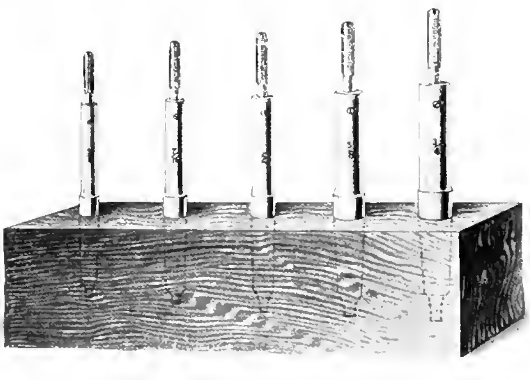
The machine is fitted for supplying water to the grinding wheel when desired, as is necessary for grinding steel. The rearward extension of the base serves as a water reservoir, from which the water is drawn and delivered to the work by a centrifugal pump.

This machine is made with a table working surface 70 inches wide, and of any length up to 130 inches. The machine shown has a working surface 50 inches long. On the larger sizes, a central base is used, with pedestal end supports for the bed. To adapt the work to knife grinding, the builders furnish a heavy knife bar, which can be bolted to the table for grinding any length of work up to the capacity of the machine; this can be readily removed when not needed. For the heaviest grinding of this kind, such as finishing off locomotive guide bars, etc., the builders recommend a heavier form of the machine, carrying a larger wheel, with a solid head.

CINCINNATI PERMANENT TAP SOCKETS.

When drilling and tapping in a drill press or drilling and tapping machine, considerable time is often consumed in changing from the drill to the tap, difficulty often being experienced because a suitable device for holding the taps is not at hand. It also takes considerable time to insert the various taps in, and remove them from, the holders. The Cincinnati Machine Tool Co., Western Avenue and Frank St., Cincinnati, Ohio, which makes a specialty of manufacturing the Cincinnati heavy pattern upright drilling and tapping machines, has therefore placed on the market tap holders of the description shown in the accompanying engraving, which, while very simple, have proved in their own shop a very effective means for overcoming the difficulties mentioned.

Each size tap is provided with a socket, having a shank to fit in the drill press spindle, as indicated. The tap remains permanently in its socket until it is worn out, and is then replaced by another tap. By this arrangement, the changing from the drill to the tap becomes very simple, the tap with its holder being simply slipped into the drill spindle socket, the same as if the tap itself had a taper shank. This entirely



Set of Five Cincinnati Permanent Tap Sockets.

eliminates the loss of time incident to the use of other tap holders. In the illustration, five tap holders are shown placed in a convenient wooden block ready for use. These holders are regularly provided with Morse taper shanks, but holders are also furnished with any other taper shank, or with straight shanks suitable for the "Presto" or "Magic" chucks.

HORIZONTAL MILLING ATTACHMENT FOR VERTICAL MILLER.

The design and construction of the vertical milling machine was immediately followed by the vertical spindle attachment for the horizontal type of machine: the accompanying illustration shows how this, in turn, is followed by the horizontal milling attachment for the vertical machine. The line engraving, Fig. 1, shows the design of a horizontal milling attachment for a vertical milling machine as made by the Becker-Brainard Milling Machine Co., Hyde Park, Mass. In Fig. 2 this attachment is shown applied to the vertical spindle of a Becker-Brainard vertical milling machine, at work on a steam turbine rotor.

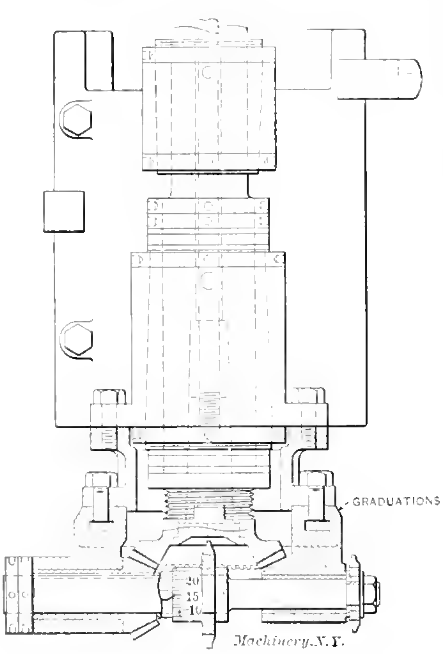


Fig. 1. Design of Becker-Brainard Horizontal Milling Attachment for Vertical Millers.

The attachment as shown in Fig. 1 consists essentially of two parts, the upper one of which is stationary, while the lower one is attached in such a manner that it can be swiveled completely around in a horizontal plane. The stationary part is attached to the column of the milling machine, and the swiveling part is provided with graduations at the place where it joins the stationary part, so that it can be accurately set and adjusted to any angle required, when it is clamped in position by the T-bolts shown. The horizontal spindle which is driven from the vertical spindle through bevel gears arranged as indicated in the line engraving, has a long bearing at each end. The milling cutter may be placed either on the outside end of the horizontal spindle, beyond the right-hand bearing, or between the two bearings. In the latter case, of course, the size of the cutter is limited by the driving bevel gear. The end play of the horizontal spindle is taken up by a nut provided with a check nut placed at the left-hand end of the spindle. At the other end, the cutter is clamped with a nut and washer, but the spindle may also be provided with a taper hole, taking the taper shank of an end milling cutter or shank mill.

The cutter when placed between the two bearings, as indicated, is specifically intended for cutting spirals, although it may also be used for general requirements. This cutter is held between two nuts as shown, one of which is graduated so that if adjustment has once been made for any given thickness of cutter, it being required to hold the cutter exactly in the center of the vertical spindle, any cutter of the same thickness may be set without requiring a new adjustment. It is evident that this attachment materially increases the usefulness of the vertical miller. It gives the vertical miller the same range as the horizontal type in the cutting of worms, spur gears, spirals, hobs, racks, etc., while, at the same time the machine retains the advantageous characteristics peculiar to the vertical type.

As mentioned above, a practical application of the horizontal attachment in connection with the No. 6 Becker-Brainard vertical milling machine, is shown in Fig. 2. It is here employed in milling the buckets of a Sturtevant steam turbine

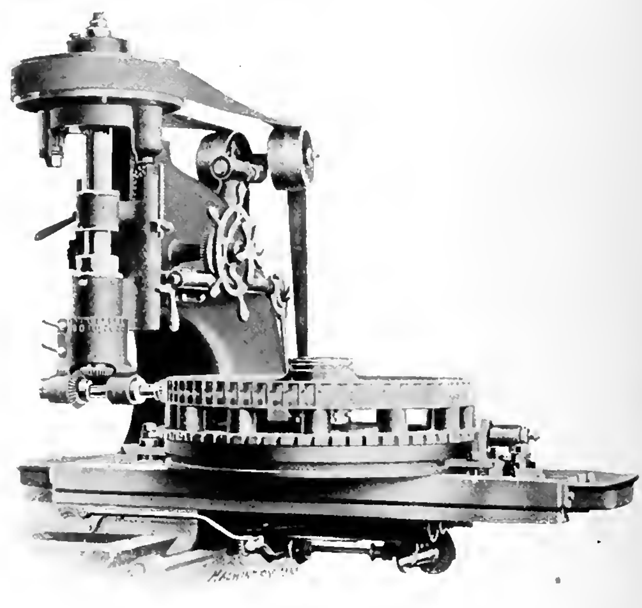

Fig 2. Horizontal Milling Attachment at Work on Steam Turbine Rotor.

rotor. The rotor is mounted on and clamped to a special index plate, which revolves freely on a stud projecting from a circular face-plate, which, in turn, is securely clamped to the table of the milling machine. An index pin entering the slots in the indexing plate, as plainly indicated in the half-tone, permits the rotor to be indexed around while each bucket is being milled. On account of the limited space between the column and the table in a horizontal milling machine, work of this character would be difficult, if not impossible, to perform on an ordinary horizontal machine, even with the use of a universal milling attachment. On the vertical miller, however, the space is not so limited, owing to the design of the column, and the use of this horizontal attachment in a vertical miller will permit a large variety of work to be performed on the vertical machine, for which either a larger horizontal machine or special machinery would be required.

TOSCOT FLEXIBLE METALLIC BELT COUPLING.

One difficulty common to flat belt couplings is that they form a rigid joint where the two ends are coupled together, so that if a belt provided with such a coupling runs over a small pulley, heavy strains are produced at the extreme edges of the coupling, which cause the belt to break along this line. In Fig. 1 is shown the Toscot flexible coupling, which overcomes this defect. This coupling is manufactured by the Tostevin & Cottie Mfg. Co., 635 Kent Ave., Brooklyn, N. Y.

It is provided with a joint in the center where the ends of the belt meet, and therefore permits the belt to come in close contact with the pulley all the way around.

Another improvement is that the coupling is so designed that it can be easily unhooked whenever it is desired to take

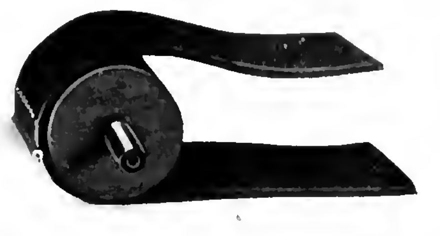

Fig. 1. Toscot Flexible Belt Coupling applied to Small Pulley

the joint apart or remove the belt. The hooking arrangement is shown plainly in Fig. 2, where the two ends of the belt, each having one section of the coupling attached, are shown as they are being uncoupled. The two sections of the coupling can be attached to the belt ends in any convenient place, and the belt taken to the respective pulleys where it is to be used, laid over the pulleys and simply hooked together. The attaching of the coupling to the belt is accomplished very easily. The end of each section of the coupling, which

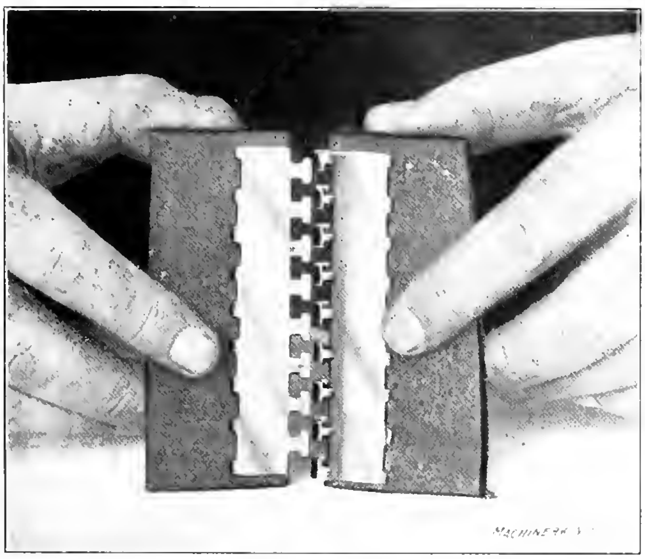

Fig. 2. View of Joint of Coupling showing Simplicity of Unhooking Belt.

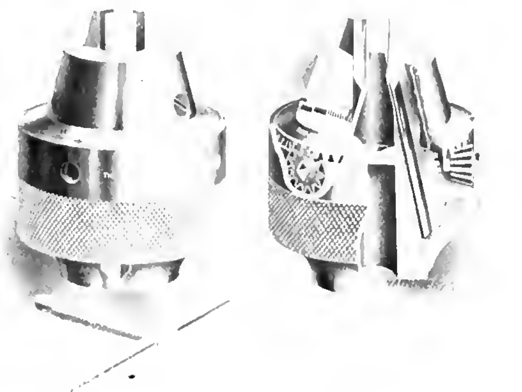
is attached to the belt end, is provided with teeth. These teeth are driven through the belt with a hammer, using a backing consisting of a soft wooden block. The belt is then turned over, and the ends of the teeth clinched, the points being driven well into the leather. The convenience and simplicity of this operation is evident. These couplings are made for all standard widths of belts, varying from one inch to six inches.

SKINNER GEARED PATTERN DRILL CHUCK.

The Skinner Chuck Co., 94 N. Stanley St., New Britain, Conn., is making the improved style of drill chuck shown in the accompanying halftone. In the previous chuck of this type made by the same builder, the jaws were tightened by twisting the knurled sleeve by hand. When a strong grip was desired, it was obtained by the use of the spanner wrench. This latter means of tightening the chuck is sometimes objectionable on a light drill press, where the spindle has a tendency to turn with the wrench. In this new geared pattern chuck it is possible to operate it by hand as before, and, in addition, provision is made for using the common form of key wrench, by which the jaws may be tightened sufficiently to drive a high speed twist drill to its limit. In tightening the chuck in this manner, there is no strain tending to revolve the spindle of even the lightest machine.

As may be seen in the engravings, the improvement consists in sinking bevel pinions into the body of the knurled sleeve, and providing these pinions with a stationary gear for them to mesh with, fast to the body of the chuck. These pinions have square sockets, which may be reached by openings in the sleeve as shown, and may be operated with a common square key. As the chuck is tightened by the operation of these pinions and the key, the pinions travel on the gear, giving a very powerful grip. The key, however, is only used for giving the final tightening and for unloosening the chuck. All adjustments for different sizes of tools are effected more quickly by revolving the chuck by hand. Two pinions are provided, thus insuring longer life to the gearing and making it more convenient to apply the wrench. In case one pinion should break, the chuck would still be available for service, with the remaining pinion.



New Pattern of Skinner Chuck which allows Tightening without Revolving the Spindle.

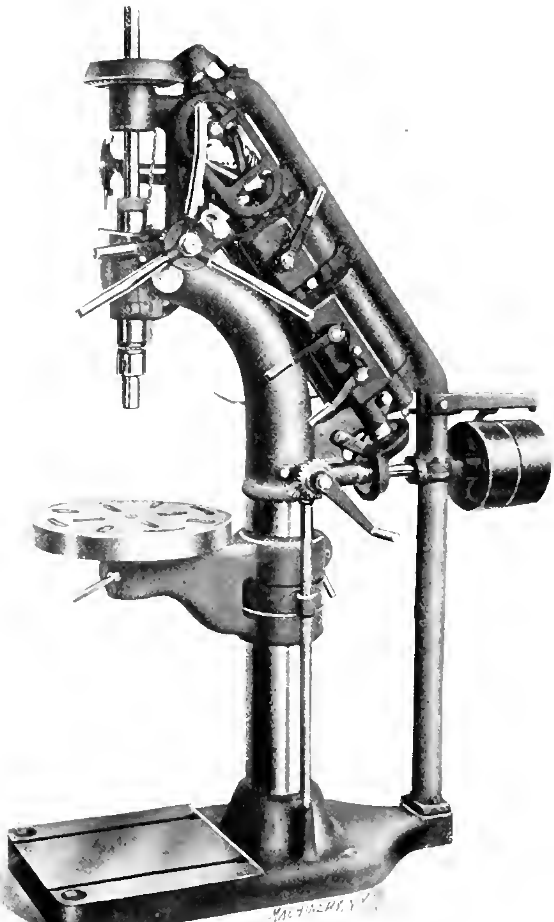
This tool is made with the same care used by the makers in the rest of their line. As in their other chucks of this design, a standard brand of steel is used for the jaws, this same make and brand having been used for years without change. Each jaw is hardened to an exactly uniform heat, this being made possible by the use of an electric furnace. Every chuck is tested for accuracy before leaving the works and the error carefully measured. No inaccuracy of over 0.002 inch is allowed to pass. Attention is called to the long bearing of the jaw in the solid threaded nut, and the angular bearing of the jaws on the bottom of the slot milled in the chuck body. Owing to the way in which these jaws are supported in these milled slots, they have no tendency to turn or rotate from the strain of driving the tool. The gears and pinions are hardened, and the jaws and cap are hardened and ground. The appearance of the chuck is neat, and there are no projections to injure either the work or the workman.

This chuck can be furnished with a hole through the center of the full capacity of the chuck, when it is desired to use it on a hollow spindle machine. It is readily taken apart for cleaning and oiling, a screw driver being the only tool necessary. Two sizes are now ready for delivery and other sizes will be furnished later.

BARNES 20-INCH UPRIGHT DRILL.

A medium-sized drill press of an entirely original design has been placed on the market by the Barnes Drill Co., Rockford, Ill. The novelty of the design and arrangement of the component parts is at once apparent upon examination of the accompanying halftone. The drill press, as shown, is provided with geared drive, located in the gear box at the lower end of the part of the frame where the driving and feed mechanism is placed. The main shaft in this gear box is driven from the horizontal pulley shaft by means of bevel gearing. There are four changes of speed in this gear box, without resorting to the back gears, and these speeds can be easily and quickly obtained without stopping the machine, by operating one of the two shifting levers shown on the front side of the gear box. The back gears, contained in a cover or box by themselves, are placed diagonally above the gear box, and operated by the lever shown. By means of the back gears operated in connection with the gear box eight changes of speed can thus be obtained, which is sufficient for all twist drills from 1/4 to 1 1/2 inch in diameter. The ratio of the back gears is 4 to 1.

Diagonally above the back gear box is placed the mechanism for the positive power feed. Any feed from 0.001 up to 0.025 inch can be instantly obtained while the drill is in motion by shifting the small index lever shown directly in front of the drill spindle between its two bearings. The feed changing mechanism is of an entirely new design, and its practicability and convenience add much to the utility of the drill. An automatic stop for the feed is also provided. The hand feed is operated through the spider or star wheel having three handles, located as shown in the half-tone. On the shaft on which this spider is placed a pinion is provided which runs with an internal gear, which in turn is connected with the pinion engaging with the feed rack. By this arrangement the leverage of the handles on the spider is equivalent to levers of hand-feed mechanism of the common design four times as long. The spider or star wheel also acts as a quick return lever.



Barnes 20-inch Upright Drill Press with Geared Drive of Original Design.

The remaining details of the machine are plainly shown in the halftone. The round table is regularly furnished, but square tables are also supplied on request. The table is raised and lowered by operating a crank connected by bevel gears with a screw located as shown. The bracket holding the table may be swung in an arc of nearly 180 degrees around the post.

If this machine is required to be fitted out as a tapping machine, reversing friction pulleys are put in place of the tight and loose pulleys shown in the half-tone, and this arrangement permits the machine to be used for tapping purposes as conveniently as machines with expensive geared tapping attachments. The engraving shows the machine driven from the counter-shaft, but these drills are also fitted with electric motors and starting rheostat, which makes the machine completely self-contained.

The frame of the machine, as can be easily perceived from the illustration, is of a rigid design; the column is heavy for this size of drill, and the back brace for supporting the gear boxes and feed mechanism makes it very rigid. This will be understood when it is known that the tool will drive a one-inch high speed twist drill, running at 190 revolutions continuously, at a feed of 2 inches per minute in steel, and 3 inches per minute in cast iron, without engaging the back gears. All levers and handles are easily within the reach of the operator when standing in front of the drill.

The height of the drill is 70 inches, the distance from the column to the center of the table is 10¼ inches, the maximum distance from the spindle to the table is 26¾ inches, and from the spindle to the base, 42 inches. The vertical travel of the spindle is 10 inches, and of the table 16 inches. The spindle is bored to take a No. 3 Morse taper. The floor space required, exclusive of the tight and loose pulleys, which overhang 7 inches, is 37½ x 16 inches, and the complete drill, back-geared, with positive power feed, weighs 740 pounds. The machine will, however, if required, be furnished without back gears, and also without a power feed and automatic stop, having simply the plain star-wheel feed lever for hand feed only. It should be noted that this machine is made by the Barnes Drill Co., and not by another firm of similar name.

EDGEMONT WET TOOL GRINDER.

The Edgemont Machine Co., Dayton, Ohio, is building the wet tool grinder herewith shown. This tool is intended to take the place of the cheap dry grinders so extensively used for tool sharpening. It costs very little, and offers a number of advantages. The danger of burning tools is avoided, and the wheel does not have to run as fast as in the dry grinder.

Wet Tool Grinder built by the Edgemont Machine Co.

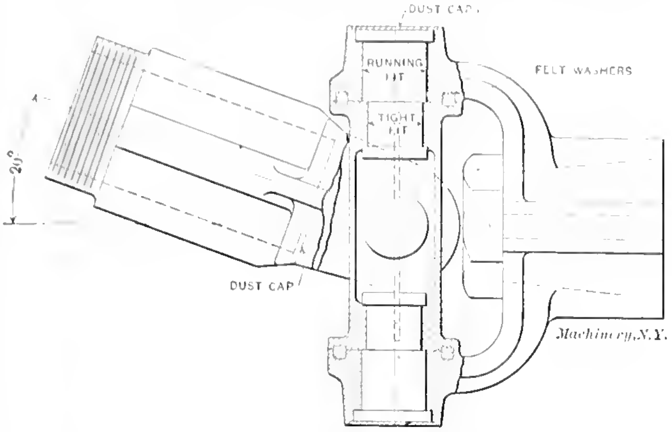
In comparison with the more elaborate wet grinders on the market, this machine is exceedingly simple and inexpensive. Water is supplied by a small tank on the top, and is allowed to run on the wheel until a sufficient quantity has accumulated on the lower wheel case. Owing to the special design of the casing the wheel is caused by the latter to pick the water up and spray it continuously over the work. There is no pump to get out of order, and no mechanism of any kind to deteriorate from grit and rust.

The machine is well built, with a large spindle of special steel, running in ample journals and self-oiling bearings. The height of the machine from the floor to the spindle is 40 inches. The floor space occupied is 14 x 23 inches. The weight complete is 200 pounds. A corundum wheel 12 inches in diameter and 2 inches face is used, and it should be speeded from 1,200 to 1,500 revolutions per minute. As may be surmised from the engraving, the grinder may be used as a bench machine when desired, the column being separate from the head, so that it may be used or not as convenience dictates.

MUTUAL MACHINE CO.'S UNIVERSAL JOINT.

The growth of the automobile industry has brought forth a great many designs of universal joints; in the accompanying line engraving we illustrate one of these, the Warren patent universal joint, manufactured by the Mutual Machine Co., 25 Wells St., Hartford, Conn. This device is known as the 1909 Universal Joint. One of its important features is the fact that the parts are joined together with rivets, instead of with bolts, as there is no reason to ever take the joint apart after it has once been put in place. To make the mechanism dust-proof, felt dust washers are compressed and placed in cavities in the fork before assembling; after the oil and grease come in contact with the felt, it expands and fills the corresponding cavities in the center blocks, the arrangement thereby becoming dust-proof. The hollow space in the center

blocks is filled, when assembled, with non-fluid grease, which is sufficient to last for several months, and when it is necessary to fill the receptacle again, a small screw, not shown in the illustration, is loosened, and the hollow space supplied with fresh grease. A strong point in favor of this joint is

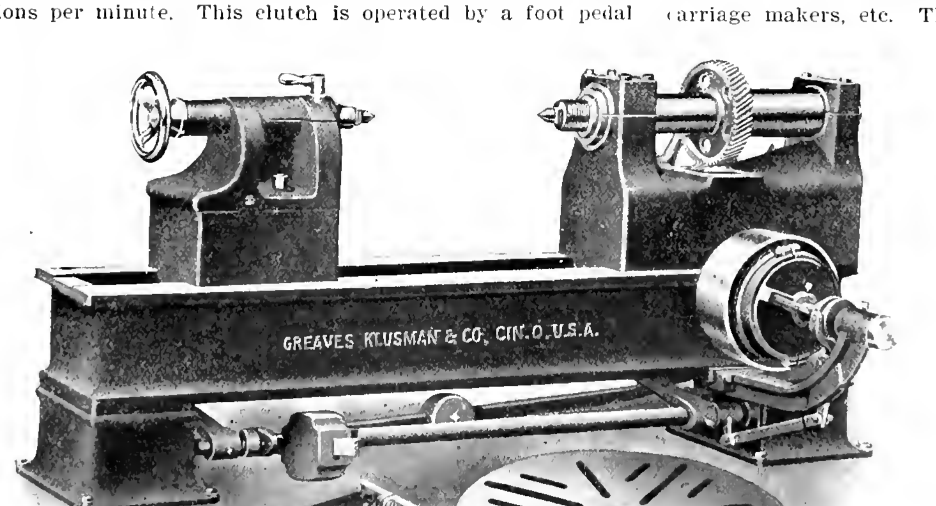


Warren Patent Universal Joint

that it is free from bolts, screws, nuts, cotter pins, etc., which are liable to work loose, and that it is unnecessary to apply any protective dust covers. An examination of the design, as shown in the engraving, will give a clear idea of the simplicity and rigidity of the construction.

ARMATURE BANDING AND FIELD COIL WINDING LATHE.

The engraving shows a special lathe built by Greaves, Klusman & Co., Cook & Alfred Sts., Cincinnati, Ohio. This machine is expressly designed to meet the requirements of electric motor and dynamo manufacturers and electrical repair shops, for the banding or armatures and the winding of field coils. For this purpose, the spindle is very strongly driven through the spiral gearing shown, which runs in a bath of oil. The gear casing has been removed in the engraving to show the construction. The change gears provided are attached to the front of the lathe (the engraving shows the rear view) and give four different spindle speeds of 15, 30, 60, and 120 revolutions per minute, respectively. The lower driving shaft passes through the bed and is equipped at the rear end with a self-releasing friction clutch pulley, 14 inches in diameter and 5 inches face, which should run at 360 revolutions per minute. This clutch is operated by a foot pedal



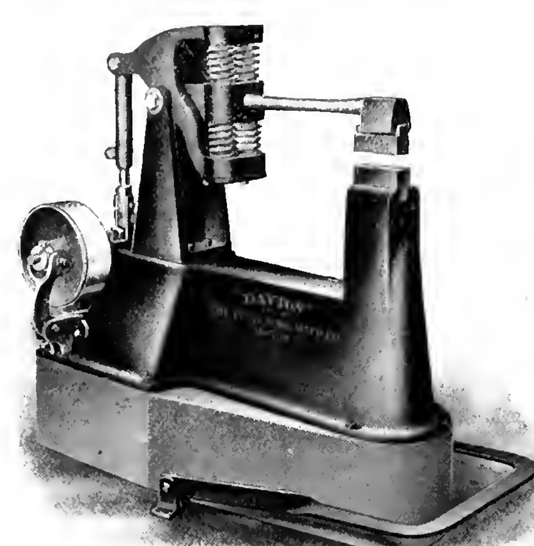
A Special Lathe for Winding Operations in Electrical Work

running the entire length of the bed, so that the operator can conveniently stop and start the machine from any point. This permits belting the machine direct from the line shaft without the use of a counter-shaft. When a motor drive is desired, a spur gear is substituted for the driving pulley, meshing with a pinion on the motor shaft, the motor being mounted on a bracket attached to the lathe bed.

The machine has a height of 36 inches from the floor to the center line of the spindle, being somewhat lower than the usual dimension, thus making it convenient for the operator when handling heavy armatures of large diameter. The equipment consists of the parts shown in the engraving, including the large face-plate. A counter-shaft is not furnished or required. A 12-foot bed is usually furnished. This will take 8 feet between centers. Longer or shorter beds are furnished if desired. With a 12-foot bed the machine weighs about 3,300 pounds. A special long travel slide rest for turning commutators can also be furnished with this machine if desired.

DAYTON POWER HAMMER.

The accompanying half-tone illustrates a power hammer, manufactured by the Foglesong Machine Co., Dayton, Ohio, and known as the Dayton spring-cushioned helve hammer. The machine is intended to meet the demand for a first-



Power Hammer with Friction Clutch Drive

class, moderate-priced machine, adapted for the requirements of general manufacture, blacksmith shops, wagon and carriage makers, etc. This machine has been in use in the factory of the makers, subjected to all kinds of work, and under all kinds of conditions, for a long time, and although embodying some interesting features in its design, it is by no means experimental. One of the features of this machine is a friction clutch instead of the common belt tightener for starting and stopping the machine, and controlling the stroke. Another feature of importance, not possessed by the upright style of hammer, is that of permitting such work as welding of circular pieces, tires, etc., to be done very conveniently, as there are no parts in the construction of the hammer which will obstruct the placing of work of any shape on the anvil. This feature will be greatly appreciated by blacksmiths. The driving shaft and the helve are made of hammered spindle steel. The helve is made a tapered fit, and keyed into the head, which is placed between strong and durable steel springs. Provisions are made so that all necessary adjustments can be made instantly, and the foot treadle is arranged so that

the operator can stand in the front or on either side of the hammer when operating it, the variation of the foot pressure on the treadle regulating both the rapidity and the force of the blow.

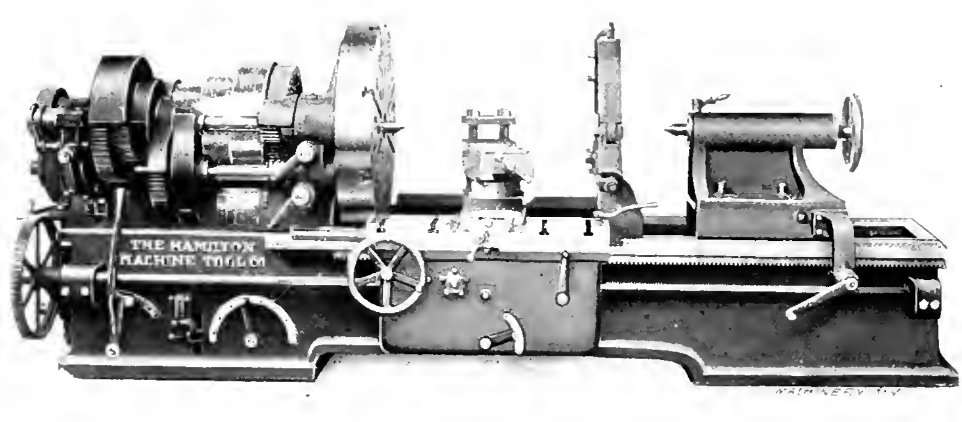
This hammer is made in two sizes, No. 2 and No. 3. The No. 2 hammer weighs 900 pounds, and occupies a floor space of 48 x 20 inches. The distance from the base to the top of the anvil is 24 inches, the length of the helve is $26\frac{1}{4}$ inches, and its diameter at the large end 2 inches. The length of the stroke is 8 inches. The speed of the driving pulley is 300 revolutions, its diameter being 12 inches; the width of the belt is $2\frac{1}{2}$ inches, and the power required for driving is from $\frac{1}{2}$ to $\frac{3}{4}$ H.P. On this hammer the manufacturers themselves have welded $1\frac{3}{4}$-inch steel axles and $\frac{3}{4}$ x 3-inch tires. The No. 3 hammer is larger and weighs 1,500 pounds, occupying a floor space of 50 x 20 inches. The distance from the base to the top of the anvil is 28 inches, the length of the helve is 34 inches, the diameter being 3 inches. The length of the stroke is 8 inches. The speed of the driving pulley is 250 revolutions per minute, its diameter being 18 inches; the width of the belt is 4 inches, and the power required from $\frac{3}{4}$ to 1 H.P.

HAMILTON 42-INCH HEAVY LATHE.

The Hamilton Machine Tool Co., of Hamilton, Ohio, has brought out a new 42-inch lathe of rigid construction, known as the Hamilton 42-inch heavy pattern lathe. This machine is shown in the accompanying half-tone, and, as will be readily seen, is of an exceptionally powerful design. It is intended particularly for heavy work, and embodies all the modern features common to the Hamilton lathes, such as quick-change gear mechanism, hollow steel spindle, automatic feed stop, and double apron. The machine may also be equipped with taper attachment, but this is not regularly furnished.

As shown in the illustration, the spindle is driven from the counter-shaft by a 6-inch belt. The cone pulley is provided with three steps, 16, 20, and 24 inches in diameter, respectively, and the speed variations thus obtainable, in combination with the quadruple gearing in the head-stock, allow ample speed changes as well as ample power for the heaviest work to which this lathe would be put. A feature of considerable importance is that the bed is considerably wider than customary, so that when turning work of the largest diameter within the capacity of the machine, the cutting tool is still supported by the outer V in the front of bed.

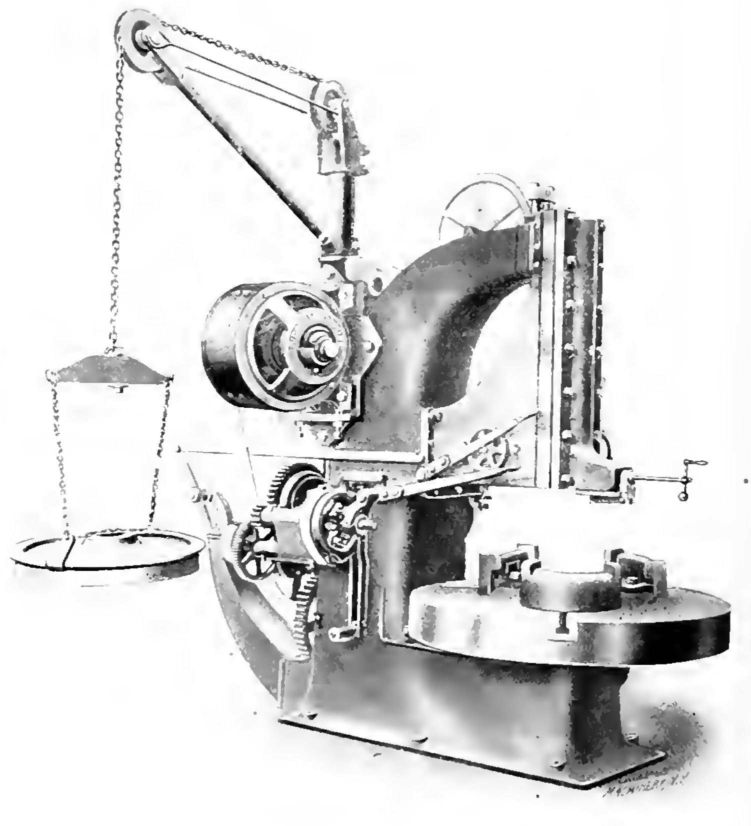
The principal dimensions are as follows: Swing over shears, $42\frac{1}{2}$ inches; swing over carriage, 30 inches; swing over compound rest, 28 inches; length between centers on 12-foot bed, 4 feet 6 inches; range of screw pitches which can be cut, 5/16 to 16 threads per inch. The range of feed is from 2 to 85 turns of the spindle per one inch forward motion of the carriage; the pitch of the lead-screw is one double thread per inch. The face-plate, which is internally geared, is 42 inches in diameter. The speed of the counter-shaft is 160 and 185 R. P. M., the size of the counter-shaft pulleys being 24 x 7 inches. The net weight of this machine, with a 12-foot bed is 24,000 pounds, and the increase in weight for each additional foot in the length of the bed is 450 pounds.



Hamilton 42-inch Lathe of Exceptionally Heavy Design.

IMPROVED MOTOR-DRIVEN CAR-WHEEL BORING MILL.

The accompanying half-tone illustrates a motor-driven car wheel boring mill manufactured by William Sellers & Co., Inc., Philadelphia, Pa., which embodies a number of improvements in car wheel boring mill machinery. The noteworthy features of this machine are the improved automatic chuck, the friction feed mechanism, and the crane attachment. The machine is known as a 54-inch wheel boring mill, and is of particularly heavy construction, and provided with powerful gearing, rendering it capable of taking the heaviest cuts required for the class of work for which it is intended.



Sellers' Motor-driven Car-wheel Boring Mill with Automatic Chuck and Crane Attachment.

The improved automatic chuck is self-closing, self-opening, and self-centering. It has three adjustable abutments, as shown in the half-tone, each of which is provided with an equalizing steel jaw, having two bearing points, so that the work is held and centered by six points on the circumference, thereby insuring accuracy in centering. This automatic chuck enables the work to be secured in its correct position in the machine, and subsequently released without any loss of time and labor. The power of the clutch grip increases with the resistance of the cut, and this feature is very important, as it obviates the necessity of stopping the table in order to tighten the chuck. The general action of this chuck is as follows: The first movement of the driving shaft causes the jaws to close in around the work, after which the motion is transmitted to the table to produce rotation. When the work is completed, the chuck is released by disengaging the driving clutch, and retarding the driving shaft

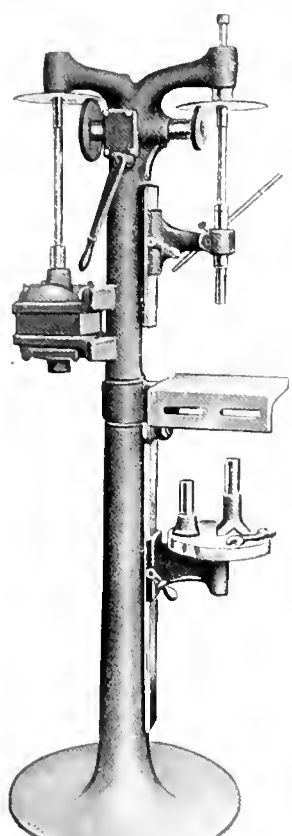
by means of a friction brake, provided for the purpose. The inertia of the table and work will then impart the necessary force required for opening the jaws.

The machine is motor driven, the motor being mounted, as shown in the half-tone, on the side of the machine frame. The motor is a Westinghouse type "S," of 7½ horse-power, capable of a variation in speed of approximately two to one, thereby eliminating all cone pulleys for speed variation. The efficiency of the machine is also increased by this motor drive, because the variable speed motor gives the required speed range in smaller steps, permitting the mill at all times to be run at its maximum capacity.

On the top of the rear part of the housing a crane is fitted, as shown, for lifting the car wheels into place on the table of the machine. This makes the machine very handy to operate, and self-contained in all its features.

MOTOR-DRIVEN VARIABLE SPEED SENSITIVE DRILL PRESS.

Last month we illustrated and described the principal features of a friction-driven sensitive drill press, built by the Washburn Shops of the Worcester Polytechnic Institute. The machine then described was of the belt-driven type. The accompanying half-tone shows the same machine with somewhat different arrangements in its driving parts, designed for motor drive. The arrangement of the motor and the driving mechanism, present novelties which make this modification of the machine very interesting from a mechanical point of view.



Washburn Motor-driven Sensitive Drill Press.

The machine, arranged as shown, has proved a great success, and it is stated that a noticeable feature to every-one who has operated this machine is the smoothness with which the drill is fed into the work, this being due to the entire elimination of belts. The induction motor (which, by the way, is furnished with the machine for either 110 or 220 volts, 2 or 3 phase, 25, 40 or 60 cycles) is bolted to the rear of the column, high enough to clear the square table of the machine when this is swung aside to enable the use of the round table. It also permits chips to be brushed from the table, without the liability of damage to the motor. At the same time, a motor placed in this position presents a neat appearance, and serves in a way to balance the machine against the weight of the square and round table on the other side of the column.

The motor is of constant speed, the speed variations being provided by mechanical means through the friction disks. The details of the friction drive were described in the April issue of MACHINERY, and it will only be necessary to mention the driving arrangement in a general way. The motor runs at 1,200 revolutions per minute, and by means of a double friction disk arrangement, shown at the top of the machine, a speed variation of the spindle ranging from 100 to 1,600 revolutions per minute is obtained. The drill spindle can be stopped without stopping the motor by throwing the speed lever to its extreme position. When in this position, the driver disk is released from contact with the friction roll, the disk being recessed in order to accomplish this. When the friction roll is in contact with the driving disk, its shaft or spindle is raised slightly and the weight of the rotor is taken by the disk, but when in the released position, the weight of the rotor is carried by a special collar. On starting the motor, the friction roll should not be in contact with the driver disk, the motor starting without load; then the friction roll is thrown into contact with the disk. Very little power is required for driving the machine, as the normal pressure on the roll is very slight until the drill is in use, when the pressure increases or decreases with the working pressure on the tool. The machine has some very commendable features, and will, undoubtedly, prove a very efficient sensitive drill.

CENTER GRINDER AND FRAME FOR PORTABLE DRILL.

In Fig. 1 of the accompanying half-tones is illustrated a new type of electrically-driven center grinder made by The United States Electrical Tool Co., of Cincinnati, O. This

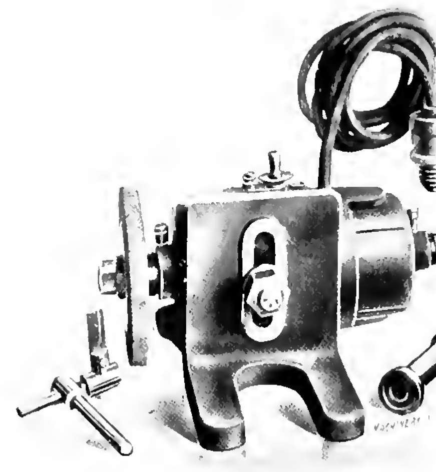


Fig. 1. Electric Center Grinder.

grinder is mounted on an angle plate, as shown. The lower part of the angle plate has a slot provided which straddles the tool-post of the lathe, and the device is clamped to the tool-post slide by means of the tool in the tool-post. In this way the grinding wheel with its motor may be held very rigidly, and there is no vibration in the motor of the kind

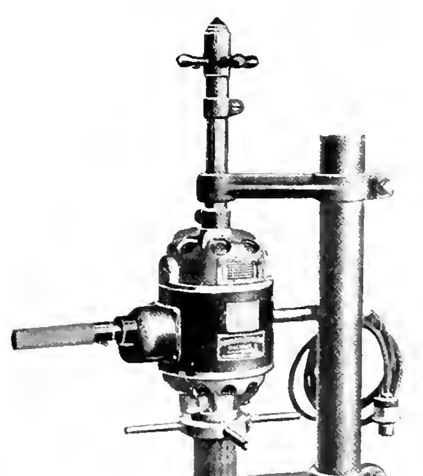

Fig. 2. Improvement of the "Old Man" applied to the Electrically-driven Drill.

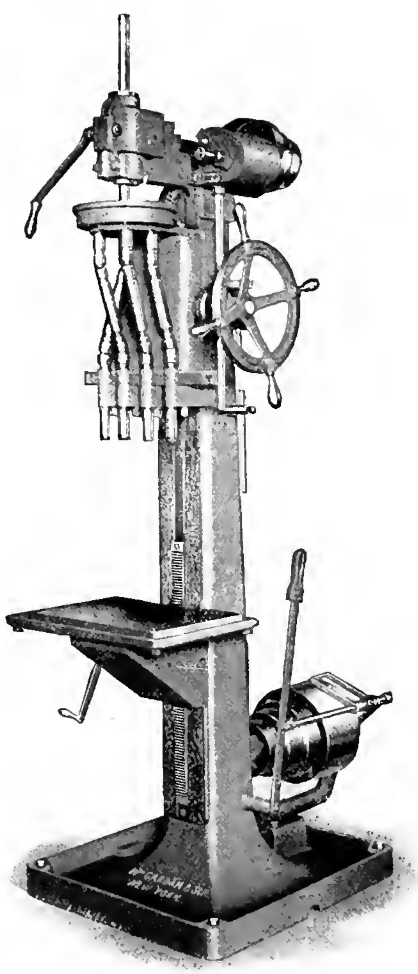
so objectionable when the motor is attached to a shank. The motor and grinder can be raised or lowered to suit the height of the centers of the lathe by means of oblong slots provided in the vertical part of the angle plate, as plainly shown in the half-tone. The device can also be swiveled to any angle. The bearings are adjustable for taking up the wear, and provided with caps, making them dust-proof. The motor is of the air-cooled type.

Another handy device brought out by the same company is an improvement on the "old man" or a frame for portable drill, as shown in Fig. 2. This device consists of a rigid post, provided with two brackets, one having a plain bearing and the other arranged for feeding the drill. This post is placed in a base provided with oblong slots for clamping purposes. This improvement on the "old man" as usually constructed, will be appreciated and found very handy around the shop where portable electric drills are employed.

GARDAM ADJUSTABLE MULTIPLE SPINDLE DRILL.

The adjustable multiple spindle drill shown in the accompanying illustration is one of a series recently designed and placed on the market by Wm. Gardam & Son, 45-51 Rose St., New York, and intended to take the place, for manufacturing purposes, of the ordinary multiple spindle drilling machine with fixed spindles. The machine shown in the half-tone is adapted for drilling at one time a number of small holes up to ½ inch diameter, and a special feature of the tool is the ease with which it can be handled and the rapidity with which the changes can be made from one series of holes to another. While this particular drill is designed for four spindles, others are made with a varying number of spindles



Gardam Adjustable Multiple Spindle Drill.

having an adjustment forward and back of 3 inches, and sideways of 15 inches, the minimum distance between any two spindles being ordinarily 1¼ inch. The spindles can also be adjusted vertically to allow the use of drills of different lengths, and all are bored to take a No. 1 Morse taper shank. The head which carries the spindles is counterbalanced by a weight inclosed within the column.

The table is supported on a very rigid box knee, and is adjustable by rack and pinion. It is rectangular in shape, 16 x 12 inches, giving an ample working surface, and is surrounded by an oil groove. The size and shape of the table, however, can be adapted to special needs. In order to provide simple means for taking up the wear, the table and head bearings are scraped and provided with gibs. The base is cast with a rim to form an oil pan, preventing the overflow of oil, chips, etc. These drills are very suitable for working in gangs, and several of them may be mounted on a common base, and arranged to work together in groups. When set up in this way, one attendant can easily take care of and operate several machines. The counter-shaft is attached to the base, and is fitted with tight and loose pulleys, and has self-oiling bearings. The driving gears are made of carbon steel, and the machines can be supplied with or without direct-connected all-gear feed, and with or without tapping attachment. If required, they can also be easily adapted for individual motor drive.

THE HELE-SHAW CLUTCH.

One of the severest, and undoubtedly the most difficult and most delicate of all clutch problems, has been presented to the designer by the development of the automobile, and a

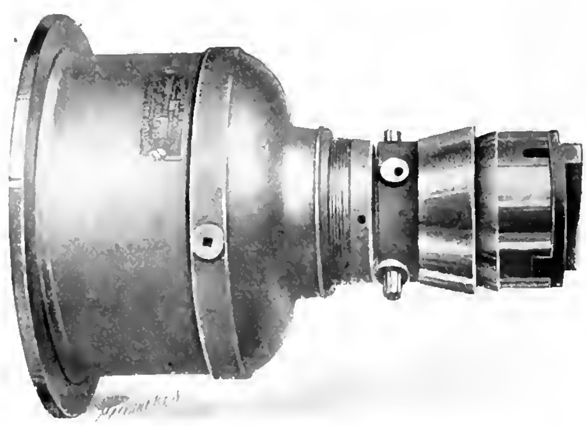


Fig. 1. General Appearance of the Hele-Shaw Clutch.

great many different ideas in clutch design have been due entirely to the development of the motor car. An interesting type of clutch for this as well as for other industrial purposes is shown in the accompanying half-tone, Fig. 1, and the line engraving, Fig. 2. The principal feature is that the power is transmitted through the friction between grooved disks of the cross section shown by the heavy black line at A in Fig. 2. A number of these disks are placed in the clutch, the V-groove of each fitting into the V-groove of the next. The power is transmitted by means of the outer edge of one, and the inner edge of the other, of each pair of disks engaging, respectively, with ribs in the outer casing B and inner drum C, engagement being through special notches cut in the edges of the disks. The outer casing is then attached to the motor or other prime mover, and the inner drum to the driven shaft, or *vice versa.* The spring D holds the disks in engagement with each other, until the disengaging lever is moved to the left, pulling with it the part E and the sleeve over the shaft F, thereby compressing the spring D, and releasing the pressure on disks A. The action, it is thus seen, is very simple.

It has been found that the V-shaped disks transmit considerably more power and permit a more even "pick-up" than clutches with flat disks. Other advantages claimed are also that the form of the disks permits the bodies of the plates to always be well separated, and leave free access for the oil circulation until the clutch is under engagement. This greatly increases the radiation of heat, as compared with flat disks. The special form also secures greater transverse strength, and the disks do not distort easily. The disks are oiled under ordinary circumstances, but if the oil should be lost by accident, the strength of the disks prevents injury even under the most unfavorable working conditions.

One of the most important features of the Hele-Shaw clutches, however, is their uniform rate of engagement or "pick-up," the engaging qualities being greatly enhanced by the special shape of the groove in the plates. The great number of surfaces and their large area make the clutch flexible and easily manipulated in case of slipping. The load is distributed over all the contact surfaces and therefore but a fraction of the load is placed on each disk, thereby preventing undue wear. When the clutch is first applied, the plates being pressed together by springs, the V-grooves intermesh gradually, bringing the driven series slowly to the speed of those driving, and forcing the oil out between them. The cushion of oil between the plates makes sudden engagement impossible, a factor which is of the greatest importance for motor car purposes. When the oil is finally squeezed out, the plates engage firmly with one another, and all slip ceases. As all lubricated clutches drag minutely the supposedly stationary disks when the car is not running, a small brake is used to stop the spinning of the driven shaft.

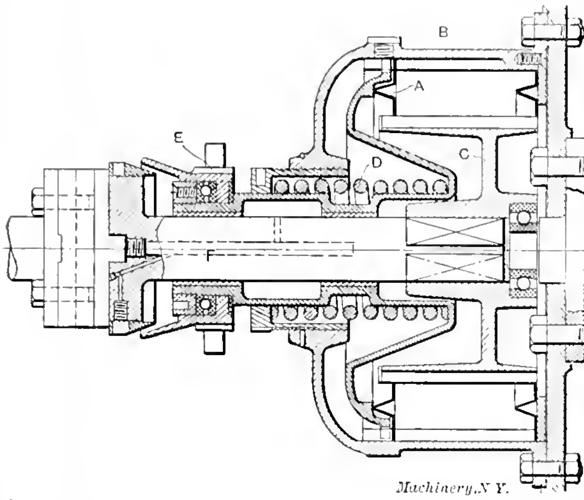

Fig. 2. Section of the Hele-Shaw Clutch, showing Design of Details.

The V-shaped plates are termed "Hele-Shaw friction disks" from their inventor, Professor Hele-Shaw, a description of whose original clutch appeared in the October, 1903, issue of MACHINERY. The clutch is manufactured in the United States by the Merchant & Evans Co., 517 Arch St., Philadelphia, Pa.

HENDEY SINGLE PULLEY AND MOTOR-DRIVEN GEARED HEAD LATHES.

In Figs. 1 to 3 are shown the designs adopted by the Hendey Machine Co., Torrington, Conn., for its single pulley driven lathes, and for those which are to be motor driven. The forms of construction adopted present a number of interesting features. For instance, a considerable range of mechanical speed changes, nine for the larger sizes and eight for the smaller ones, is obtained from a single speed pulley by a comparatively simple mechanism. The few gears and clutches required are very liberal in size, possessing ample strength and wearing qualities to meet all the requirements of high-speed turning.

The design of the drive for the 20 and 24-inch lathes is best seen in Fig. 2, which shows the head-stock of Fig. 1 with the cover removed. The driving pulley, as shown, is mounted on a shaft at the front of, and in the same longitudinal plane with, the spindle of the machine. It carries a set of three sliding gears, which may be shifted, by means of the horizontal handle near the top of the casing in Fig. 1, to engage with any one of three gears on a sleeve which runs loosely on the spindle. The shifting gears on the driving shaft are thrown out of engagement before their position is changed by rocking the lever shown at the front end of the head-stock in Fig. 1. This rotates the eccentric sleeve in which the driving shaft is mounted, so as to move the latter away from the spindle far enough to permit the gears to be moved without interference. At the back of the gear casing is a third shaft corresponding in function to the usual back gear shaft. The two gears of this shaft mesh with mating gears on the spindle sleeve, while the pinion at its right-hand end engages the large spindle driving gear.

The handle at the front of the casing, seen in both Figs. 1 and 2, carries double cam grooves which operate two rock shafts, one of which is connected with a positive clutch on the back gear shaft, to connect the latter with either of the two driving gears on its left-hand end, while the other operates a positive clutch on the spindle, connecting the spindle with either the sleeve at the left or the large spindle gear at the right. By this means it will be seen that nine different speeds are provided, the three obtained from the sliding gears being multiplied by three by the operation of the positive clutches, it being possible to transmit the motion either directly to the spindle from the sleeve, or through either of the two back gear ratios. The arrangement of these controlling handles is very convenient. The handle on the front side of the head-stock operating the positive clutches is used for stopping and starting the machine independently of the counter-shaft. It may be so quickly done by this means that an appreciable saving of time results in cases in which frequent changes of work are required.

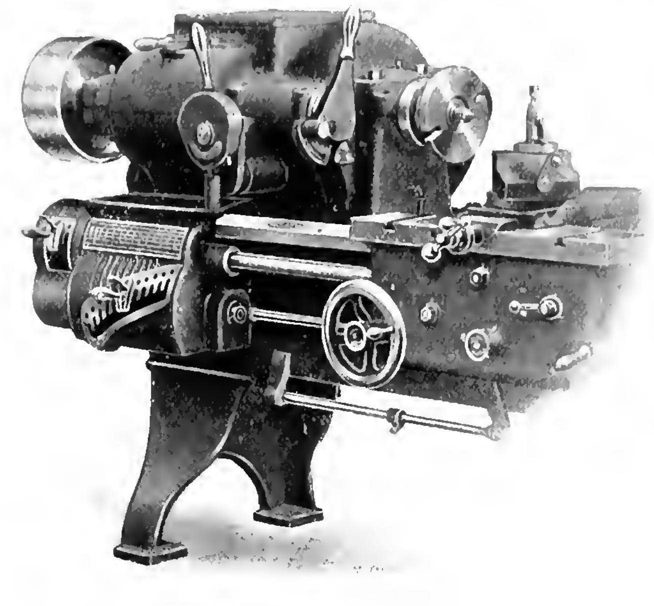

Fig. 1. Hendey-Norton 20-inch Lathe with Geared Head.

The head-stock casing forms a pan or reservoir for oil so that the gears which are enclosed are constantly lubricated. By this means they are caused to run more smoothly and they wear for a materially longer time, as well. Special attention has been given to the matter of continuous and efficient lubrication for the bearings, and for the gearing rotating freely on the shafts in the head. The spindles have taper journals running in annular bearings; and these, with the driving shaft and back gear bearings, are fitted with ring oilers, feeding from oil pockets in the casing; an exception is made in the case of the driving shaft of the 20- and 24-inch heads, which runs in babbitt-lined bearings formed in either end of the sliding gear cradle or rocker which throws the gears

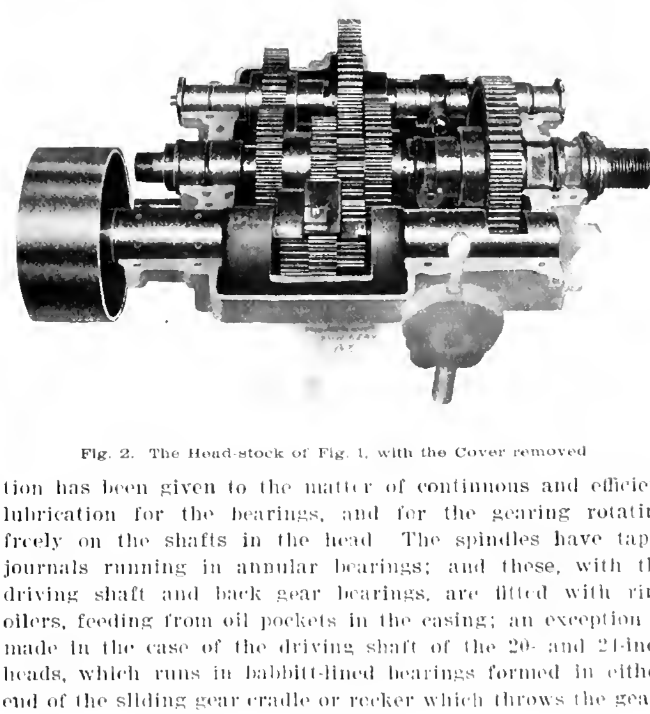

Fig. 2. The Head-stock of Fig. 1, with the Cover removed

out of mesh, as previously explained. All bearings of the free gears and of the clutches are automatically oiled from the oil bath. The removal of the upper half of the casing, as may be seen in Fig. 2, exposes all the bearings and journals and allows the component parts of the mechanism to be freely removed.

The driving pulley is 12 inches in diameter on the 20-inch lathe in question, and is driven by a 5-inch double belt. At the highest spindle speed the belt travels 3.14 feet per revolution of the spindle, while at the lowest spindle speed this is increased to 81.5 feet per revolution. By comparing this with like conditions on a 20-inch belt cone-driven lathe, it will be found that in addition to using only a 3-inch belt in place of the 5-inch one, the amounts of belt travel are but 1.24 feet and 37 feet, respectively. The difference in belt power is about 4 to 1 in favor of the geared head lathe. In all Hendey-Norton lathes, two speeds are available in the countershaft, since there is no necessity for providing a reverse drive for threading. By this means the nine mechanical spindle speeds are doubled, giving 18 in all, in geometrical progression. In the case in question this range is from 10 to 324 revolutions per minute, but may be varied, of course, to suit the class of work to be done. For motor-driven machines it is only necessary to mount the motor on top of the casing, and connect it with the driving shaft by gearing or by a chain drive.

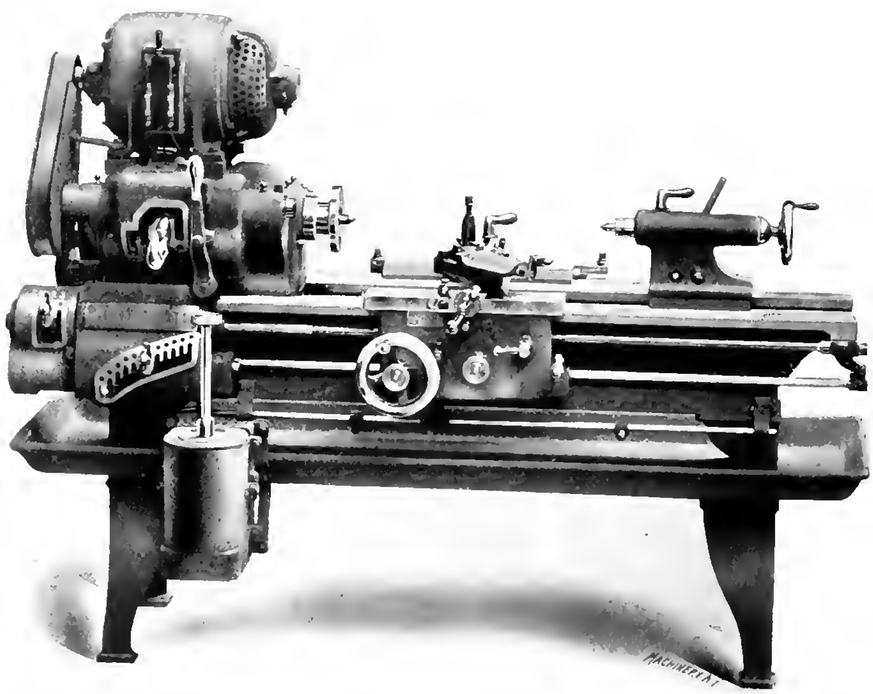

Fig. 3. Hendey-Norton 14-inch Motor-driven Lathe, showing Geared Head used on Smaller Sizes.

In Fig. 3 is shown a motor-driven machine, in which, however, a somewhat different mechanism is used for obtaining the mechanical speed changes. This lathe (which is smaller than the one previously shown, having 14 inches of swing) is suitably driven by a modification of the makers' well-known change gear mechanism used in their standard line of lathes. The intermediate shifting gears, mounted on the driving shaft, are controlled by a lever working in a slot in the gear casing, which is also provided with locking holes for the plunger pin of the lever. In this head there are 4 direct speeds and 4 through the back gears with the driving shaft running at a constant rate, giving 8 in all. The large lever at the front of the head controls a single positive clutch on the main spindle, and is used to start and stop the machine in the same way as a similar lever on the 20-inch machine shown in Figs. 1 and 2. In Fig. 3 a variable speed motor is used in place of the belt transmission to a single pulley; 20 gradations of speed are provided by the controller used, so that the operator has at his control 160 possible speeds in all. By this means he may adjust the rate to give all that the cutting tool will carry within very close limits. The power transmission from the motor to the driving shaft of the lathe head is effected by a silent chain which, with the sprockets on which it runs, is enclosed in a guard as shown.

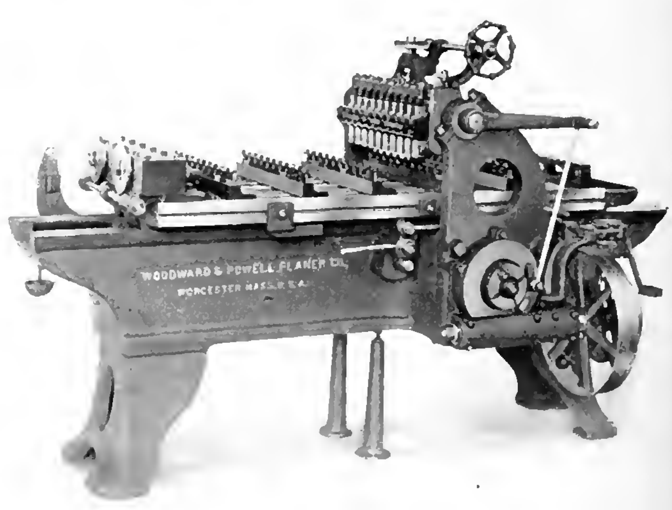
It will be seen that with either of the styles shown in Figs. 1 and 3 the mounting of the motor on top of the head is neatly done, the resulting combination not being at all top heavy. There is as well no over-hang in any direction, and the whole mechanism may be readily dismounted at any time when occasion may require. These gear-driven lathes are manufactured in all swings from 12 to 24 inches inclusive.

WOODWARD & POWELL PLANER FOR FLUTING FEED ROLLS.

We show herewith an illustration of a special planer recently built by the Woodward & Powell Planer Co., Worcester, Mass., for the special purpose of fluting feed rolls such as are largely used in textile machinery of various kinds. The construction of the planer involves a number of special features which are ingenious enough to warrant bringing the machine to the attention of our readers.

The feed rolls which are to be planed, are about 1¼ inch in diameter. The table of the planer is provided with 10 centers to accommodate 10 rolls side by side. These rolls, which are provided with square tenons on one end and corresponding square mortises on the other, are mounted on centers, those at the front end being squared to fit the mortise in the work, while the tail centers correspondingly fit the tenons. The rolls are supported throughout their length on V's, in which they are lightly held by clamps adjusted by the screws shown.

The head centers are arranged in two groups, the center spindle on each of which has a dial on the outer end. The 5 spindles in each group are geared together. These dials are left blank in the engraving, so that they may be cut with the requisite number of notches for the work in hand, the number depending on the number of grooves desired in the feed rolls. The hole in these dials is placed a little out of center, so that the space between consecutive notches will not be the same. This irregular spacing is necessary to break up the contact of the feed rolls against the leather-covered rolls they work with when assembled in the finished machine. If



A Planer fitted with Special Work- and Tool-holding Devices for Fluting Rolls.

the notches were spaced the same, a series of impressions would be formed in the leather rolls, making gears out of them. On the horizontal shaft which runs crossways of the front end of the table are two pawls engaging notches in the dials. When the table is returning, the back end of this shaft strikes the inclined latch, shown attached to the bracket

at the back side of the bed. This latch forces the shaft over and turns the two dials, consequently turning each of the ten spindles and indexing the rolls ready to cut the next groove. When the table starts back on the cutting stroke, a spring forces the shaft back to its original position, and the end of it strikes the latch which swings to the right until the shaft is cleared.

A tool is of course provided for each of the ten rolls. These tools are all mounted in the multiple holder shown, which is fastened to a slide mounted on a frame which can be rocked on trunnions in the housings fastened to the side of the bed. The friction box usually applied to operating the feed is, in this case, used for relieving the cutters on the return stroke. The friction disk is connected by the reach rod shown with a lever attached to the rocking tool-holder, so that the cutting blades are raised on the return stroke and brought back into position again at the beginning of the cutting stroke. The tool slide in which the blades are mounted fits vertically in dove-tail ways, being adjusted by a feed-screw operated by the bevel gears and hand-wheels shown.

It will be seen that the table of the planer is worm driven, being provided with a belt shifting mechanism of the type commonly used on spindles. The whole arrangement is an interesting modification of a standard machine for work of a highly specialized character.

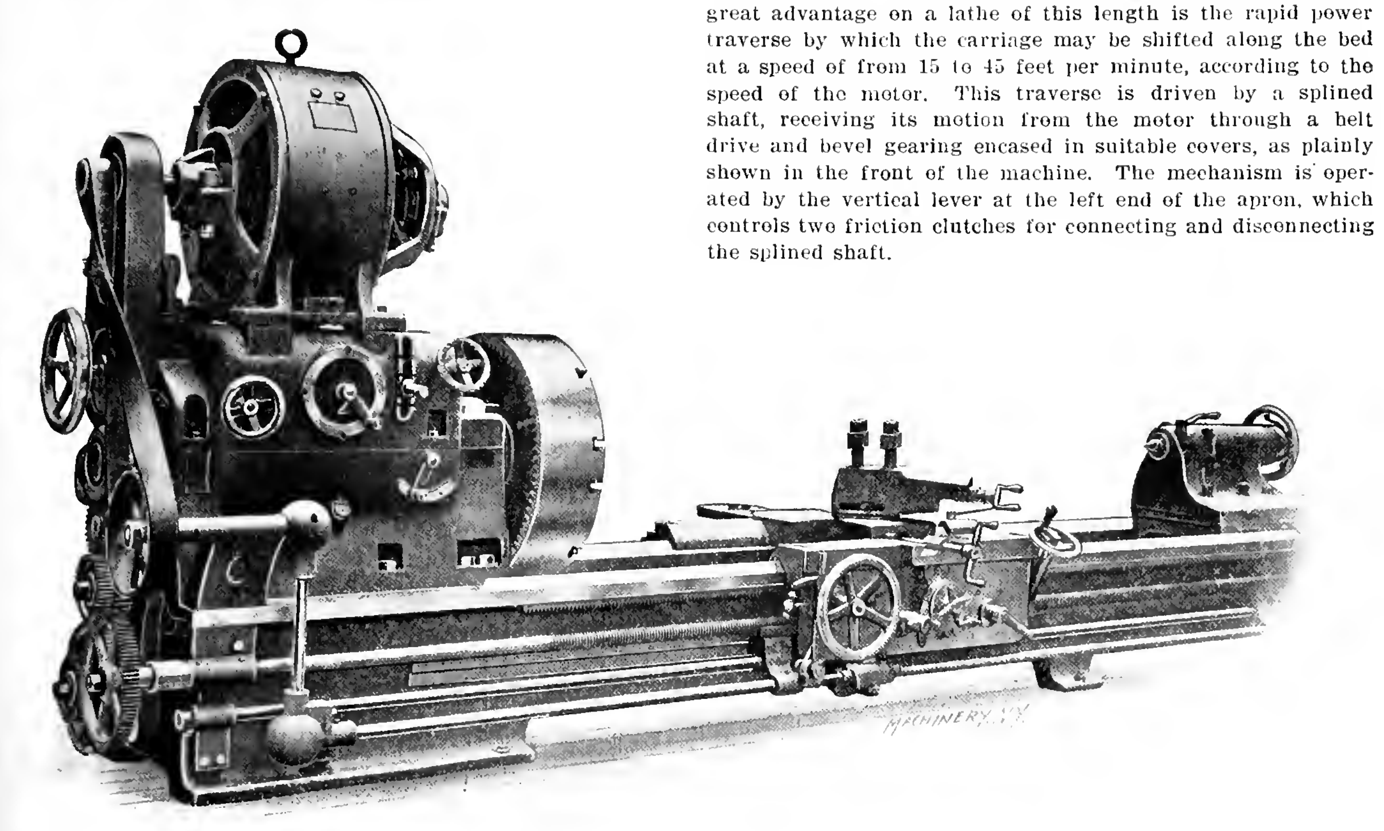
BRIDGEFORD 36-INCH GEARED HEAD LATHE.

The accompanying half-tone illustrates a new design of geared-head, motor-driven lathe, containing several features of mechanical interest; it is one of three machines recently built by the Bridgeford Machine Tool Works, Rochester, N. Y., for the Jones & Laughlin Steel Co.'s new shops at Woodlawn, Pa. One of the principal features of this lathe is that it has been designed exceptionally heavy, so as to meet the severest requirements placed on a machine of this kind through the use of high speed steel.

The drive is from a 15 H.P. Westinghouse motor, placed on the top of the frame of the geared head-stock. This motor provides a speed variation of from 300 to 900 R. P. M., and is direct-connected with the driving shaft of the head-stock through a rawhide intermediate gear. The arrangement in the geared head-stock provides for fifteen changes of speed, arranged in geometrical progression, obtainable through an easily operated speed variating mechanism in the head. The variable speed motor, however, adds to the efficiency of the tool, as it enables the operator to obtain a wide range of speeds without leaving his position at the carriage. The controller lever for the motor is mounted on the apron, and operates through a splined shaft. The controller and the resistance are placed on the back of the machine.

When the lathe is belt-driven, the speed variation obtainable through the motor is not available, but the 15 speeds provided for by the gearing in the head-stock give ample variations for different classes of work. In the case of belt-driven machines, the gear on the driving shaft is replaced by a pulley, running at a constant speed of 300 R. P. M. The spindle speeds then obtainable range from 3 to 150 R. P. M., which is sufficient for all purposes. All the driving gears within the head-stock are made of steel, and run in oil, and the bearings are so arranged as to receive a constant oil supply, thus insuring a minimum of loss of power through friction, and the durability of the tool, through the elimination of wear.

The lathe bed is 32 feet long, and a feature which is of great advantage on a lathe of this length is the rapid power traverse by which the carriage may be shifted along the bed at a speed of from 15 to 45 feet per minute, according to the speed of the motor. This traverse is driven by a splined shaft, receiving its motion from the motor through a belt drive and bevel gearing encased in suitable covers, as plainly shown in the front of the machine. The mechanism is operated by the vertical lever at the left end of the apron, which controls two friction clutches for connecting and disconnecting the splined shaft.



Heavy Bridgeford 36-inch Geared Head Lathe.

The lead-screw, the motor-controlling shaft and the rapid traverse shaft are all supported by automatic carriers which slide on a planed way on the front of the bed or frame. These carriers are plainly shown in the illustration; one of them always remains at the center of the travel, while the other is pushed along by the carriage. This method of supporting the lead-screw and the controlling and traverse shafts is a decided improvement over supporting them from the top of the frame, because by the former method the tail-stock is allowed free and unobstructed travel.

The lathe is designed to give a pulling power of 20,000 pounds on a 36-inch diameter, which is about four times that of the average cone-driven lathe of equal size. Motors varying from 15 to 25 H. P. are used, according to requirements. A constant speed motor can be employed instead of the variable speed motor referred to, but it is evident that variable speed is preferable. The total weight of the 36-inch lathe is about 29,000 pounds. It can be obtained with any length of bed desired, and the same type of machine is also built with 26, 32, 42 and 46-inch swing. It will be noted that in the half-tone part of the long bed has been omitted, in order to show the essential details more plainly. In the original photograph the omitted portion of the bed carries a rigid center rest, which is also furnished with the lathe.

IMPROVEMENTS IN THE UNIVERSAL MULTIPLE SPINDLE AUTOMATIC SCREW MACHINE.

Important improvements have recently been made in the driving mechanism of the multiple spindle automatic screw machine made by the Universal Machine Screw Co., of Hartford, Conn. We have previously described this tool (see New Machinery and Tools in the February, 1906, issue of MACHINERY). A comparison of the description and illustrations given in that issue with the ones here given will at once show the difference in the two designs. The new arrangement provides for a single-belt drive in place of the three-belt drive required in the older machine. Besides reducing the cost of the belting used, an important feature is the fact that it permits greater flexibility in the arrangement of the machines, gives greater driving power to the spindle, and, by means of provisions to be described later, permits of varying through a wide range the ratio between the turning and threading speeds.

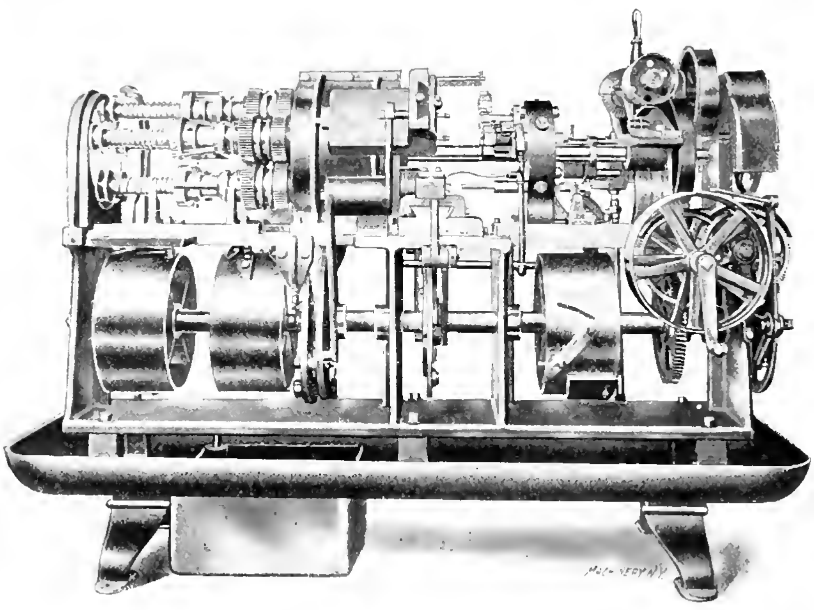


Fig. 1. Improved Design of the Universal Multiple Spindle Automatic Screw Machine.

As will be remembered, in this machine five spindles are employed, carried in a cylinder which is indexed to bring each spindle in turn opposite each of the five tool-holders, for which provision is made in the tool slide. The bars of stock which are held and rotated by these spindles project to the rear of the machine, where they are carried by reels supported by stands bolted to the floor. The tool-holder is fed forward by a cam on the cam shaft in the base of the machine, advancing all the tools simultaneously, and completing a piece of work at each revolution. The various cross-slide operations, the indexing of the cylinder, and the feeding and gripping of the stock, are also controlled by cams on the same cam shaft.

The threading is effected by reversing the spindle. The spindles normally revolve in a left-hand direction for all the turning, drilling, forming and cutting-off operations. For threading on the die, they are reversed to give a slow right-hand rotation suitable for the threading operation. When the die is advanced to the proper point on the work, the spindle carrying the latter is again reversed to throw in the regular left-hand movement, and the die is rapidly threaded off again. To obtain this alternate forward and backward rotation of the spindles in the cylinder, they are driven by two sets of gearing from their left-hand ends, of which the one nearest the turret is driven by a gear on a sleeve passing through the axis of the cylinder and leading toward the right of the machine, while the gear for driving the thread is keyed to a shaft passing through this sleeve, also extending toward the right. In the older design, this shaft and this sleeve were each driven by separate pulleys, belted to the counter-shaft. This has been changed in the new design to the method of driving shown in Figs. 1 and 2.

Sleeve A for driving the left-hand or turning movement, see Fig. 2, has keyed to it a gear F, driven by pinion E on shaft D, to which is keyed the driving pulley C of the machine. This driving pulley revolves at a high rate of speed, and the ratio of the driving gearing provided is such that it furnishes ample power for rotating the spindles. The right-hand end of short shaft D is connected by change gearing M with shaft B, which drives the spindles for the threading operation, as previously described. By this means a spindle speed suitable for threading can easily be obtained by changing gears M, the same as the gears for threading on a lathe are changed. The fact that an intermediate stud is introduced between D and B in this change gearing reverses the rotation of shaft B as compared with sleeve A.

The cam-shaft is also driven from the same pulley C. The left-hand end of shaft D (Figs. 2 and 3) carries a bevel pinion G, meshing with bevel gear H on shaft I. This shaft has loosely running upon it pulley J. J may be clutched to I by throwing lever K over, thus engaging the conical clutch surface shown. When lever K is thrown to the right so that the clutch is disconnected, a spring brake L is applied to pulley J which is thus instantly stopped. As may be seen in Fig. 1, J is to be belted to the driving pulley of the cam mechanism. It will thus be seen that the feeding and idle movements may be stopped or started independently of the spindle, greatly facilitating the setting up and operation of the machine.

Another improvement in the design is the new locking arrangement provided. Previously, the locking was done by a taper pin entering seats in the periphery of the cylinder. This has been replaced by a locking bolt of considerable size, thus giving great area of locking surface and reducing the possibility of error. This enters milled seats in the body of the cylinder, the milling being done on a fixture which has been very carefully made so as to divide these slots with great accuracy. As constructed, the upper face of the locking bolt is radial. A wedge adjustment is provided for keeping this radial face properly adjusted against the cap which confines the bolt in the slot in which it is held. The mechanism for operating the locking bolt and indexing the cylinder has been described in MACHINERY in the article previously referred to. The increased ruggedness and wearing surface given the lock-

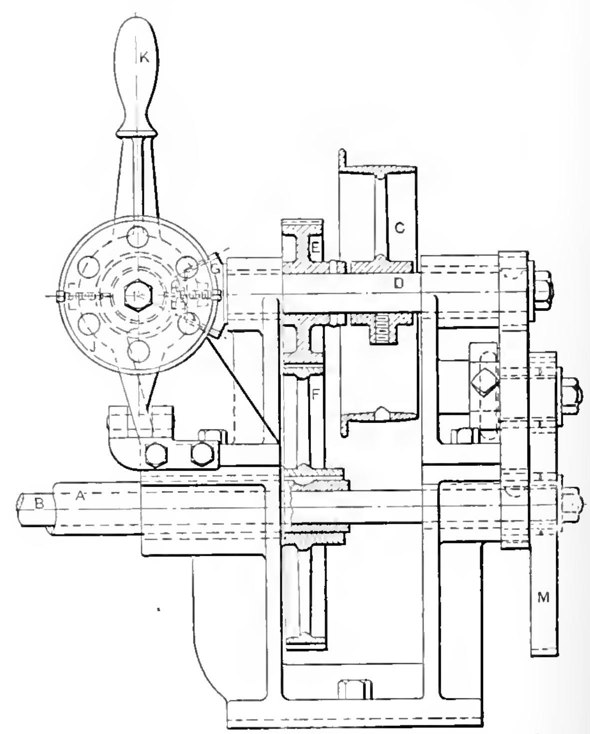

Fig. 2. The Spindle and Cam Shaft Driving Mechanism, Operated by a Single Belt.

ing bolt in this design should result in a lengthening of the effective life of the indexing mechanism.

The pump used in supplying the cutting tools with oil is also gear driven, from large gear *F* on the center sleeve. This does away with the belt drive commonly used on machines of this kind in which the belt often becomes oily and slips,

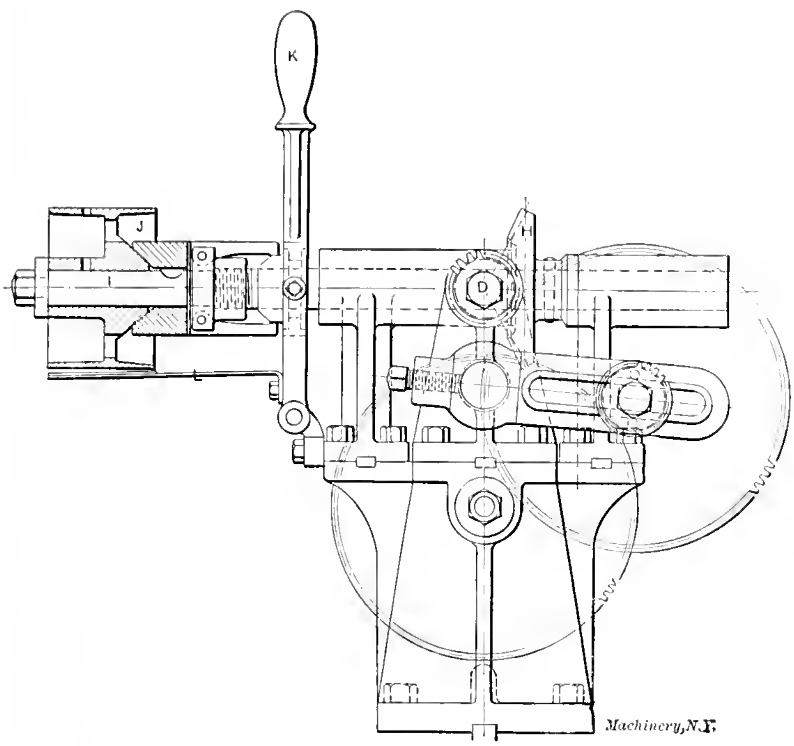

Fig. 3. End View of the Spindle and Cam Shaft Driving Mechanism.

thereby decreasing the flow of oil on the tools, resulting oftentimes in seriously heating and damaging them. Another new featnre of the machine is the design of the positive clutch used for connecting the spindles with either the left-hand turning or the right-hand threading movement. We hope to publish a description of the design of these new clutches in a later issue.

The capacity of the machine shown in Fig. 1, which is the No. 3 size, allows the use of stock up to $1\frac{1}{2}$ inch in diameter. It will turn up to 5 inches in length and will feed stock to 6 inches in length. Two smaller sizes are made.

TAYLOR & FENN AUTOMATIC SCREW SLOTTING MACHINE.

In the automatic screw slotting machine shown in Figs. 1 and 2 and described in the following paragraphs, the builder, the Taylor & Fenn Co., of Hartford, Conn., appears to have succeeded admirably in its attempt to design a simple and effective machine in which the possibilities of error on the part of the operator are reduced to a minimum, while the rate of production is set at the highest attainable pitch. The machine is entirely automatic in its action, and requires no attention beyond the filling of the hopper with blanks, the removal of the finished work, and the occasional sharpening of the saw with which the slotting is done.

The larger pulley at the left of the machine, driven by a constant speed belt, operates the work-holding and feeding movements. This pulley revolves on a stud, and drives a long pinion, which at the front meshes with a gear on a shaft extending beneath the bed of the machine and driving the hopper at the right, through the bevel gears shown. This hopper and the feeding mechanism connected with it, thus operate at constant speed, regardless of the size of the screw, and serve to keep full of blanks the chute leading to the work-holding disk. The principle of the feeding mechanism is the same as that employed on practically all machines of this kind. The slowly revolving hopper is filled with screws. A fork which dips into the hopper is raised from time to time to allow to slide downward into the chute, the screws whose heads have been caught between the adjustable bars which form the sides of the fork. If the chute is already filled, the blanks slide back down the fork when it is again dipped into the hopper. The raising and lowering of the fork is effected by a cam on the bevel gear shaft which drives the hopper. This cam operates a vertical rod passing through the center of the hopper which, in turn, acts on the fork through the radial bars shown. The chute is composed of a second pair of adjustable bars, which catch the heads of the screws and allow them to slide down to an escapement. This escapement, operated by cam mechanism to be described later, permits the blank to fall into position in the work-holding disk, when the proper time comes for grasping it and presenting it to the saw.

A particular feature of this feeding mechanism is the ease with which it may be adjusted for screws of different sizes. There are no parts which have to be removed and replaced for others in making changes, everything being permanently attached to the machine. Changing from one size to another is a matter simply of adjusting the distance between the guiding bars of the fork and the chute to the size of the body of the screw, and adjusting the top bar of the chute and the escapement to the size of the head of the screw.

The work-holding and cutter-feeding movements are operated from a cam shaft at the back of the machine, connected with the large driving pulley at the left by change gearing, so that the rate of operation may be altered to suit the size of work in hand. The mechanism for holding the work and presenting it to the saw will best be understood by comparing the top view of the machine, Fig. 2, with the line drawing, Fig. 3. After being released from the chute, the blank falls into the position shown at *A* in Fig. 3, where it is held between a seat in bushing *B* and spring *C*, which is attached to escapement lever *D*. This escapement lever, which thus both operates the escapement and holds the work in place in bushing *B*, is operated by cam *E* on the cam shaft at the rear

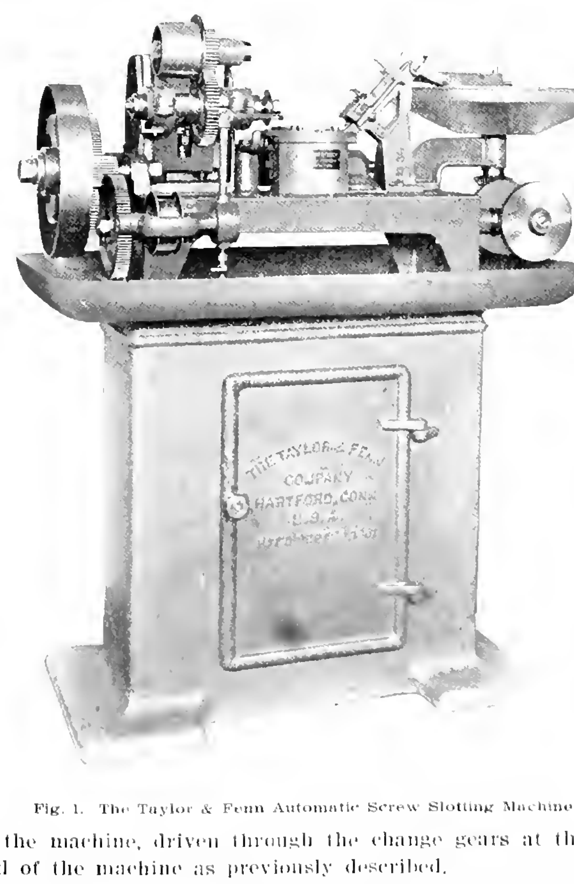

Fig. 1. The Taylor & Fenn Automatic Screw Slotting Machine.

of the machine, driven through the change gears at the left end of the machine as previously described.

At *F* is a vertical shaft extending down through the bed of the machine, driven by the bevel gears shown, from the shaft on which *E* is mounted. This shaft carries a revolving arm *G*,

which strikes locking lever *H*, pivoted at *J*, and raises it from the slot in disk *K*, in which it is seated. All these parts are shown in dotted lines, being located beneath the base of the machine. Continuing its movement, *G* strikes against the teeth of the star wheel *L* as shown, revolving it one-sixth of a turn. When this revolution has been completed, *H* again drops into the slot in *K*, locking the latter. The locking disk *K* and star wheel *L* are keyed to a vertical shaft passing up through the bed of the machine and operating turret or work-

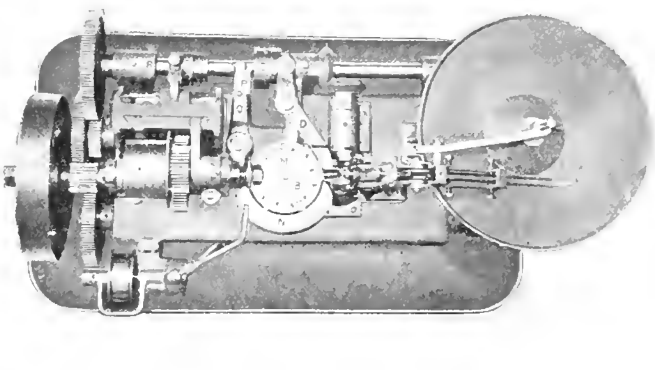

Fig. 2. Plan View of Screw Slotting Machine, showing Work-feeding and holding Mechanism.

holder *M*. As shown in Fig. 2, this work-holder carries six bushings *B*, and in its rotation receives the work from the chute and delivers it to a position directly beneath the slitting saw. The work is held loosely in place in the bushing by guard *N*, which is adjusted in or out to agree with the diameter of the body of the work.

As the work is indexed step by step around to the saw, and finally brought in position beneath it, a cam surface on the face of cam *E* operates lever *O*, whose inner end is thus pressed firmly against the work, clamping it to its seat in the bushing. Cam *E* does not bear directly on the end of the lever

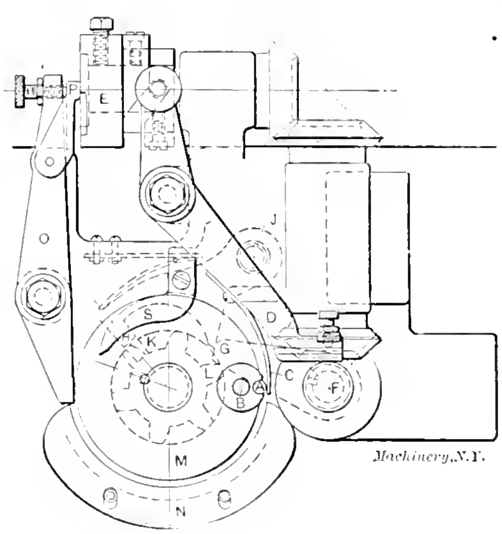

Fig. 3. Partial Plan View, showing Work-holder Indexing Mechanism.

O, but acts through the intermediate lever *P*, which is adjustable by means of the thumb screw shown. It is thus possible to regulate the pressure with which *O* bears on the work, varying the adjustment as the size of the stock varies.

The saw is mounted on a slide, gibbed to the face of a short column, and is driven by the constant speed pulley and gearing shown. It is held normally at the upward extreme of its travel by springs beneath it, seen in Fig. 1. The saw is fed down into the work by cam *Q* (see Fig. 2) acting on lever *R*. This cam operates in such a way as to bring the saw quickly down into contact with the work and feed it rapidly in, slowing the feeding motion gradually as the saw cuts to greater depth and takes a wider cut. As soon as the depth has been reached, the point of lever *R* drops off the cam and the slide flies back. Contact *P* on lever *O* then drops into the relieving space in the face of cam *E*, thus releasing the work from the bushing *B* and allowing it to drop into a chute by which it is carried to a box placed to receive it. Should the work not fall freely from its seat in the bushing, it is, by the continued rotation of the turret, finally ejected by the curved edge of ejector *S*. An oil pump is provided, as seen in Fig. 1, which keeps the saw and the work flooded so that the slotting operation can be performed at the highest possible rate.

It will be noted in Fig. 2 that bushings *B* are provided with a number of seats in their periphery. It is thus possible to provide for holding screws of a number of different sizes without requiring new bushings, as it is only necessary to loosen the screws holding the bushings and revolve them until the proper seat is brought to position to hold the work.

An important feature of the method of holding the work and presenting it to the saw is the fact that inaccuracies in indexing do not affect the centering of the slot in the head of the screw. An inaccuracy in the indexing only takes place in a direction lengthwise of the slot, and not at right angles with the face of the saw.

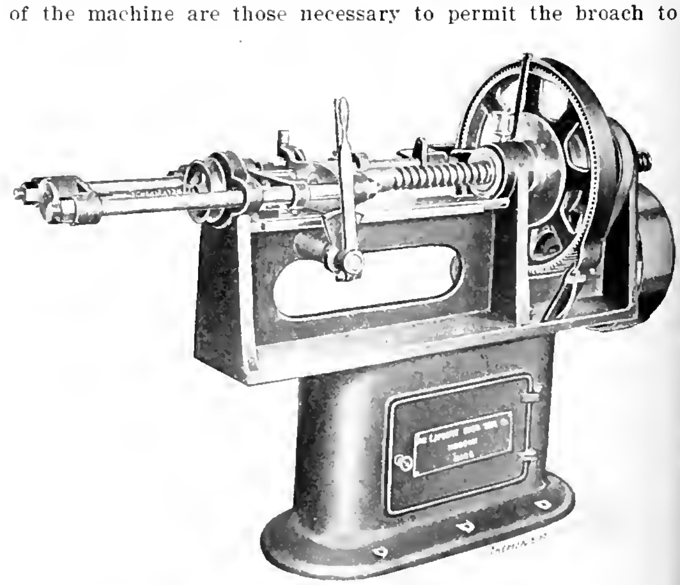
A screw adjustment is provided for shifting the spindle endwise in centering the slot, though this only needs to be done to make allowance for cutters of different thicknesses. The seats in bushings *B* are cut to such depth as to always present the screw in the same position whatever the diameter of the stock.

One of the provisions for making the machine fool-proof is the means furnished for allowing the driving pulley to slip on the hub of the pinion it drives, if any unwonted resistance is met in the mechanism. The pulley is not keyed to the pinion, but drives it by frictional contact, being clamped between collars with a degree of pressure adjusted to suit the requirements.

All gears are guarded, these guards being removed from the machines to show the mechanism better. This prevents the possibility of injury to the operator, as well as danger to the gears themselves from the accidental falling into them of screw blanks or chips. These provisions, together with the adjustability provided in the feeding and holding, should make the machine a thoroughly practical one for the work it is intended to perform.

LAPOINTE SPIRAL BROACHING MACHINE.

In the accompanying engraving is shown an ingenious modification of the well-known broaching machine built by the Lapointe Machine Tool Co., Hudson, Mass., which adapts it to the broaching of spirals, performing this operation in a very simple and effective fashion. The changes made in the design of the machine are those necessary to permit the broach to



Modification of the Lapointe Broaching Machine, adapting it to the Cutting of Spirals.

revolve freely while being forced through the work. The machine here shown should be compared with the standard design, which we have previously illustrated. (See the New Machinery and Tools Department of the July, 1907, issue of MACHINERY.

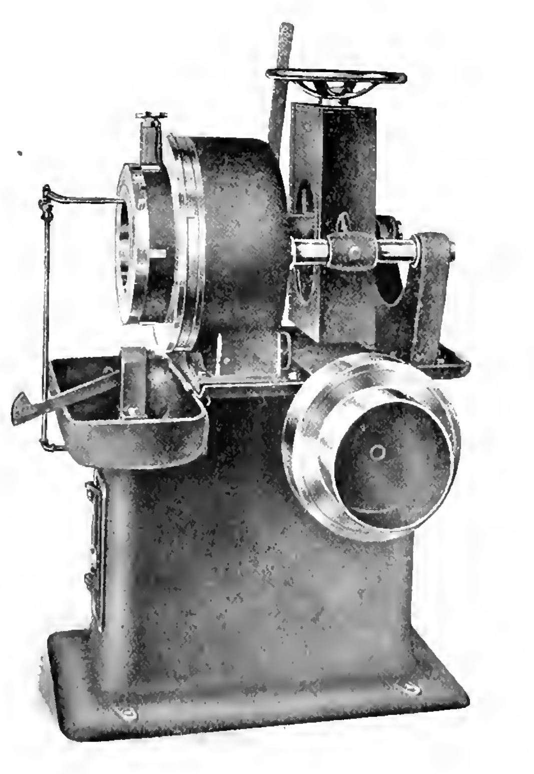
As in the standard machine, the broach is reciprocated by a ram with a screw thread cut in it, engaging a nut which

may be revolved in either direction, so as to drive the ram in or out. The reversal is effected in this machine by the shifting of belts, being controlled by reversing dogs which may be set to limit the stroke in the same way that a planer table is controlled. Instead of fastening the broach in the end of the ram and pulling it through the work, the broach is pushed, by a cross-head out in front of the machine, which is itself pulled by the two sliding rods shown, connecting it with the head of the ram. In this way the ram pulls the cross-head and the cross-head pushes the broach through the work, the latter being mounted on the front face of the bed of the machine in the same way as in the usual design. The broach is not held in a holder, but is supported on a hardened center, which thus allows it to revolve in accordance with the spiral of the grooves which the broach is to cut. The broach is revolved by its own lead, so that no complicated mechanism is necessary for obtaining the pitch of the spiral.

In the work shown, the lead of the spiral is about 6 inches per revolution. A twist considerably more rapid could be obtained if it were necessary, the limit for work of this diameter being about 3 inches lead. The number of grooves or threads makes no difference with the work of the broach. It will be seen that the arrangement is very satisfactory from the standpoint of rapid working, as neither the tools or the work have to be clamped in any way, it being merely necessary to place them in position and start up the machine. When the broach is passed through the work the operator picks it out from the bed, removes the work and inserts a new piece, proceeding as before.

THE LOEW IMPROVED VICTOR PIPE-THREADING MACHINE.

A machine embodying several new features of design which will tend to enhance the value of the pipe-threading machine, has been placed on the market by The Loew Manufacturing Co., of Cleveland, Ohio. This machine is known as the 1908 model of the Loew Victor pipe machine. The most important improvement in the design of the machine is the added strength given to parts subject to stresses, it having been the



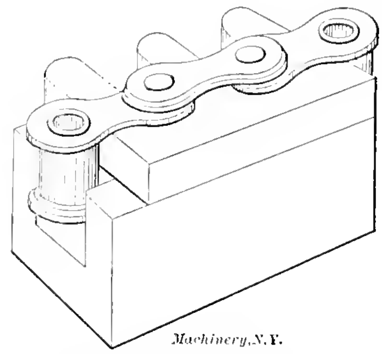
Improved Pipe-threading Machine of Heavy and Rigid Design

manufacturer's object to build a machine sufficiently strong and durable to withstand the same hard service to which all so-called lathe-bed machines are subjected. The increase in size from previous designs is indicated by the fact that the length of the base has been increased 8 inches; the diameter as well as the bearing surface of the head has been increased; a new oil pan has also been added to the machine; and, in all, this design is about 450 pounds heavier than its predecessor.

Outside of these specific improvements, the machine contains all the special features characteristic of the Loew Manufacturing Co.'s machines in general, which may be summarized as follows: The die-head is self-locking, and holds the die absolutely rigid, without the use of wing nuts or other locking devices; the machine is provided with automatic die releasing attachment, opening the dies and removing the burrs from the thread at the same time; there is no gearing on the outside of the machine, a feature of great importance for safety as well as convenience; and a self-locking, adjustable guide is provided which holds the pipe absolutely rigid. The power required to drive the machine fully loaded is about 1 H.P. The design of this machine enables it to do the same class of work as others of the regular lathe-bed type, although it is practically only one-third of the size of that class of pipe-threading machines.

DEVICE FOR HOLDING ROLLER CHAIN WHILE REPLACING LINKS.

During the last few years roller chain drives and link belts have come into use to a very great extent where short belt drives formerly had to be resorted to. The advantages of the chain drives in such cases are well known. The chains will not stretch like the belts, and all the common troubles of belt slip, slack belts, etc., are eliminated. One difficulty with chain drives, however, has been that sometimes a link proves defective or is accidentally injured, so that it is necessary to replace this link. Repair links are always supplied, but it is not always easy with the tools or apparatus at hand to place these links in position. For this purpose the Diamond Chain and Mfg. Co., 240 W. Georgia St., Indianapolis, Ind., has placed the Diamond repair block on the market. With this tool which, as shown in the accompanying engraving, is small enough to be carried in the pocket, it is very easy to repair a riveted chain. The chain is placed in the block as indicated, and by giving both rivet heads in the link to be replaced a light tap with a hammer on a center punch, placed with its point at the center of the rivet, the old link may be detached and a new one put in its place, the chain drive being placed in action within a few minutes. This little tool will be appreciated by anybody who uses roller chain drives in any form.



Diamond Repair Block for Holding Roller Chain while replacing Links.

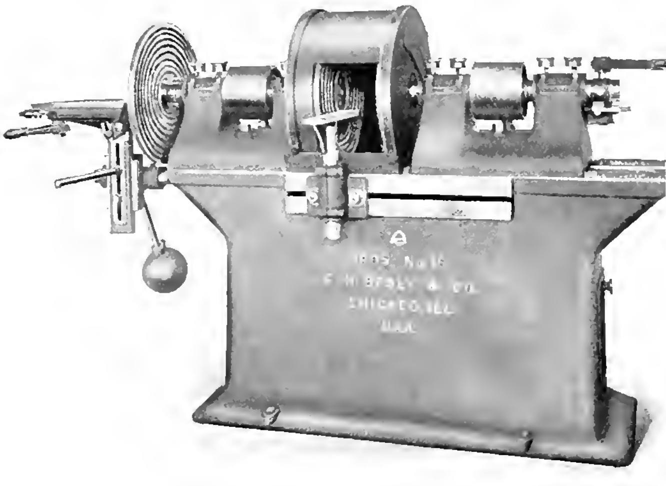
BESLY NO. 6 HEAVY SPIRAL DISK GRINDER.

This machine, built by Chas. H. Besly & Co., 15-17-19-21 So. Clinton St., Chicago, Ill., is a double disk grinder with a third disk for ordinary plain grinding at the left-hand end of the machine. This use of three disks makes the machine available for the full range of work which may be done on the disk grinder, the tool combining the advantages of both the single and double disk types.

The disk at the left-hand end of the machine may be provided with any one of the various styles of tables built by the makers. That shown is a geared lever feed table, which may be used for a large variety of grinding operations. The top is so designed that jigs and fixtures of all descriptions may readily be attached thereto. It may be clamped in a stationary position, or oscillated back and forth across the face of the disk at the will of the operator. For beveled work, it may be tipped to any angle up to 30 degrees from the horizontal position. It has a very powerful feeding mechanism controlled by an easily-operated short lever; a micrometer adjusting screw is provided for grinding to size. The bearing of the table on the shaft is very long and the thrust is

taken by collars which are rigidly clamped to the shaft, and so protected that dust and grit are excluded from the bearing surfaces, insuring long wear and continued rigidity throughout the life of the machine.

A special feature of the double disk portion of the machine is the adjustable dust hood arrangement. This is so constructed that the gap where the work is inserted between the disks, opens and closes automatically, according to the height or width of the work the machine is operating on. The parts of which it is made telescope together. The right-hand end of the hood, being attached to the movable head, is always brought into position by it, narrowing the gap or opening it as this head is moved in toward, or away from the opposite disk. It is also hinged at the back side of the machine, so that it can be instantly thrown back, giving free access to the disks. The dust pocket in the base of the machine is so arranged as to collect naturally practically all of the waste from the grinding operation. An exhaust pipe can be attached to the rear of the base or go up through the floor directly underneath, the latter being a desirable arrangement for some cases. When connected with a suitable exhaust fan, this machine in operation is entirely free from dust. A hood is also provided for the outside wheel on the left-hand end of the machine, though this is not shown in the engraving.



Combined Double Disk and Single Disk Grinder.

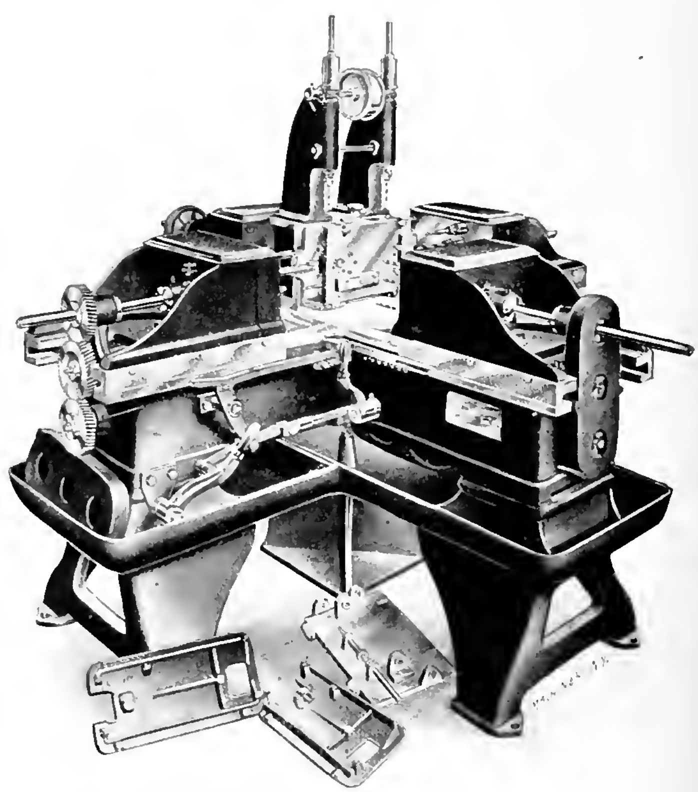
The machine as here shown, is equipped with 20-inch spiral disk wheels 13/16 inch thick. The spindles are driven by 6-inch belts at a speed of about 3,000 feet per minute, thus insuring ample driving power. The bearings are long and well protected from dust and grit. The sliding spindle is moved to and fro by rack and pinion arrangement giving the operator great leverage and making his work easy. An adjustable micrometer stop screw is provided for this movement. On the front of the base is cast a pad having a T-slot through its whole length on which the work rest brackets may be secured. Special fixtures may be fastened to the machine in the same way. The spindles are made of crucible machine steel ground all over, with special attention given to the matter of lubrication. The net weight of this machine with all accessories is 3,600 pounds. This includes work rests of various widths, a setting up press, counter-shaft and an assortment of spiral grinding surfaces. Solid wheel chucks can be furnished with this machine if desired.

NATIONAL AUTOMATIC FIVE-WAY DRILLING MACHINE.

The National Automatic Tool Co., Dayton, Ohio, is the builder of machinery which automatically performs machine shop operations on parts which are made in large quantities. We show herewith an example of its product in the shape of a five-way drilling machine, which, in the case shown, is engaged in drilling a sewing machine bed-plate having 19 holes, 5 of which are counterbored and one of which is 7/8 inch in diameter and 1 inch long. The work is done in forty-five seconds. The tool is universal and can be arranged for any other class of work.

As may be seen in the engraving, the machine is mounted on a cross-shaped bed-plate of great depth in proportion to its length and width, and heavily ribbed on the inside, making it free from appreciable deflection. This is an essential feature where combination drills and counterbores and large drills are used, and where accurate alignment between spindles and jigs is desired. This bed is mounted in an oil pan which keeps the dirt and chips from the floor, and forms a receptacle for the oil or drilling compound used. In the case shown, in which all four sides, as well as the top of the piece are to be operated on, each of the four branches of the bed is provided with a drilling head mounted on a slide, by which it is fed into the work. These drilling heads are each made up for the particular work to which the machine is set, carrying drills of the required sizes, rotated by suitable gears of the proper speeds. The work is held on a bracket in the center of the bed in a jig, to permit the rapid clamping of the work and to guide properly the various drills and counterbores used. Where holes are to be drilled in from the top, as in this case, brackets are also provided for the vertical spindles.

After the work has been clamped in place in the jig, the machine is started and the four heads are fed in toward the work by cams, one for each head. These cams, which are of the cylindrical type, give a rapid forward movement until the drills have reached the work, when they are fed in slowly to the proper depth and quickly returned again. The cam shaft stops at the end of the backward movement, mechanism being provided for this to obviate the possibility of the injury which would result to the workman if the machine should not be shut off, but should again return while he was removing the work. The cams for feeding the heads are mounted inside the four ends of the bed, and control rolls attached to adjustable bars, which may be clamped in any suitable longitudinal position with relation to the slides, thus furnishing means for adjusting the depth to which the drills are set. Power is transmitted from the rear of the machine to the several ways by means of miter gears of liberal proportions and carried to the driving shafts of the drill heads by means of twisted tooth gears and raw-hide idlers. The main driving shafts have their bearings in a sleeve which is rigidly fastened to the bed, and about which the cam drum revolves.



A Machine for Automatically Drilling Five Sides of Work made in Large Quantities.

The removable drill heads are securely fastened and dowelled to the sides. Each is composed of two sections, dowelled together, each section being a receptacle for oil, giving thorough lubrication to the spindles, driving shaft and gears. Each spindle has three bearings and its driving gear

is located between two of them. Where long life and great accuracy of alignment is desired, spindles are made of tool steel hardened, ground and lapped. Ordinarily, however, it is sufficient to have the spindles ground all over, running in bushings of high grade phosphor bronze. All of the spindles are provided with ball thrust bearings with lock nuts at the rear to take up end motion due to wear. Idler studs are hardened and ground and supported at both ends, the gears running in the middle of the studs between two bearings.

Each removable drill box with its spindles carries its own master gear, so that by taking out the spindle driving shaft, the whole drill box may be removed and another one fastened in place for machining a new piece of work. Each spindle carries a chuck made especially for the size of the drill to be used. Morse tapers are used on all the chucks.

These machines are made in two, three and four-way designs, as well as for drilling in five directions, as shown in the engraving. The machines are universal and can be arranged for any class of work within the range of the machine. They are in use at the present time for drilling sewing machine bed-plates, phonograph side frames, gun receivers, etc.

LAPOINTE DOUBLE DRILL PRESS.

In Figs. 1 and 2 is shown a drill of novel design, made by the Lapointe Machine Tool Co., of Hudson, Mass. The novel feature of the machine, as will at once be seen, is the arrangement by which two drill spindles are mounted on the same column—not side by side as in the orthodox double-spindle drill, but on opposite sides of the column, forming two separate machines. The driving and feeding mechanisms of these two drills are so arranged that one of them is a sensitive

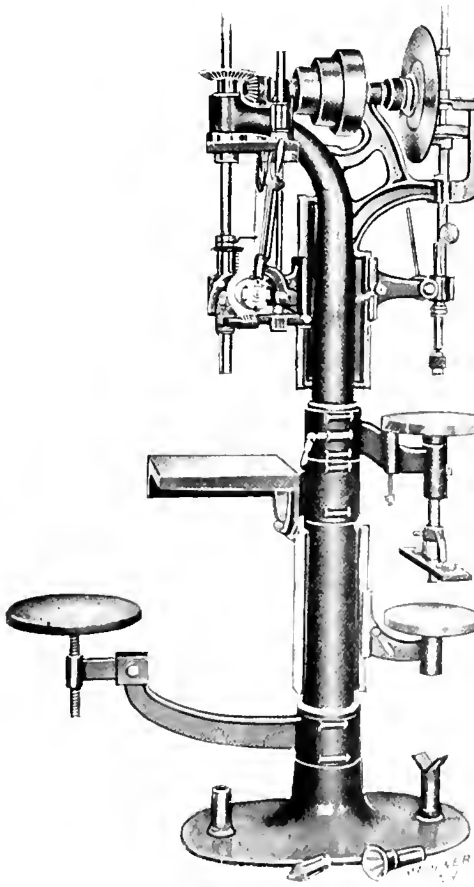


Fig. 1. The Lapointe Double Drill Press

drill, while the other has all the conveniences of the small standard drill press. The full range of the machine provides for drilling holes up to 1 inch in diameter. It will be seen that this machine is a "double drill press" rather than a "double spindle drill press."

The two engravings show opposite sides of the machine. The sensitive drill is on the right of Fig. 1. As may be seen, this drill is of the friction type, in which the changes of speed are obtained by shifting a friction wheel across the face of the driving disk. The spindle is stopped by pushing the driving wheel to the upper limit of its travel, where it enters a recess in the face of the disk; this recess is seen in Fig. 2. The other side of the machine carries a drill spindle driven by bevel gears from the cone pulley shaft. The driving bevel pinion may be thrown out of engagement by the lever shown, so that this spindle, as well as the other one, may be

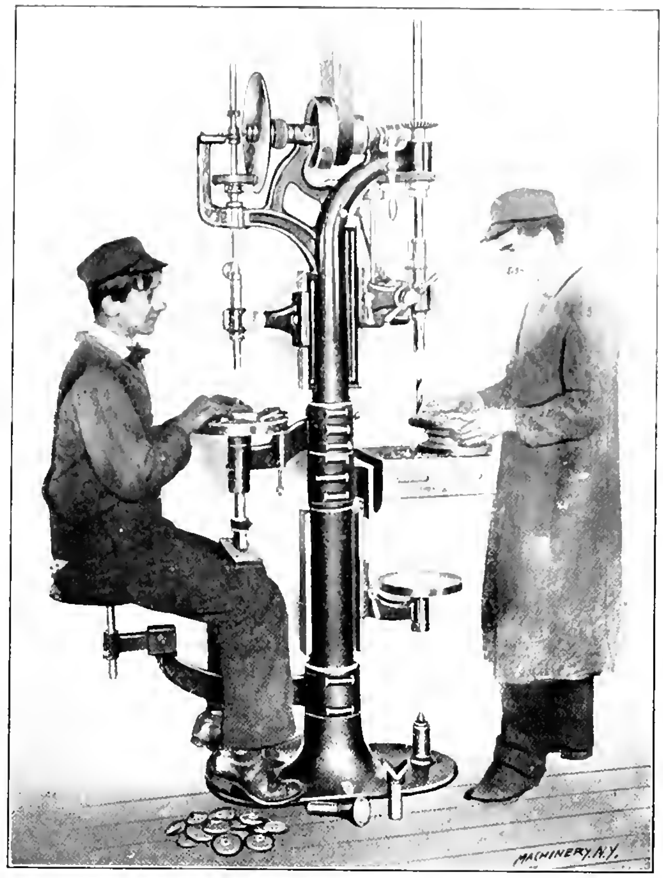

Fig 2. The Drill Press in Action, the Knee Feed being used by Operator on the Left.

stopped independently of the driving shaft. This spindle is carried by a sliding head, and is provided with power feed, a lever feed and a quick return. An automatic stop is also incorporated in the mechanism. This is seen best in Fig. 1.

A variety of work tables is provided. Any one of these may be used with either of the two spindles, so that a great range of work is provided for. At the left of Fig. 1 is shown a rectangular work table, which may be swiveled to any angle about a horizontal axis. It has a narrow clamping surface on its side, as well, for the work which is more conveniently held in such a position. At the left of Fig. 2 the round table is shown in use. This is being fed to the drill, in the case shown, by the knees of the workman, who sits on a stool which is part of the equipment of the machine. This arrangement allows both hands to be used for the insertion and removal of work, and in the case of small pieces and quickly drilled holes thus materially increases the product of the machine. Besides this, a second small round table is provided, on a bracket sliding on ways on either side of the column. The latter table may be removed and a V-block, a pointed center or a cup center used in its place. The latter parts may also be inserted, as shown, in sockets provided for them in the base, when it is desired to center long shafts or do other similar work.

Aside from the compactness obtained by incorporating two machines in one, this design gives the advantage of providing an unusually large combination of work tables and holding devices, permitting work of any kind to be done in the most satisfactory manner. The arrangement of the tables and the spindles is such that the work can be clamped on the sensitive drill side, for instance, and have a hole drilled in this position, and then be swung around to the opposite side to counterbore or drill a larger hole with a heavier drill. This may be done without unclamping the work.

AN AMERICAN MECHANIC IN EUROPE—2.

THE SECOND OF A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

Nuremberg, April 15th, 1908.

During the time which has elapsed since the writer's previous letter, he has met all the prominent machine tool dealers in Berlin, Magdeburg, Leipzig, and Chemnitz, who have freely given their views in regard to the present business conditions in Germany. It may be said, in general, that the machine tool trade has improved somewhat during the last month. All large dealers seen during the last week of February reported business dull throughout the machine tool field, but, with a few exceptions, all the dealers whom the writer has come in contact with during the last two weeks have reported conditions brighter and business better. One dealer in Dresden said that he had done a good business during March.

One difficulty of the American machine tool trade in Germany seems to be that the German user wants to get machines exactly according to his own preconceived ideas, and is not willing to vary these ideas to suit the manufacturer's standard models and designs. This creates a demand for many special designs which the manufacturers here have to meet, and it prevents the German machine tool builders from going far into the specialization of their product. At the same time it is a serious drawback in the selling of American machinery. This condition has been responsible for a new departure in the policy of many German concerns, which originally did not make machine tools, but which now have their own departments for making all the tools they themselves use. This, of course, takes away a large part of the work from the firms specializing in machine tools.

Decentralization of Machine Industries.

Regarding the location of the large machine shops, the same conditions are visible in Berlin as are in evidence in New York, London, and many other large American and European cities. As the population of a city increases, the centrally located portions become crowded and overpopulated, so that the ground rent becomes higher, and with it, as a matter of consequence, the price of land, the cost of living, and the cost of labor prices. Because of this, many industrial concerns, especially the larger ones and those developing most rapidly, have established plants in the suburbs, where land is cheaper, and where ample space is available for present needs and future expansion. The cheaper price of land makes the living expenses for the employes smaller, and they are therefore able and willing to work for smaller wages than they could accept when forced to either live in the city, or to pay railroad fares to and from the factory. At the same time the employes live a more comfortable and pleasant life in the suburbs, in spite of their nominally smaller earnings.

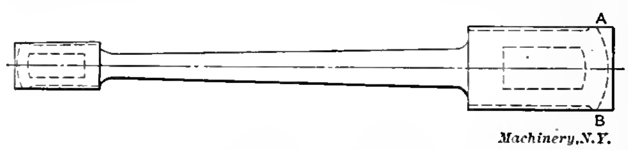
Works of the Firm of A. Borsig.

A direct example of this condition is that of the works of the firm of A. Borsig, Berlin-Tegel. These works were, up to a few years ago, located in Berlin, but as the premises became too crowded, the works were moved to Tegel, a suburb a few miles out from Berlin. This plant has grown so that it now employs about 6,000 men throughout the various departments. In addition to the Tegel plant, this firm has one plant in Oberschlesien, where about 1,200 men are employed. This latter plant consists of a steel mill, with blast furnaces, rolling mills, etc. All the raw materials, cast iron, steel, sheet iron, boiler plate, etc., which are required in the various kinds of manufacture in the Tegel plant are taken directly from the works in Oberschlesien.

The principal product of the Borsig plant is locomotives, but boilers, steam engines, pumps, and refrigerating machinery are also built. Up to a short time ago this firm also built the Oechelhäuser gas engine, but, as there was not enough commercial return to warrant the building of these engines, the firm has discontinued this line of manufacture. The gas engine industry, in general, seems to be waning at the present time in Germany. It is not as lively now as it has been for a few years past. It was interesting to notice the extent to which portable machines were used in the Borsig works. Such machine tools as drills, milling machines, and riveting machines, with the exception of the largest and heaviest ones, are all portable and mounted on wheels, so that they can be easily moved from one place to another, enabling the finishing of large pieces of work without the expense and difficulty of moving large boilers or heavy locomotive frames. The floors are all made of concrete, as this facilitates the movement of the portable machines, and in the concrete floor are embedded a large number of tracks running in different directions for accommodating small trucks. The portable machine tools in this plant are partly electrically, and partly pneumatically, driven, and are equipped with devices by means of which they can be fairly well secured to the floor, so as to enable the tools to work with the greatest possible efficiency.

Interesting Use of the Oxy-hydrogen Blow-pipe.

The use of the oxy-hydrogen blow-pipe method for cutting steel is not fundamentally new to technical men, as this method and various applications of it have been described from time to time in the technical press. The following use of this appliance in the Borsig works, however, is rather novel, and should be of particular interest to the readers of MACHINERY. The accompanying engraving shows the outlines of a connecting-rod. This rod is first forged and the two side surfaces



Connecting-rod from which Surplus Metal is removed by the Oxy-hydrogen Blow-pipe Method.

are planed, after which the connecting-rod has an outline as represented by the full lines. Now lines are scribed on the connecting-rod as shown by the dotted lines, and a heavy punch-mark line is made a trifle outside of the scribed lines. This line is followed by the blow-pipe gas jet, and a slot about 1/8 inch wide is thereby cut through the rod, leaving for finishing about 1/16 to 1/8 inch. All the surplus material is removed in this manner, and the surface left from the cut is fairly smooth and true. For locomotive connecting-rods of medium size, the time required for cutting the length shown at AB is about 2 to 3 minutes. The apparatus for applying the gas flame to the work consists of a plain nozzle connected to a flexible pipe, with the apparatus mounted on two small wheels, which makes it easy for the operator to apply the jet exactly where wanted, and to get the cut square with the planed surface. The edges of the connecting-rod are afterwards finished by milling.

Use of Magnetic Chucks.

Prominent German machine builders make extensive use of magnetic chucks. The writer saw in particular a large number in use in the shops of Ludwig Loewe & Co., Berlin. For small work particularly, when quick clamping is of importance and comparatively small power is required to hold a piece of work in position during the operation performed on it, the magnetic chucks have there found a wide field of usefulness. On machine tools there are many small parts like washers, sliding pieces, etc., having flat surfaces, which, for the sake of accuracy and smooth finish are required to be finished by grinding. To clamp such pieces in ordinary chucks is usually difficult and slow; in such cases the magnetic chucks are always used. As is well-known, when finish-grinding but very little power is required to hold the piece of work in place, and the magnetic chuck does not need to have a very high holding power, so that a piece of work may even be removed by hand without disconnecting the current. The current is taken from ordinary lamp sockets.

German Foundry Practice for High Grade Castings.

The casting of cylinders for automobiles is considered to be one of the most difficult problems that the foundry man has to deal with. The casting must be of the very best material, and, as far as possible, be free from blow-holes and other defects, because of the high temperature and pressures on automobile cylinders. A prominent German firm, which makes a specialty of casting automobile cylinders and is considered as turning out a very high grade article, places spe-

cial emphasis on the importance of the design and the making of the cores for obtaining good and sound cylinder castings. As these cores are very small, the problem of making them is a rather difficult one. The sand used for making the cores is of a rather coarse grain, and for binding purposes dextrin is employed. This produces a very strong and hard core. For making the vent holes in these small cores a tallow-coated thread is put in the center (or wherever wanted). When the core is heated for the purpose of drying, the tallow melts, and the thread can be pulled out, leaving behind it a very small vent hole. The gases produced when pouring the metal have an easy access to the vent hole, due to the coarseness of the sand, and pass through the vent hole out into the atmosphere. Resistances for electric apparatus which are only about 3/32 inch thick are cast by using cores made on similar lines.

General Observations on the Machine Tool Industry in Berlin.

The leading machine tool building concerns in Berlin are the firm of Ludwig Loewe & Co., and the Deutsche Niles Werkzeugmaschinen-Fabrik, Oberschoeneweide, near Berlin. In order to avoid undue and unnecessary competition, these two concerns are working under a trade agreement, so that the former one is specializing on small tools and machine tools of small and ordinary sizes, and the latter concern is devoting itself to large heavy machine tools. A short time ago the Deutsche Niles Werkzeugmaschinen-Fabrik built a giant planer, which in size and working capacity is claimed to have been superior to the one recently built by the Bement-Miles Works in Philadelphia. This large German planer was built for a German turbine building concern. [The Bement-Miles planer was described in the January, 1908, issue of MACHINERY.—EDITOR.]

In addition to the two large concerns mentioned, there are in Berlin a great number of smaller ones, employing all the way from 25 to 150 men. A few of these have already followed the American practice of specializing on certain types and kinds of machine tools, but the large majority of them are building any one particular machine which they think will sell best at the moment, be it shaper, lathe, gear-cutting machine, or any other kind of machine tool. Although these concerns are not, according to American ideas, strictly up to date, they are still filling a certain want. They make the cheap grade of machinery required by many small manufacturers, who cannot afford to pay the price of, or do not need, a strictly first class type of machine tool. These small firms seem to be reasonably prosperous.

The Machine Industry in Magdeburg and Dresden.

A concern which is well-known for good workmanship, and for the high efficiency of its products, not only in Germany, but all over Europe, is the firm of R. Wolf, of Magdeburg-Buckau. This firm originally built only portable steam engines, but having had great success in this business, the building of larger stationary steam engines of the same type as the portable engines was also taken up. It may be mentioned in this connection that in Europe stationary steam engines are often used which are built entirely along the lines of the type of engines known as portable in the United States, though they are installed for stationary use in manufacturing establishments. These larger stationary engines of the portable type are now built in units up to 600 H. P.

Through the introduction of an improved design of superheated steam, compound, condensing, portable engine, a point of efficiency has been reached, which, as a rule, is attainable only in units of very large size. A 50 H.P. engine, recently built, consumed during the test run only 1.12 pound of coal per H.P. hour, and in a 100 H.P. engine of this design the firm has brought down the consumption to one pound of coal per H.P. hour. [This is as low a coal consumption as is attained by triple or quadruple expansion condensing engines on large ocean-going steamers.—EDITOR.] The old shops of this firm in Buckau have proved too small for the amount of business done at the present time, and a large new plant is being built some distance out from the city. This new plant, which will be of the most modern construction, is to be used for the building of large stationary engines of the portable type, while the old plant will be used for building small sizes exclusively. The new shops are located alongside the railroad, and are arranged so that all the raw materials, castings, etc., will enter the shop at the end farthest away from the railroad, and the finished engines will be assembled, tested, and made ready for shipment, at the end nearest the railroad, where they can conveniently be loaded directly on the railroad cars.

The machine tool industry in Magdeburg and Dresden is largely represented by a few small concerns belonging to the same class as the small concerns in Berlin, previously mentioned. The Dresdner Bohrmaschinenfabrik, Dresden, however, is an exception to this rule. This concern employs about 300 men, and makes a specialty of drill presses and chucks, and the specialization of these tools has been carried to a high degree of perfection. The unit principle of design has, in particular, been highly developed in their machines. The units are manufactured independently of the completed machines, for which they are intended, and are often made in lots of 100 at a time, and kept in stock until needed for assembling purposes. The same detail units are often used for several different types of machines, a feature which is highly important in bringing down the labor cost in specialized manufacture.

Chemnitz—a Center of Machine Tool Industry.

During the last few decades Chemnitz has succeeded in establishing itself as one of the largest and most important centers of the machine industry in Germany, and this in spite of its location far from navigable rivers, and its lack of water power. At the present time, Chemnitz, according to the United States Consul in that city, exports more machinery to the United States than any other German city, Berlin not excepted.

Nearly all branches of machine industry are here represented. One of the largest locomotive works in the world, the Sächsischen Maschinenfabrik, is located here, and is, as regards size, the leading concern. In addition to a large locomotive department, this firm has departments for steam engines, boilers, steam turbines, and machine tools, principally those of heavy design. One branch of the machine industry that has largely helped to give Chemnitz a well-known name is machinery for various uses in the textile industry, most particularly knitting machinery. These machines require a high degree of precision work, and their manufacture necessitates the designing and using of many special machine tools. This fact has forced, or, at least, greatly encouraged, some concerns originally only making textile machinery to add a department for the manufacture of machine tools. An example of this is the firm of Schubert & Salzer. The machine tools obtainable in the market could not entirely satisfy their needs, and therefore they were forced to make all special tools themselves. Having once started in this line of business, when the demand for high grade machine tools increased, they extended this department, and commenced to make machine tools for the market.

The manufacturing of machine tools occupies now one of the foremost places in the Chemnitz machine industry. Here are located concerns engaged solely in machine tool manufacture, employing up to 2,000 men, making strictly first-class machinery, and there are also a large number of concerns with from 25 to 50 men, many of whom make only cheap grades of machines. All kinds and sizes of machine tools are being built here, from the large and heavy machines built by the Sächsischen Maschinenfabrik down to the very smallest machines for fine precision work.

The Reinecker Works in Chemnitz.

The firm of J. E. Reinecker is one of the leading concerns for the manufacture of high grade machine tools of all types. This firm has also a large department for small tools. It was founded by J. E. Reinecker in 1859, and was, at first, only a very small concern, devoting itself to the making of machine tools. The development of the firm has been rapid, and 2,000 men are now employed in the shops. Although this firm builds all kinds of machine tools, the specialties given most attention are the most commonly used sizes of plain and universal milling machines; milling machines of the planer type; heavy duty relieving lathes, grinding machines—especially tool grinders; and gear-cutting machinery.

The department for gear-cutting machinery is highly developed and would deserve more than incidental mention. A large variety of machines are manufactured for cutting bevel gears, spur gears, worms, worm-gears, and racks. The Bilgram bevel gear planer is manufactured by the Reinecker firm for the European market, and its excellent design and workmanship has gained for it a high reputation and a large number of users. Careful methods of selling, and of placing the machines in the customers' shops, must also be given some credit for the success. In most cases, a competent man is sent with the machine sold to teach the buyer to use the machine to best advantage, to the great satisfaction of the customers. A great deal of the success of this department is due to the energy of, and the work done by, Mr. August Hoffman, an American, who introduced the Bilgram bevel gear planer in Europe, and who is in charge of the gear-cutting machinery department of the Reinecker firm.

Schubert & Salzer and other Chemnitz Machine Tool Builders.

The firm of Schubert & Salzer, as previously mentioned, originally specialized in building textile machinery, but they now, in addition to these, make also cash registers and machine tools. It has also already been referred to that, by the force of circumstances, this firm was carried into the manufacture of machine tools. It should, however, also be mentioned that, according to their own statement, one reason for this was that they found the American machines which were formerly largely employed in their shops, with a few good exceptions, too weak for their material and kind of work. This was one of the causes that forced them to make ordinary machine tools. They are now, in addition to making all their own special machines, devoting themselves to milling machines, drill presses, and planers which are designed to have a number of cutting tools working simultaneously—in some cases, as many as six. The Wanderer Fahrradwerke began the manufacture of machine tools for reasons similar to those mentioned in the previous case. This firm originally engaged solely in the bicycle industry, but later added a department for typewriting machines and machine tools, and is now carrying on all these three lines of manufacture. In addition to making the machine tools for their own special purposes, they have specialized in milling machines and gear-cutting machinery.

As mentioned about small Berlin firms, there are also in Chemnitz a large number of small concerns which have not specialized on any particular kinds of machine tools, but are making any kind required. A small concern which constitutes a remarkable exception to this rule is the firm of Messdorf & Mehnert. This firm employs about 150 men. Up to a few years ago all kinds of machine tools were built, and not less than four different designs of gear-cutting machines were manufactured; now, however, nothing but certain types of milling machines are built.

Secrecy in the Trades.

The German machine manufacturing concerns have gained the reputation of keeping what they choose to call "trade secrets" with a jealous zeal, and they are claimed to object to any visitors in their shops, because of fear that these would carry away with them some valuable suggestions or new designs of special tools, or whatever it may be that they call trade secrets. Whether this reputation be justified or not is perhaps difficult to say. The writer's experience regarding this has been that large well-known concerns, well equipped with new modern machine tools and employing up to date methods, and making and turning out a first class product, are the ones who least object to visitors in their shops, but the old, conservative concerns with ancient tools and methods do not "for their life" allow anybody to visit the shops under any conditions. In many cases the writer has succeeded in learning something about the concerns which, from principle, never allow any visitors, and he has seen some of their machines either in the stock rooms of machinery dealers, or in other shops, and he has found indications of the truth of the above statement. On one occasion the writer was refused permission to visit the shops of a certain concern because, as they said, they had so many special things which they did not want anybody to see. The same day he had occasion to meet a gentleman who was well acquainted with the shops referred to. Upon hearing of their refusal to allow him to visit the shops, he said: "You did not miss much, but you saved your clothes from being spoiled by dirty oil, dripping down from the counter-shafts and hangers."

Criticisms of American Machine Tools.

In my previous letter I mentioned that American machines and tools were too weak for the German demand. A dealer who handles both American and German machinery to about the same extent, and who, therefore, can be considered as impartial on the subject, gave a few statements as to which parts usually suffer from lack of strength, and which are not made by manufacturers according to the requirements of German buyers.

The American plain face-plate is not accepted in Germany. German dealers, in order to sell American machines, many times at their own expense substitute German chucks for the plain face-plates on American lathes.

Tool-posts on lathes are often made too weak. Heavier turning tools are used in Germany, and sometimes the American tool-posts are not large enough to take these tools.

The speed boxes on the drill presses and on milling machines are not made strong enough, and, besides, the German buyer objects to cast iron running with cast iron in gearing. He prefers to have cast iron gears meshing with steel gears.

As a personal opinion, the dealer from whom the writer obtained this specific information, expressed the idea that if the American manufacturers would simply meet these requirements of the German buyers, the American foreign trade in machine tools would be greatly benefited thereby, and would gain considerably more ground in Germany.

* * *

EXPOSITION OF SAFETY DEVICES.

The American Institute of Safety Devices and Industrial Hygiene, a sub-organization of the American Institute of Social Service, has opened an exposition of safety devices on the fifth floor of the new building of the McGraw Publishing Co., 231 W. 39th St., New York City. The exposition was opened on April 13, and will remain open until June 1. It is free to the public, and open from 10 A. M. to 6 P. M., except Sundays. The exposition embraces all kinds of safety devices employed in manufacturing, mining, transportation, and in electrical and chemical industries. Some of the exhibits are of special interest to machine tool builders, in particular some selections of large photographs from the Brown & Sharpe Mfg. Co., and from the various plants of the Niles-Bement-Pond Co., showing installations for safeguarding the workmen in these establishments, as well as machines built by these companies, provided with proper guards over gearing, emery wheels, etc. There are very few actual exhibits as yet of safety devices pertaining directly to the machine tool trade. A number of photographs are shown, giving interior views of the prominent museums for safety devices in Paris, Berlin, Munich and Vienna, as well as photographs of safety devices employed in the industries in Europe.

Some of the exhibits appear to be more of an advertising nature than embodying actual safety devices, and as long as the space permits the exhibits of objects of this kind there can be no objection to their presence, but in case the interest shown by our manufacturers in this exhibit should be large enough so that the space allowed became limited, it might be suggested that exhibits which appear to be of a commercial nature, rather than embodying an interest in the safety of American life and labor, should be carefully scrutinized. The aim which the Institute of Social Service has in view is to increase the realization among our American people of the terrible tribute paid annually in our industries in the form of loss of life and limb of our workers, and to arouse a public spirit which will demand that proper safeguards be placed around the industrial worker, so that his risks may be lessened as much as possible. Most of the 500,000 industrial accidents, which annually occur in the United States alone, could be prevented without great expense, simply if the general public became fully aware of, and interested in, the possibilities of safety appliances in various forms.

MISCELLANEOUS FOREIGN NOTES.

Italian Imports of Machinery.—Figures published by *La Métallurgie* indicate that in 1905 the imports of machinery into Italy from Germany had a value of about $12,000,000. The value of the machinery imported from Great Britain had a value of about $7,000,000, and from France, $1,300,000. The value of the imports of machinery from the United States is not mentioned in the table published by the journal referred to.

Machine Tools in Turkey.—The increase of railways in Turkey and its possessions, and the general impetus given to trades in general, has caused a demand for machine tools. The conditions of the country, however, are peculiar, and, at present, the greatest demand is for small machines driven by foot power, but the increase in the use of machine tools has also increased the need and demand for motors of various kinds, and it is likely that machine tools of ordinary descriptions will soon find a market in the country.

German Imports and Exports.—The figures for the imports and exports of Germany during the first month of the year indicate that its foreign trade was depressed, and that business conditions were not satisfactory. The imports dropped from 4,194,000 tons for January, 1907, to 3,644,000 tons for the same month, 1908. The exports dropped from 3,264,000 tons to 3,168,000 tons. In January, 1906, the imports and exports were 4,578,000 tons and 3,611,000 tons, respectively, so that there has been a steady decline in foreign trade for the last two years.

Demand for American Agricultural Machinery in Sweden.—According to *Engineering*, the Swedish government lately sent a special agent to the United States and Canada for the purpose of examining and studying such agricultural implements and machinery, used in these countries, as might be suitable for the conditions in Sweden. A report has been forwarded to the government, in which it is proposed that the state should appropriate a certain sum for the purchase and thorough testing, under proper supervision, of such implements.

Machinery Business in Germany.—The past year appears to have been exceptionally profitable to the German machine builders. The Gritzner Machine Co. reports a profit of 888,500 marks ($215,000)—a considerable increase over the previous year—and is paying 15 per cent dividends. The Wülfel Iron Works, Hanover, are paying 10 per cent. The East German Machinery Company, Heiligenbeil, is paying 9 per cent, and most firms show considerably higher profits for the past year than for the year previous. However, recent reports indicate a falling off in the trade, even if this falling off is not serious enough to cause any anxiety on the part of German machine builders.

Chinese Exposition.—Consul-General W. Roderick Dorsey reports that it is proposed to hold an exhibition in Shanghai during 1909, under the name of The Shanghai International Exhibition. This exposition will be confined to staple manufactures and machinery. The project is as yet, not fully worked out, and it is impossible at the present time to secure any particulars as to the space available for different exhibits, or the terms on which space may be rented. Seventy acres of land, however, have been secured in a suitable location. American manufacturers and exporters interested may secure further information as soon as available by addressing Mr. L. E. Canning, Secretary China Association, 6 Peking Road, Shanghai, China.

German Trade Conditions and the Tactics of the German Steel Trust.— It is understood that the manner in which the German steel trust treats its customers has caused considerable opposition. The steel trust is said to control 95 per cent of the iron and steel output of Germany, and consequently dealers and buyers are completely at the mercy of the combination. The trust leaves to each dealer only a very limited territory, and insists upon being supplied with the names of the buyers, the prices, and all particulars concerning the sale. The dealers are therefore somewhat apprehensive of the fact that this might mean that the trust will finally do its business directly. This, of course, would not impose any hardship on the German industries as such, for direct dealing is as a rule always preferable to dealings through intermediate agents, but the manner in which the trust goes about to accomplish its purpose seems rather arbitrary. It is also complained that the trust charges higher prices in such parts of Germany where it is difficult for foreign steel to compete on account of the longer shipping distance by rail. It is stated, however, that the steel industry itself is not in as prosperous a state at the present time as before the renewal of the syndicate. Thousands of employes have recently been dismissed by works belonging to the trust. Krupp's works alone have reduced their force by about 3,000 men. The German motor car industry, which held its own rather longer than that of France and the United States at the time when the inevitable reaction came, also commences to show signs of depression.

* * *

A novel feature of the coming Master Mechanics' Convention at Atlantic City will be the exhibit of the Committee on the Apprenticeship System. It is expected that all the railroads operating apprentice schools will send models, drawings and photographs to show in a comprehensive manner the rapid advancement which is being made in this phase of railroad activity. The Central Railroad of New Jersey, the Grand Trunk, the New York Central Lines, and the Santa Fe have already arranged to exhibit.

SPRING MEETING OF THE A. S. M. E.

The semi-annual meeting of the American Society of Mechanical Engineers will be held in Detroit, Mich., June 23-26. Among the papers to be presented at this session are: "A Method of Cleaning Gas Conduits," by W. D. Mount; "A Method of Checking Conical Pistons for Stress," by Prof. George H. Shepard; "Clutches," with special reference to automobile clutches, by H. Souther; "Horse-Power, Friction Losses, and Efficiencies of Gas and Oil Engines," by Prof. L. S. Marks; "Some Pitot Tube Studies," by Prof. W. D. Gregory; "The Thermal Properties of Superheated Steam," by Prof. R. C. H. Heck; "A Journal Friction Measuring Machine," by Henry Hess; "A By-Product Coke Oven," by W. H. Blauvelt; "Tests of Some High Speed Steam Engines," by F. W. Dean. There will be a symposium upon machinery for conveying materials, with papers by several authorities. The Society for the Promotion of Engineering Education and the Society of Automobile Engineers will also hold their annual meeting in Detroit at this time, which will enable members of each society to participate in the sessions of the other.

* * *

THE MACHINERY CLUB.

The new quarters for this club in the Hudson Terminal Building are nearly completed, and it is expected will be ready for occupancy soon after May 15th. The intention is to open the rooms with a formal reception which will be held about May 20th. The total membership to date is nearly nine hundred. The officers of the club are as follows:

Officers—F. H. Stillman, president; R. C. McKinney, vice-president; Walter L. Pierce, treasurer; W. Seton Henry, Acting Secretary.

Governors—O. C. Gayley, Pressed Steel Car Co.; George A. Post, Standard Coupler Co.; Walter L. Pierce, Lidgerwood Mfg. Co.; F. H. Stillman, Watson-Stillman Co.; C. A. Moore, Manning, Maxwell & Moore; H. L. Shippy, John A. Roebling's Sons Co.; T. N. Motley, T. N. Motley & Co.; Henry Prentiss, Prentiss Tool & Supply Co.; H. B. Kirkland, National Metal Molding Co.; W. P. Pressinger, Chicago Pneumatic Tool Co.; A. B. See, A. B. See Electric Elevator Co.; W. H. Marshall, American Locomotive Co.; R. C. McKinney, Niles-Bement-Pond Co.; E. H. Wells, Babcock & Wilcox Co.; W. L. Saunders, Ingersoll-Rand Co.; Otis H. Cutler, American Brake Shoe & Foundry Co.; J. R. Vandyck, Vandyck, Churchill Co.; Kenyon B. Conger, Hudson Companies; Wm. B. Albright, Sherwin-Williams Co.; Chas. A. Schieren, Jr., Chas. A. Schieren & Co.

Executive Committee—F. H. Stillman, Chairman; R. C. McKinney, Walter L. Pierce, Geo. A. Post, Henry Prentiss.

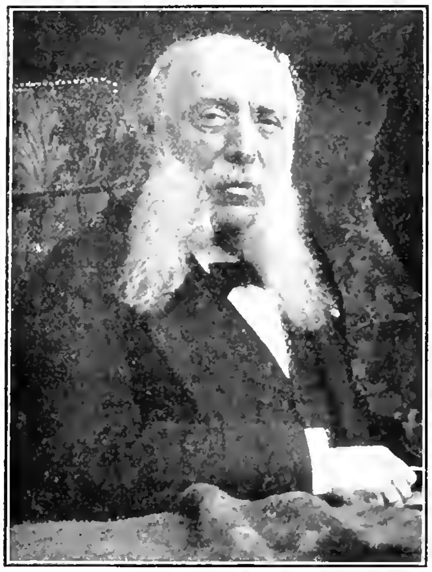
House Committee—T. N. Motley, Chairman; Chas. A. Schieren, Jr., Percy A. Ware, Geo. Howells, Edward H. Benners.

Membership Committee—J. R. Vandyck, Chairman; Geo. L. Gillon, Chas. B. Crook.

* * *

A WELL-KNOWN DUTCH TRADING HOUSE, AND ITS HEAD.

One of the largest trading houses in Europe, and one that is of considerable importance to American machine tool builders is that of R. S. Stockvis & Sons, Rotterdam, Amsterdam, Brussels, and Java. This great house was founded by R. S. Stockvis in 1844, and three generations of the family have contributed their energies to putting it in its present high position. The main warehouse and the offices of the company are in Rotterdam, where they have a long frontage on one of the principal canals, the Leuvehaven. They cover a superficial area of 776,000 square feet, and most of the buildings are five or six stories in height. The stock on hand has a mean value of never less than $1,250,000. It consists mainly of machine tools and lighter articles of hardware merchandise. Although the machine tool business is one of the recent activities of the concern, it is already one of the most important. The concern as a whole is highly organized, and a long article could be written about its various departments, systems and connections extending throughout the whole civilized world.



S. R. Stockvis.

The accompanying half-tone illustration shows Mr. S. R. Stockvis, director and chairman. Mr. Stockvis is the son of the head, R. S. Stockvis, the founder of the house. Although Mr. Stockvis celebrated his eightieth birthday a few months ago, he still takes the most active interest in the management of the concern's affairs. Associated with him as directors are his two sons Felix and Hugo, and his three nephews, Charles, Louis and Theodor The whole capital of the company is held by the six directors, and the concern, therefore, is a close corporation, its stock never being on the market.

CONSERVATION OF NATURAL RESOURCES—APRIL MEETING OF THE A. S. M. E.

A meeting of the engineering profession was held in the auditorium of the Engineering Societies building on the evening of April 14, to consider the conservation of our natural resources. The meeting was held under the auspices of the American Society of Mechanical Engineers. It was presided over by Mr. J. W. Lieb, Jr., vice-president of the society, who opened the meeting. Addresses were made by Dr. W. J. McGee, Chief of the Bureau of Soils, Washington, D. C., who spoke on the "Conservation of the Water and Woods," calling attention to the danger of stripping the country of its forests. Dr. W. F. M. Goss, dean of the College of Engineering, University of Illinois, spoke on the "Conservation of the Nation's Fuel Supply," and mentioned that the process of conservation could not successfully begin with coercion; it must begin with education. Prof. G. F. Swain, of the Massachusetts Institute of Technology, Boston, spoke on the subject of "Stream Flow, Water Power, and Navigation," thereby also bringing in the subject of preservation of the forests. This subject is highly important to all industries, as the devastation of the forests threatens some of our greatest natural resources—not the lumber resources alone; to conserve the forests means to save the water power, to prevent the erosion of the soil, and the silting of navigable rivers and harbors. The American Society of Mechanical Engineers is to be commended for the interest it has taken in this matter, and all engineers and manufacturers should realize that this subject is of more vital importance to them and to the future of the industries of the whole country than may be appreciated at first sight. The concluding address at the meeting was made by Dr. H. S. Pritchett, president of the Carnegie Foundation, who spoke of the attitude of the engineer toward the public, calling attention to the fact that engineering has become a profession which must consider not only the serving loyally of employers, but also the public interests.

* * *

AN APRIL FOOL JOKE IN A TECHNICAL JOURNAL.

The front page of a recent issue of a contemporary, whose name we forbear to mention, is decorated with a large cut of a new diving apparatus by the use of which it is expected that men will be able to work at depths of 100 feet or more without difficulty. This apparatus consists of a water-tight operating chamber, suspended from a barge and connected with it by a flexible, collapsible tube, strengthened by steel ribs to resist the pressure of the water. This tube and operating chamber are left in full communication with the open air so that the diver works under normal conditions and under atmospheric pressure. He does his work by inserting his hands in long sleeves and mittens, which project from domes in the side of the operating chamber. Lenses of strong glass are provided on all sides so that he can see clearly what he is doing.

We wonder if it occurred to the inventor of the device or to the editor of the paper in which it is illustrated that this long sleeve and mitten would be a most unhandy thing to operate. The "arm-hole" by which the sleeve is fastened to the chamber appears to have an area of at least 150 square inches. At a depth of 100 feet or thereabout the pressure on this opening would be more than 40 pounds to the square inch, or over three tons in all. This would naturally mean that the mitten and its sleeve would be blown inward with this pressure, being turned inside out, projecting into the operating chamber. We would defy the strongest "strong man" that ever drew a salary from a circus company to turn the mitten right side out again and use it in doing any useful work in the water outside.

Another interesting feature of the apparatus is that the barge from which this tube is suspended is provided with hoisting apparatus for lifting the chamber to the surface when the work undertaken has been completed. We would humbly make the suggestion that a mechanism for pushing it into the water would be more appropriate than that described for pulling it out. Would it not require a mechanism unusually powerful to force this chamber to a depth of 100 feet against the upward pressure of the water? The proper thing to do would be to fasten a block and tackle to the solid ground at the bottom, and *pull* it down. If by chance this block and tackle broke, we surmise that the chamber would be blown up through the bottom of the barge with results disastrous to everyone on board.

However, since the description of this apparatus appeared in that issue of the journal referred to nearest April 1st, it is in all probability merely a joke appropriate to the season, and the editor is doubtless enjoying a quiet laugh over the perplexity of his subscribers.

PRACTICAL IDEAS FROM AN ADVERTISING MANAGER.

The Chicago Trade Press Association and the Space Club of that city held a joint meeting on April 6th, at which Mr. C. S. Redfield, advertising manager of the Yale & Towne Mfg. Co. of New York, and Mr. J. J. Rockwell of the National Fireproofing Co. furnished the practical ideas from the standpoints of both the advertiser and the publisher.

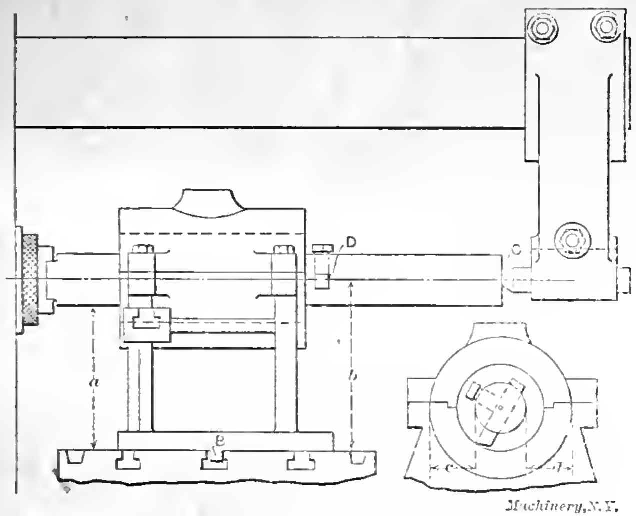
The subject matter of the addresses was naturally more interesting to people in the advertising business than to techni-

Supplement to MACHINERY, June, 1908.

Operations for the Article in this number entitled "Machine Shop Practice—Machining a Fixture Casting."

SHOP OPERATION SHEET NO. 64.

H. A. S. Howarth. MACHINERY, June, 1908.



To Set Up and Bore a Fixture Bearing in a Milling Machine.

1. Set up the fixture on the milling machine table with the tongue B against one side of a T-slot, and clamp the fixture in place. Put the boring-bar in the spindle.

2. Be sure that the center C lines up with the end center of the bar. While it is free, test the end of the bar by revolving the spindle slowly, using an indicator to detect any error. If the bar runs true, the center C must be set so that as it enters the center of the bar it does not spring it.

3. Set the table vertically so that the height a of the under side of the bar above the table, added to half the diameter of the bar, will equal the distance b from the center of the bearing of the fixture to its base.

4. Set the bar central with the bosses on the ends of the bearing, making the distances c and d equal. Clamp the knee and table, leaving the cross feed free.

NOTE.—The power cross feed of the machine should be greater, by at least two inches, than the length of the bearing to be bored. The boring tool D must be so located that it will pass clear through the bearing and extend far enough out at either end to be adjusted readily.

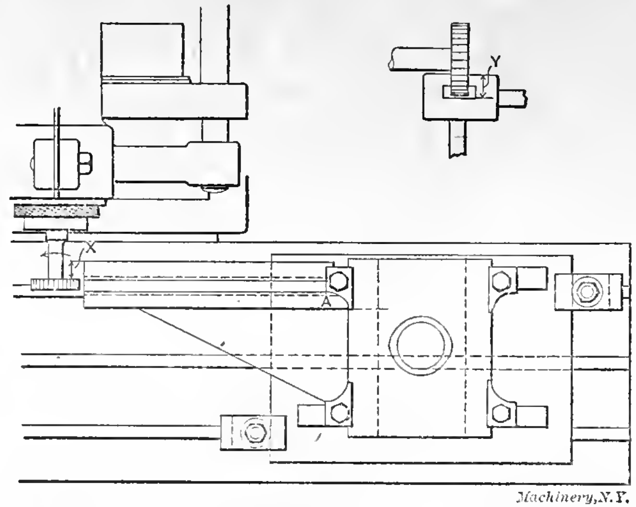
5. Set the tool point so that it will just clear the rough interior of the bearing as it passes through, and note the places where the cut will be heaviest. Set the tool to take as heavy a cut as is safe, and take a roughing cut.

6. Take the cuts in both directions when practicable. The last few cuts should be very light, removing from 0.002 to 0.004 of an inch. The finishing cut should just scrape the hole smooth.

7. Remove the bar, unclamp the knee and the table, but leave the fixture set up for the next operation.

SHOP OPERATION SHEET NO. 65.

H. A. S. Howarth. MACHINERY, June, 1908.



To Mill a T-slot. First Operation.

NOTE.—It is assumed that the fixture bearing was left set up on the milling machine table on the completion of the last operation.

1. Insert the shank of the milling cutter into the spindle of the machine. The cutter and shank may be solid, or the cutter may be mounted on an arbor and held in place by a key and nut. The diameter of the shank or arbor next to the cutter should be small, so as to permit the use of a small cutter; this will enable the cut to be run close up to the bearing as at A.

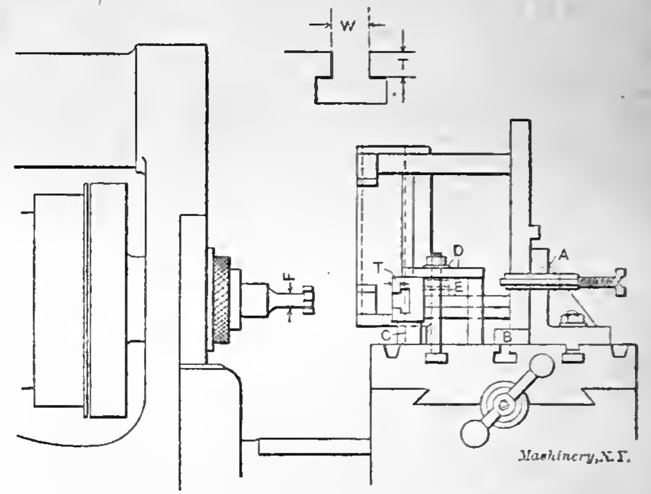
2. Adjust the table of the machine so that the cutter will be set as shown in the illustration, the distance X being equal to the required dimension. The depth of the cut should be equal to the depth Y of the T-slot.

3. Start the machine and mill the slot to the required width and depth in one cut unless the width of the slot needs to be very accurate, when two cuts may be taken, the one with a roughing, and the other with a finishing cutter. The cutter in this instance should be rotated as indicated by the arrow, as the work will then be fed against the cutter, and all slack or back lash between the nut and the feed-screw will be taken up.

NOTE.—By using an end mill, this operation could be done at the next setting of the fixture, but the foregoing method is preferable, as a very slow feed must be used with the end mill to keep it from springing. Then again, it is essential that this part of the T-slot be exactly in line with the tongue on the base of the casting, and exactly square with the bore of the bearing; therefore, it is better to partially mill the T-slot at this setting.

SHOP OPERATION SHEET NO. 66.

H. A. S. Howarth. MACHINERY, June, 1908.



To Mill a T-slot. Last Operation.

1. Remove the bearing cap from the fixture so that it will not be in the way when finishing the T-slot. The slot is supposed to have been finished to the width W, as described in the previous operation.

2. Bolt an angle plate A to the milling machine table, placing the tongue on the plate against one side of a T-slot.

3. Set up the fixture as shown, with its planed edge resting on a parallel B. Clamp the base to the angle plate with C-clamps, and insert blocks C under the casting, one beneath the end of the bearing, and another near the end of the slotted arm. These blocks should just fill the space between the table and the casting. With the clamps D and E, fasten the work securely to the table, and then, using a square, test the base of the casting to see if it is square with the table.

4. Insert a standard T-slot cutter into the spindle of the machine. The diameter F of the shank of the cutter should be slightly less than the width W of the T-slot. The cutter itself should be of a size to finish the T-slot at one cut.

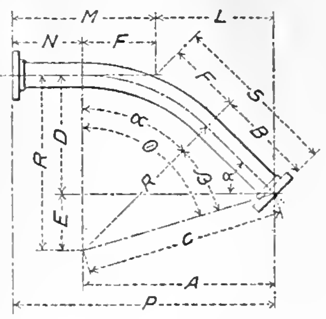
5. Adjust the table of the machine so that the cutter will be central with the slot which was milled during the previous operation, and also so that the cutter will mill the T-slot to the required thickness T.

6. Start the machine, and feed the cutter through the slot carefully. As a T-slot cutter is somewhat delicate, and as it is almost wholly surrounded by metal during the cut, a moderate feed and speed should be used to prevent springing and overheating the cutter.

NOTE.—For very accurate work, first a roughing and then a finishing cutter should be used.

I.—FORMULAS FOR PIPE BENDS.

Angle Bends. Given dimensions P, N, D, R.



$A = P - N$; $E = R - D$

$C = \sqrt{E^2 + A^2}$ or $C^2 = A^2 + E^2$

$B = \sqrt{C^2 - R^2}$

$\text{Cot. } \theta = \frac{E}{A}$ or $\text{Tang. } \theta = \frac{A}{E}.$

$\text{Cot. } \beta = \frac{R}{B}$ or $\text{Tang.} = \frac{B}{R}$

Angle $\alpha = \theta - \beta$

$F = R \times \text{Tang. } \frac{1}{2}\alpha$

$M = N + F$; $L = A - F$

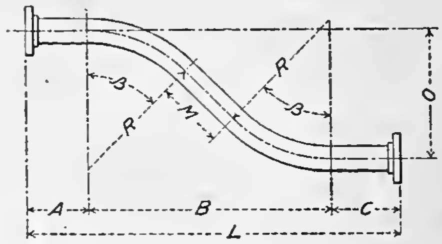
Given dimensions P, N, A, R, B.
$C^2 = B^2 + R^2$; $E = \sqrt{C^2 - A^2}$; $D = R - E$.
$\text{Tang. } \theta = \frac{A}{E}$; $\text{Tang. } \beta = \frac{B}{R}$; $\alpha = \theta - \beta$; $F = R \times \text{Tang. } \frac{1}{2}\alpha$;
$M = N + F$; $S = F + B$; $L = A - F$.

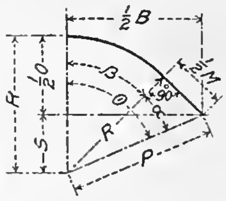
Given dimensions P, N, A, α, and R.
$F = R \times \text{Tang. } \frac{1}{2}\alpha$. $L = A - F$. $\text{Tang. } \alpha = \frac{D}{L}$. $D = \text{Tang. } \alpha \times L$.
$S = \sqrt{L^2 + D^2}$ or $S = \frac{D}{\text{Sine } \alpha}$. $B = S - F$.
$M = N + F$. Dimensions β, θ, C, E not required.

Given dimensions P, N, A, D, and α; to find R, B, and F.
$L = \frac{D}{\text{Tang. } \alpha}$. $F = A - L$. $R = \frac{F}{\text{Tang. } \frac{1}{2}\alpha}$. $B = \sqrt{A^2 - 2RD + D^2}$.

Standard radius R = 6 pipe diameters.
Minimum radius R = 3 pipe diameters.
N, or B, should not be less than 1 pipe diameter.
When R = 3 diameters, use extra heavy pipe.
When R = over 3 diameters, use full weight pipe.

Offset Bend with Straight Between Arcs.





D = Diameter of pipe.
Standard radius R = 6D.
Minimum radius R = 3D.

Given dimensions L, R, O, A, M.

To find β, B, and C.

$S = R - \frac{1}{2}O$ $\quad P = \sqrt{R^2 + (\frac{1}{2}M)^2}$

$\text{Tang. } \alpha = \frac{\frac{1}{2}M}{R}$. $\quad \frac{1}{2}B = \sqrt{P^2 - S^2}$

$\text{Tang. } \theta = \frac{\frac{1}{2}B}{S}$. $\quad$ Angle $\beta = \theta - \alpha$

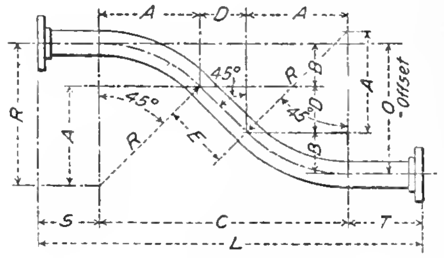
$C = L - (A + B)$

M, is usually made 12".
A or C should never be made less than D when good bends with tight flanges are required.
When R = 3D, use extra heavy pipe.
When R = over 3D, use full weight pipe.

Contributed by Wm. F. Fischer.

II.—FORMULAS FOR PIPE BENDS.

45-Degree Offsets.
Given offset O, radius R, length L and S.

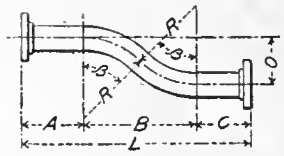


$A = R \times 0.707$
$B = R - A$
$D = O - 2B$
$E = D \times 1.414$
$C = 2A + D$
$T = L - (C + S)$

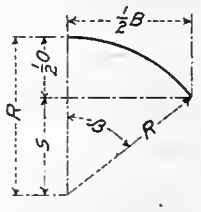
Length of each arc on center line equals $0.7854 \times$ rad. R.

Note:-
Standard radius R = 6 x diam. of pipe.
Minimum radius R = 3 x diam. of pipe
S, or T, should not be less than 1 x diam. of pipe.
When R = 3 x diam. of pipe, use extra heavy pipe.
When R is over 3 x diam. of pipe, use full weight pipe.
When possible, keep S, or T, equal to at least $1\frac{1}{2}$ x diam. of pipe or more, when screwed flanges are used.

Offset Bend.
No straight between arcs.



D = Diameter of pipe
Standard radius R = 6D.
Minimum radius R = 3D.



Dimensions given L, O, R, A.
To find β, B, C.

$S = R - \frac{1}{2}O$

$\frac{1}{2}B = \sqrt{R^2 - S^2}$. $\quad B = 2 \times \frac{1}{2}B$.

Tangent $\beta = \frac{\frac{1}{2}B}{S}$.

$C = L - (A + B)$.

When it is necessary to keep L as short as possible, make A and C each equal to one diam. of pipe. (This should be the limit for good bends), and make radius R = 3D.
To find dimensions L, B, and angle β:
$S = R - \frac{1}{2}O$. $\quad \frac{1}{2}B = \sqrt{R^2 - S^2}$ $\quad B = 2 \times \frac{1}{2}B$.
$\text{Tang. } \beta = \frac{\frac{1}{2}B}{S}$ $\quad L = A + B + C$.
When R = 3D, use extra heavy pipe.
When R = over 3D, use full weight pipe.

Contributed by Wm. F. Fischer.

June, 1908.

THE WESTINGHOUSE DOUBLE-FLOW STEAM TURBINE.

DETAILS OF RECENT DEVELOPMENTS IN THE PARSONS TYPE.

An interesting example of the greatly increased power capacity per unit of floor area, made possible by the use of steam turbines in place of reciprocating engines, is found in the Brunot Island station of the Pittsburg Railways more than the original plans had called for. An installation of Westinghouse double-flow turbine has been placed in the space originally assigned to the three reciprocating engines, and instead of gaining only 4,500 K.W., 18,000 K.W. has been added

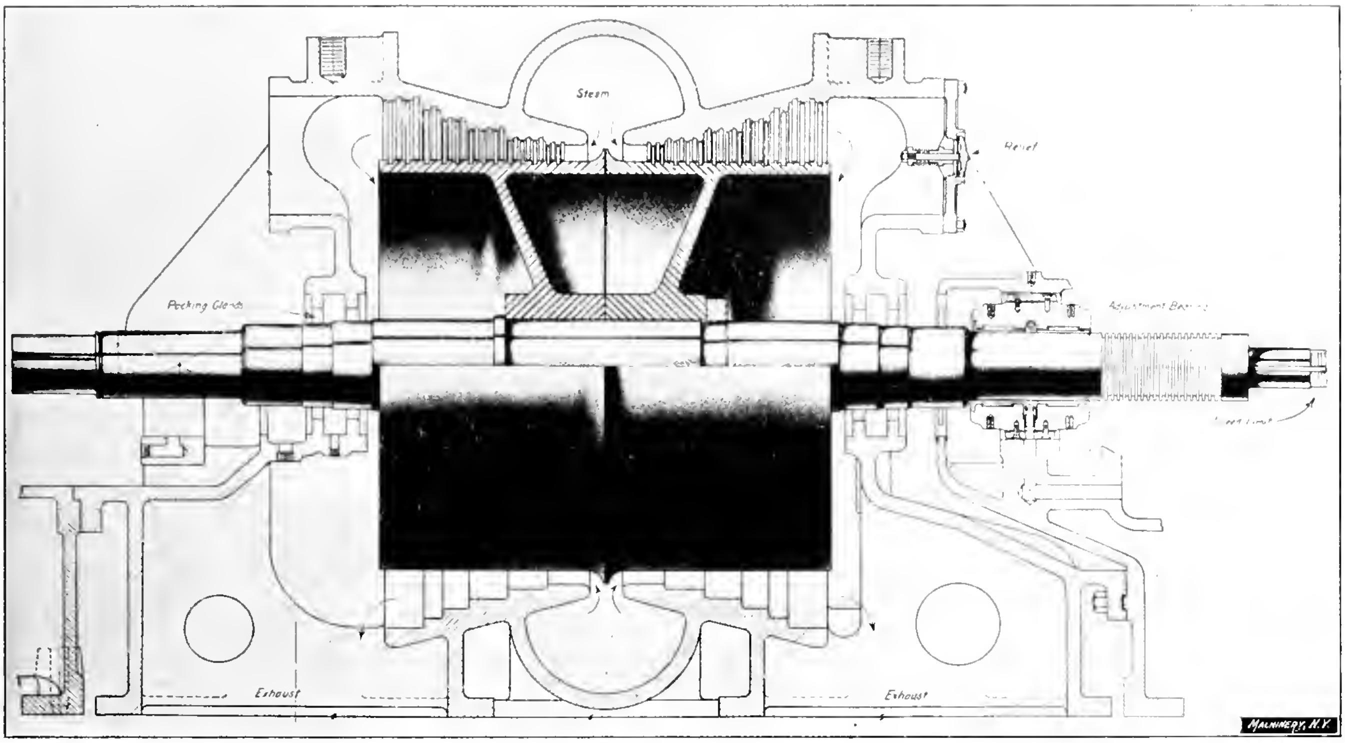

Fig. 1. The Westinghouse Low-pressure, Double-flow Steam Turbine.

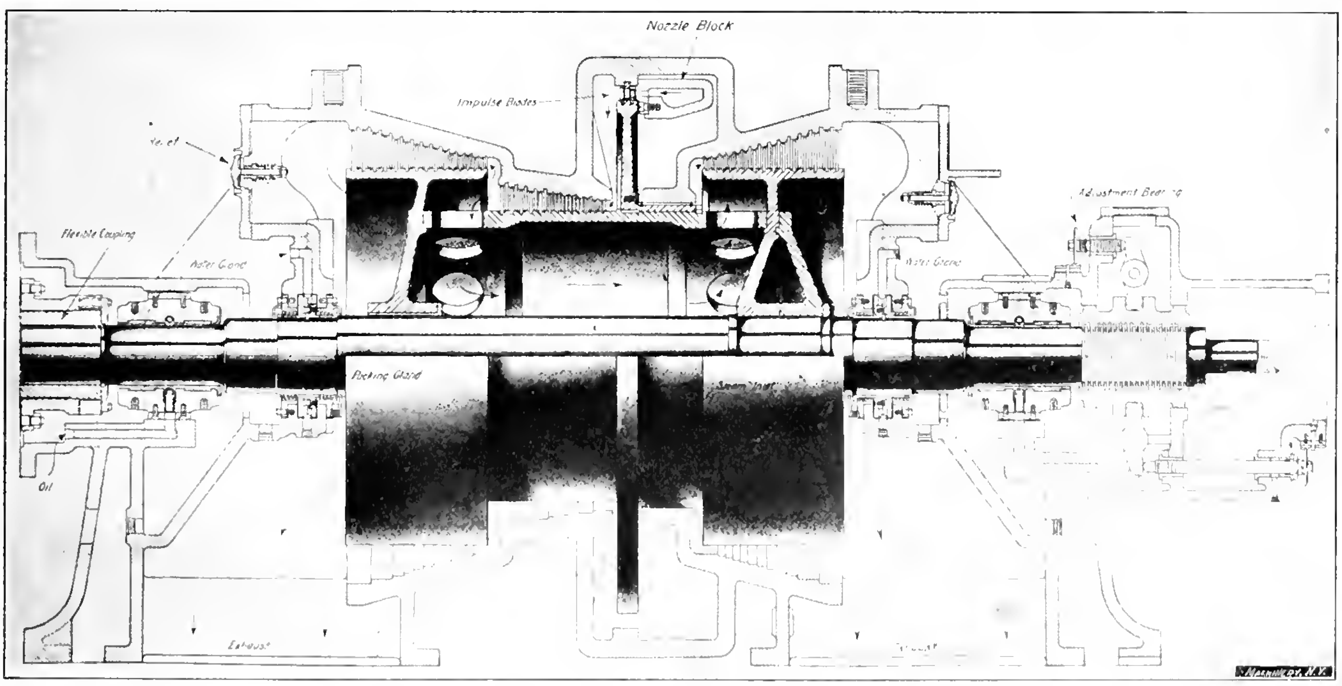

Fig. 2. The Westinghouse High-pressure, Double-flow Steam Turbine.

Co. This station is one of the scores of street railway power stations in which it has been found necessary to increase the capacity far beyond the original plans, in response to the extraordinary growth of urban and interurban transportation lines. In this station, space had been provided for three additional 1,500 K.W. cross-compound condensing engines, but the demand for power made it imperative to immediately provide much in the shape of one 3,000 K.W. and three 5,000 K.W. double-flow units, with space still remaining for another 5,000 K.W. unit. When this unit is placed there will be 23,000 K.W. developed, or *fifteen times* the power of the original lay-out in the same space.

The following description deals with the development of the double-flow Westinghouse turbine in considerable detail, inas-

much as this turbine has not been described to any extent in the American technical press. The double-flow principle as embodied in these large machines is a development brought about entirely by considerations of mechanical construction. It is not by any means without precedent—in fact, the original Parson's turbine, constructed in 1880, was of the simple double-flow type—and in hydraulic work the double-flow principle is largely used to produce a rotor running in perfect axial equilibrium. In small machines, however, the advantages of the double-flow principle are not as preeminent as in the large, principally because of the absence of the necessity therefor from a mechanical standpoint, and by reason of the fact that the economy of two small machines is not likely to be as good as one of twice the capacity. In turbines of very large size, however, where proportions exist more favorable to the attainment of high economy, the latter advantage does not obtain.

The double-flow turbine may thus be regarded as the result of an insistent demand for turbine-generating units of great capacity at high speeds. The 5,500 K.W. unit installed several years ago alongside the huge Corliss units at the Manhattan elevated station, New York City, proved to be only the beginning, and to-day 10,000 K.W. units have been built, while even larger ones are contemplated. For these large machines, the advantages of the combined impulse and reaction principle of steam expansion, together with the double-flow construction, are so important that the practical result, as embodied in the machine under description, is most fortunate, and for machines above 5,000 K.W. capacity, the double-flow construction will become standard in all Westinghouse work. For smaller capacities, the single-flow Parsons principle, as before, predominates, and in sizes below 3,000 K.W., the familiar Westinghouse-Parsons construction, therefore, remains standard.

From a thermodynamic standpoint, the Parsons is still the most efficient turbine system ever devised; but owing to the mechanical advantages inherent in the double-flow type, the net result is that as the two types are now built, they are practically upon the same basis as regards economy. This condition is largely brought about by the higher relative speeds permissible in large capacity machines with which the Parsons element works to so much better advantage as to compensate for the poorer inherent economy of the impulse section. In fact, this impulse element may be considered somewhat as a power producing reducing valve from which a lower efficiency may be countenanced.

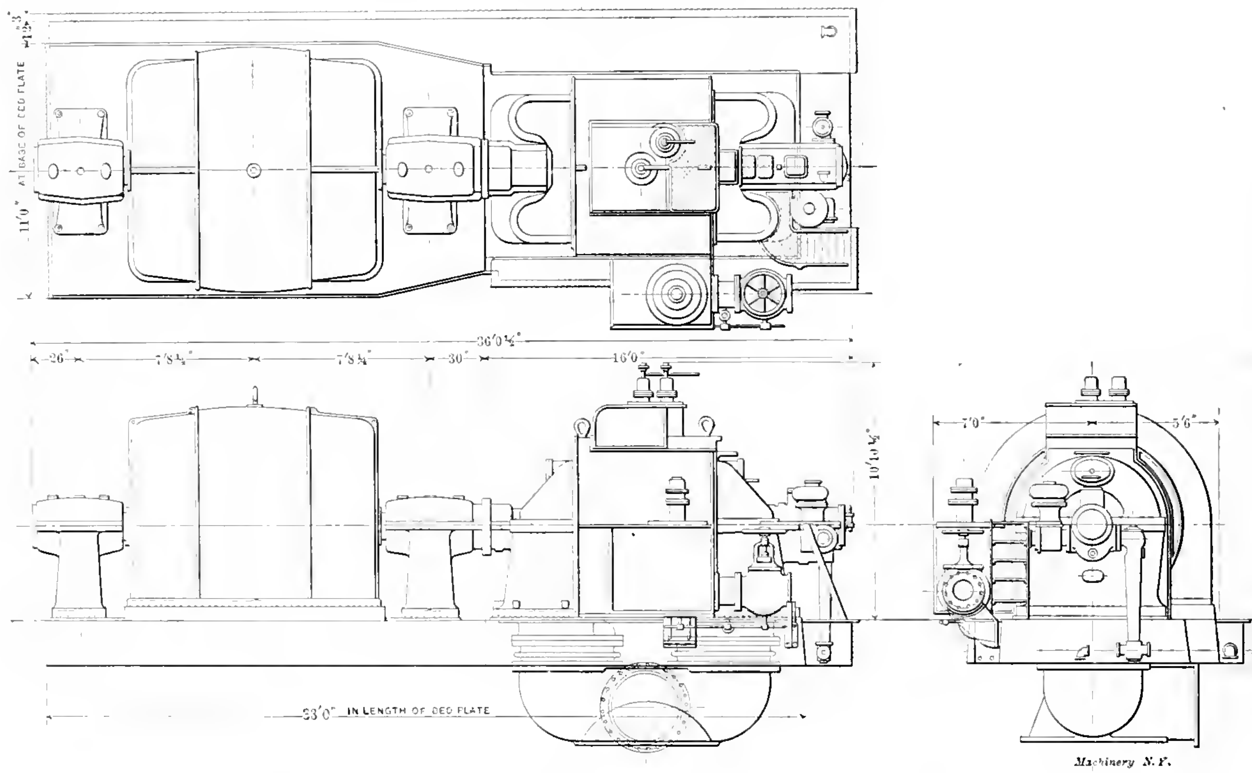

Fig 3 Plan and Elevation of the Westinghouse 5000 K. W. Double-flow Steam Turbine.

Elemental Construction.

The advantages of the double-flow construction will probably be most clearly understood by first considering the low pressure double-flow turbine shown in Fig. 1. Here we have a turbine of the simplest possible construction, consisting entirely of two identical Parsons turbines placed end to end, taking steam at the center and exhausting at both ends. It will be evident by an examination of the illustration, that since the two elements are identical, and the steam flows through them in opposite directions, the axial thrust of the steam on the blades, due to the difference of pressure between the inlet and outlet of each element, will be exactly the same in both sections. Therefore, perfect steam balance under all conditions of pressure, vacuum and load, is obtained without the use of dummy or balance pistons. As these low pressure turbines are designed to utilize all the exhaust steam from a non-condensing reciprocating engine, it is possible to tie the engine and turbine together electrically, thus making the use of a governor on the low-pressure turbine unnecessary. With the exception that, as mentioned, the governor may often be omitted from the low-pressure turbine, it is practically identical with the high-pressure double-flow turbine. In fact, the high-pressure machine is directly evolved from the low-pressure by the simple addition of a high-pressure impulse element mounted at the center of the rotor, this simple element serving in a capacity closely analogous to the high-pressure cylinder of a triple expansion reciprocating engine. Fig. 2 represents the final step in the evolution of the present complete high-pressure machine.

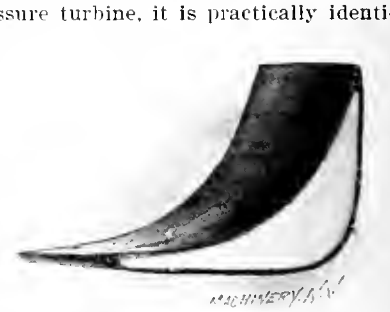

Fig. 4. Section through a Blade showing the Copper Sheathing which is chemically welded to a Steel Core.

Features of the Double-flow Construction.

At this point it may be well to review some of the features of the double-flow turbine.

1. Large reduction in bulk and in weight of individual parts to be handled in assembling. These follow from:

2. Increased speed permissible, due to reduced span between bearings.

3. Low-pressure section in two parts opposed in position and resulting in axial equilibrium, permitting the use of low-pressure blading of moderate length.

4. Cylinder not exposed to high-pressure and high-temperature steam; maximum pressure encountered about 75 pounds.

5. Relatively large volume per pound of steam at admission to first Parsons section avoids necessity of very short blades otherwise necessary with large diameters.

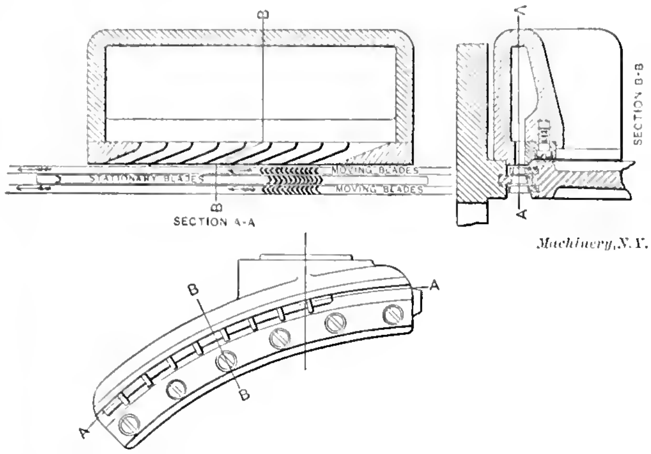

Fig. 5. Arrangement of the Blades and Nozzles.

6. Only one balance piston required, this being of moderate diameter.

7. Impulse element well suited to high-pressure and superheat; works well into dimension scheme, and reduces shaft length nearly 50 per cent.

8. Exhaust connections passing through bed plate largely reduced in size due to divided flow.

General Description.

Steam enters the turbine through a flanged opening in the lower half of the casing from which it is piped directly to nozzle blocks. For convenience in illustrating, the nozzle block, Fig. 2, is shown at the top, whereas, it may be located at any point in the periphery nearest the inlet. Expanding in suitable nozzles, the steam impinges upon the impulse blades, enters the impulse wheel chamber, and is distributed evenly around the casing so as to enter the intermediate Parsons section of the turbine, around the entire periphery of the rotor. As in the single-flow turbine, the steam then divides along two separate paths, one-half entering the left-hand section of low-pressure Parsons blading, the other passing through the interior of the rotor shell which forms the connecting passage to the remaining low-pressure section of Parsons blading at the right-hand end of the turbine. Discharging from the last rows of low-pressure blading, the steam passes into the exhaust connections and to the condenser in the normal manner.

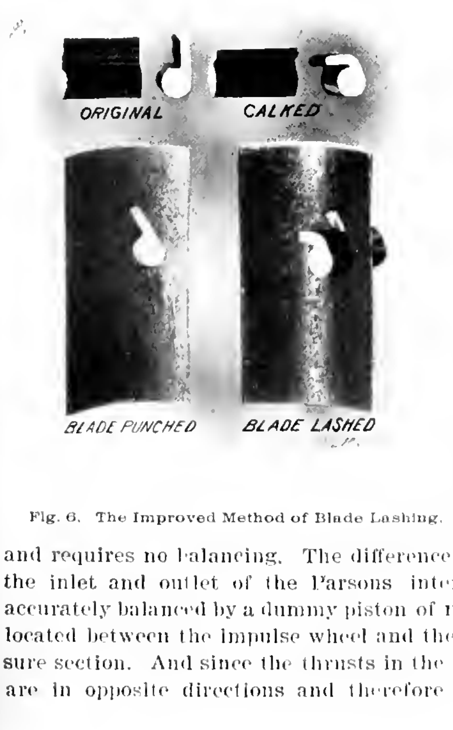

Fig. 6. The Improved Method of Blade Lashing.

As the same pressure exists on both sides of the impulse wheel disk, this is not subjected to end thrust and requires no balancing. The difference of pressure between the inlet and outlet of the Parsons intermediate section, is accurately balanced by a dummy piston of moderate dimensions, located between the impulse wheel and the right-hand low-pressure section. And since the thrusts in the low-pressure sections are in opposite directions and therefore balanced, the entire turbine runs in perfect equilibrium under all conditions of vacuum, pressure and load. It is, of course, necessary to provide means for accurately fixing the axial position of the rotor, and for this purpose, an adjustment bearing on the right-hand end of the shaft, is, as usual, fitted. It consists of a number of collars turned in the shaft, into which fit corresponding brass rings fixed in the adjustment blocks. The upper and lower halves of the adjustment bearing may be moved by means of micrometer screws, as shown, thus permitting the axial position of the rotor to be accurately known at all times.

Double-flow Cylinder.

All double-flow cylinders are made in two parts, the upper and lower halves each being a one-piece casting. The design is symmetrical throughout, devoid of longitudinal flanges except those at the center required for bolting the two parts together. The castings are first rough-bored, after the flanges have been planed and drilled, and are then "seasoned" with high-pressure steam for a number of hours to remove any local casting strains in the metal. They are then given the finishing cut, assembled, and with boring-bar running in the bearing housing so as to insure a truly concentric bore. Manholes are provided at each end of the cylinder to permit access for interior examination, and relief valves are fitted in each of the manhole covers to prevent the pressure in the exhaust passages rising to a dangerous point in case of failure of the condensing apparatus and sticking of the atmospheric relief valve. A steam- and air-tight packing gland is fitted at each

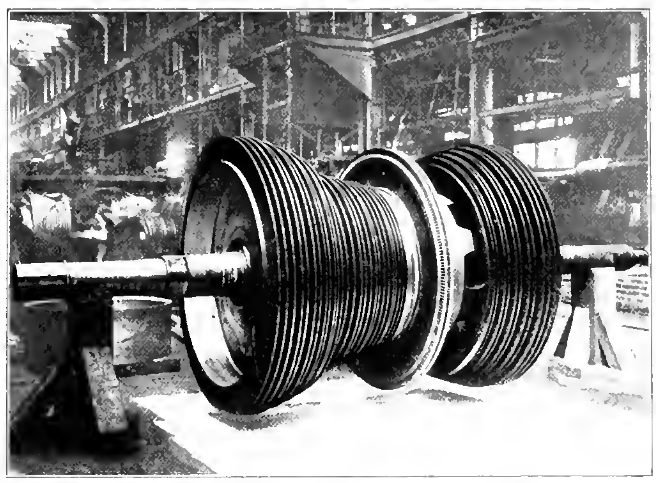

Fig. 7. View of the Rotor showing the Uniformity of the Blading

end of the cylinder where the shaft enters, and will later be described in detail.

A Y-connection fitted with two corrugated copper expansion joints located below the base of the turbine, connects the separate exhausts to the main exhaust nozzle. This is clearly shown in the longitudinal elevation of the 5,000 K.W. Brunot Island turbo-generator shown in Fig. 3. By means of these expansion joints, the desired freedom of movement of the turbine casing, due to expansion and contraction, is provided for. It will also be noted that an atmospheric exhaust nozzle opens out of the side of the exhaust Y to permit non-condensing operation.

The Rotor.

Referring again to Fig. 2, it will be seen that the rotor consists of five cast steel members mounted on a through shaft. Note that the shaft carries its load at one-third distance from the points of support, thus permitting a lighter shaft than required for distributed loading, and practically eliminating the possibility of deflection. The rotor is firmly pressed on the shaft and locked to prevent movement. To the left end of the rotor is fitted a bronze bushing surrounding the shaft, permitting it to move axially without appreciable resistance under any differential expansion of shaft and rotor body.

The impulse element consists of a flanged cast steel disk forced onto the rotor body with a pressed fit and securely keyed. The flange at the base is grooved and forms the dummy or balance piston for the intermediate Parsons section

A typical arrangement of blading and nozzles is shown in detail, Fig. 5. Note that the nozzle block is an independent casting quite separate from the turbine cylinder. This restricts the high pressure and high temperature of the steam received from the governor valve to a comparatively small casting which is free to expand and contract with changes of temperature, and may easily be designed with ample strength.

As the steam is not expanded in the impulse element to less than about half of the initial pressure, divergent nozzles are unnecessary and simple straight-sided nozzles are used. The entire nozzle block may be removed in one piece, and the construction is such that the nozzle walls may be readily renewed if necessary, at a very nominal cost, independently of the block. As practically no difference of pressure exists on the two sides of the element, the area through the bucket increases, to provide for the decreasing steam velocity in each rotating wheel. As in all high-pressure impulse turbines, the nozzle blocks cover but a small portion of the periphery of the impulse wheel, so that ample space is left around the remaining portion of the wheel to permit the free circulation of steam in all parts of the impulse wheel chamber before entering the Parsons element.

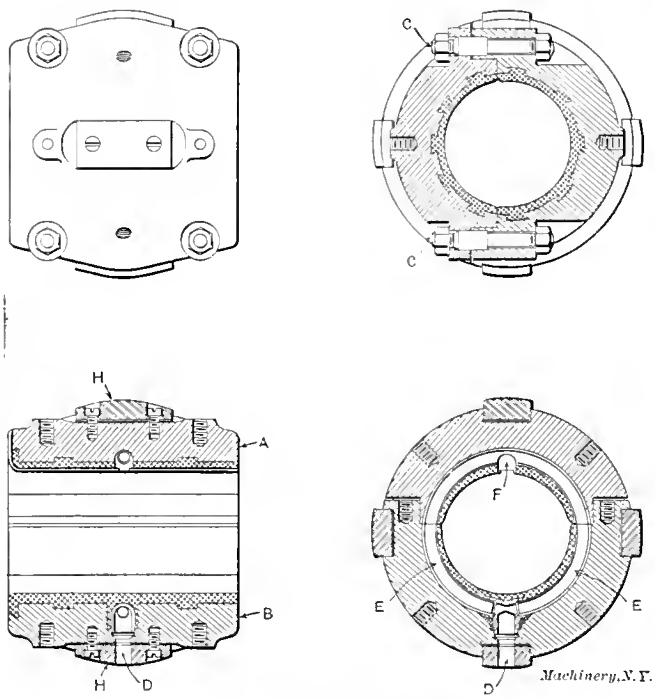

Fig. 8. The Self-aligning Babbitt-lined Bearing, which does not require Forced Lubrication.

Parsons Element.

Except for the division of the low-pressure Parsons section, this part of the turbine is identical with the single-flow construction, consisting of a series of rows of moving and stationary blades, increasing in height to allow for the increased volume of the steam. In the Parsons section, it will be recalled, the velocities from stage to stage remain practically constant. The blades are inserted in grooves cut in the spindle and cylinder body, and are securely held in place by calking the soft spacers or distance pieces inserted in the grooves between the blades. It will be noted that the diameters of the low-pressure section are chosen so as to permit the same size blades being used in both intermediate and low-pressure sections, thus simplifying the blading considerably. As there are a number of improvements in the Westinghouse-Parsons blade construction used on both the single-flow and double-flow turbines that have not been previously described, they will be of interest.

The Blading.

No one metal has all the physical characteristics desirable in a blading material. But recently a special, compound metal has been developed, which is exclusively used in Westinghouse turbines. This material, known as "Monnot," or duplex metal, consists of a steel core covered with a thin copper sheathing chemically welded to the steel in such a perfect manner that the blades may be drawn cold from the original ingot into the required finished section without in any way affecting the bond between the copper and steel. The advantages of this blade material will at once be evident, as experiments have shown that pure copper offers the maximum resistance to chemical corrosion resulting from bad feed water carried over in the steam during priming. At the same time the integrity and great strength of the steel core is maintained. How uniform the copper sheathing of the finished blade is, may be clearly seen in Fig. 4, showing an enlarged section of a duplex metal blade, the end of which has been etched to show the true thickness of the copper covering.

Fig. 9. Westinghouse Low-pressure Double-flow Turbine.

The Blade Lashing.

The original method adopted for reinforcing long blades was to insert a heavy brass wire in saw slots cut in the entrance edge of the blade, the brass wire being securely laced to the blades by a thin copper wire, and the whole then rigidly brazed together. This method has been greatly improved upon in the present blade lashing now used in all Westinghouse turbines, shown in detail in Fig. 6. First, comma-shaped holes are punched in the blades at any desired point of reinforcement. The blades are then strung onto a comma-shaped lashing wire laced through these holes. After the blades have been calked into the rotor or stator, the tail of the lashing is sheared over by a tool, as shown in the accompanying engraving, Fig. 6. This process wedges the tail of the lashing (comma section) into the contracting space between the face and back of the adjacent blades, acting as a strut, while the lashing wire itself acts as a tie, thus securely interlocking the blades and preventing vibration. Moreover, the short section remaining in the blade after being sheared off, acts as a key to prevent a broken blade from injuring adjacent rows. The quality and uniformity of the blading secured by these improved methods, is indicated in the view of a rotor, Fig. 7.

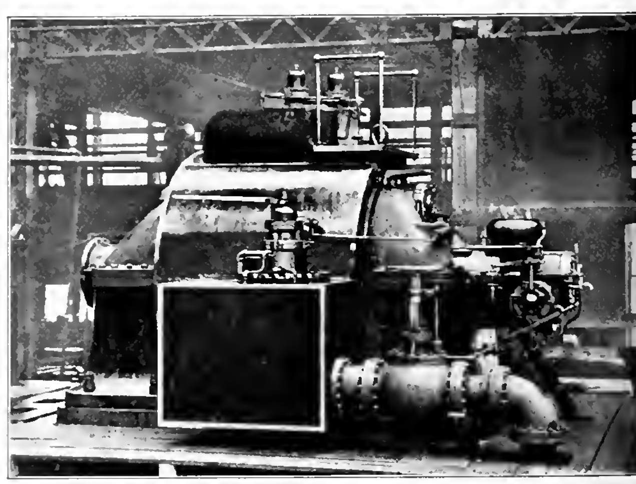

Fig. 10. One of the 5000 K.W. Double-flow Turbines installed at the Brunot Island Station of the Pittsburg Railways Co.

The Packing Glands.

A water-sealed gland is fitted on each end of the turbine shaft where it passes through the exhaust casings. This pack-

ing consists of a small centrifugal pump propeller running in an enclosed chamber to which water is supplied under a head of about ten feet, which is slightly in excess of the head due to the centrifugal force acting on the water in the impeller blades. At starting, any external leakage water is caught in circular troughs and drained away. The action of this gland is to always maintain a solid mass of water around the periphery of the impeller which effectually prevents the entrance of air to the condenser or the escape of steam to atmosphere when running non-condensing.

The Bearings.

As in all Westinghouse turbines running at or below 1,800 R. P. M., self-aligning babbitt-lined bearings are used, of sufficient area to operate without the use of a forced-lubricating system. One of these bearings is shown in detail in Fig. 8. It is made in two parts, supported in a spherical seat by four pads, by means of which the bearing and rotor can be accurately centered to preserve uniform clearances. The oil supply to the bearings is delivered at the top of the journal at the point of minimum pressure, which assures an even distribution of oil. All the bearings are supplied with oil from a central reservoir, under a static head of about 5 feet.

* * *

The Standard Oil Co. has been the chief exponent of subterranean business methods. Its greatest success has hinged largely on the policy of secretiveness, though John D. Archbold, the vice-president and chief spokesman of that great business machine, asserted in the *Saturday Evening Post* some months ago that the policy was not, in his opinion, the best one to follow. He stated that while perhaps the financial returns would not have been quite so vast, the concern would stand in much better repute to-day if a franker policy had been followed. We mention this because there is a marked tendency among certain small concerns to seclude their work with more or less mystery. They assert it is more to their advantage not to let their activities be widely known. The less there is known about their work the less fierce will the competition be. While we do not deny that there is some truth in this claim, we believe that it is an unsafe policy for the average small producer to follow. Working under cover, his product will necessarily be known and bought by comparatively few customers. So long as these customers absorb all his product, well and good, but when some of these customers drop out, as they inevitably will, the producer will be stranded high and dry until he can secure new customers, and these are not always readily picked up. When they are found it is quite probable that they will demand changes that will be very costly. If, on the other hand, the concern was generally known, the loss of one customer would not be so serious a matter, and moreover, the business would be conducted more closely in accordance with the general development of the art.

* * *

A new technical high school is being erected in Cleveland, Ohio, and will be completed next September. It is claimed that this institution is the largest of its kind in the United States. It will have accommodation for about 1,000 regular students, and is well equiped with laboratories for physics and chemistry, a forge shop, a machine shop with heavy equipment suitable for the best of trade instruction, an iron and brass foundry, completely equipped with core-room, core ovens, etc., a power plant for generation of the electric light and power required in the building, a pattern-making shop, and departments for instruction in joinery, wood turning, and cabinet making, etc. The mechanical equipment will cost in the neighborhood of $100,000. All machines will be driven by individual motors. An innovation in the instruction will be that, by eliminating the long summer vacation, a saving of an entire year in the high school course will be accomplished, so that a three-year course will be offered in which work usually covered in four years can be completed. In addition to the day classes, there will be night classes for men and women already engaged in the trades. These night classes will be divided in two sections, each accommodated three nights a week from 7 to 9:30. In this way the night trade school can give instruction to 1,400 men and 600 women.

ALIGNMENT TESTS OF LE BLOND MILLING MACHINES.

In the April, 1904, issue of MACHINERY a general description was published of the then comparatively new plant of the R. K. Le Blond Machine Tool Co. in Cincinnati, and in the article a set of boring-bars and reamers for boring the

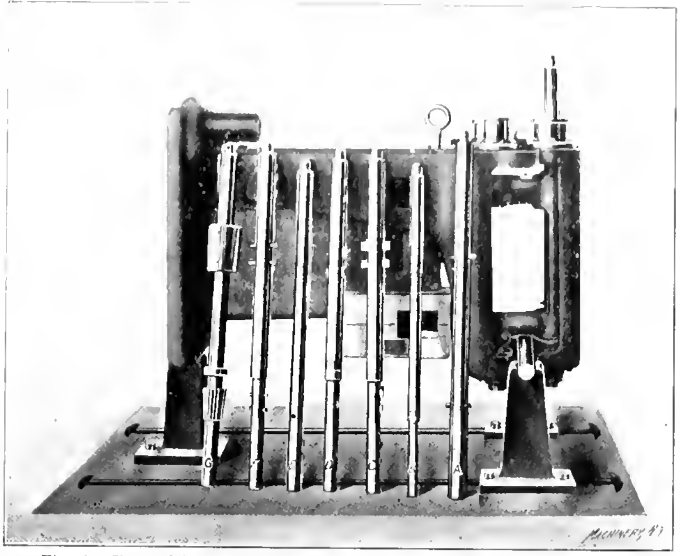

Fig. 1. Jig and Boring-bars used for Boring Bracket Holes, Spindle Bearings, and Over-arm Hole.

bracket holes, main spindle bearings and the over-arm holes of the Le Blond milling machines was illustrated. These tools, whose proper working is so necessary to the accurate alignment of a milling machine, are again reproduced in Fig. 1 in connection with illustrations of the alignment tests to which all Le Blond milling machines are subjected on the

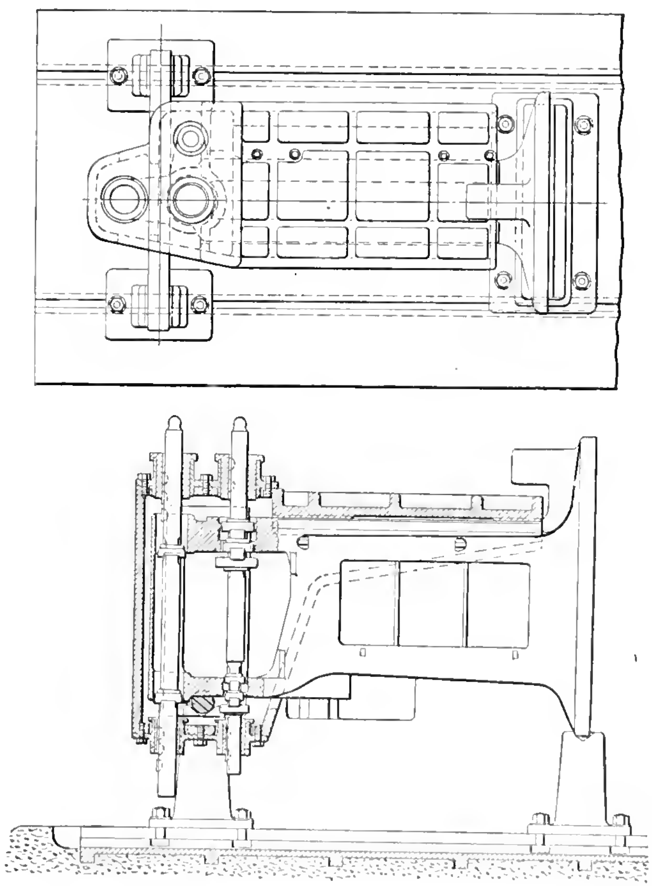

Fig. 2. Plan and Elevation of Milling Machine Column Mounted on Floor-plate for Boring

testing floor. For the description of these tests we are indebted to Mr. William F. Groene, the superintendent of the company.

Before passing to the alignment tests, attention is called to the manner of supporting the machine column during the boring operation, and to the construction of the boring jig

shown in section in Fig. 2. Formerly the milling machine column was supported on a three-wheel truck for convenience in transporting to and from the drill press, but now the truck is displaced by an electric traveling crane, and the support is a cast iron floor-plate, bedded in concrete and provided with suitable pedestals for the column casting. It may be said in passing that the boring-bars are entirely supported by the boring jig, and that the power from the radial drill press is transmitted by a "floating" or universal joint connection. The jig bushings are mounted in protected bearings, proof against chips and drill dust, and are keyed so as to revolve with the boring-bar, thus eliminating the wear of the bars and preserving a close fit. The jig encloses the upper part of the column and is supported by the front face of the column and produces holes at right angles to this face.

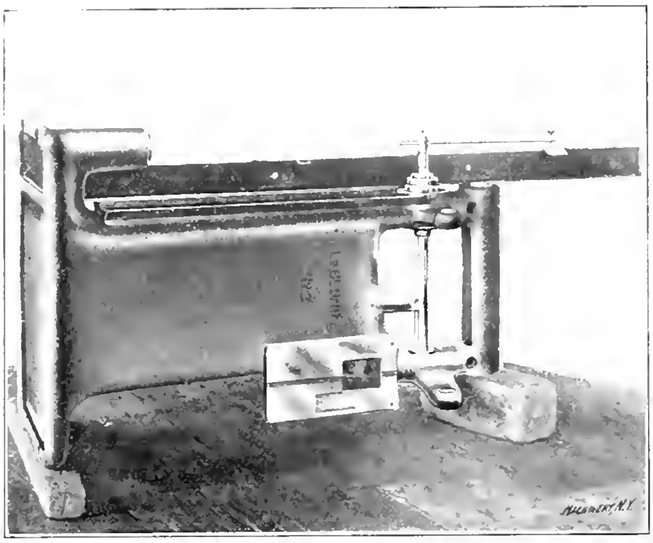

Fig. 3. Aligning Test made when Scraping Boxes Square with Face of Column. The Test is made Alternately at Top and Bottom by Drawing Tissue Paper between Straight-edge and Tram.

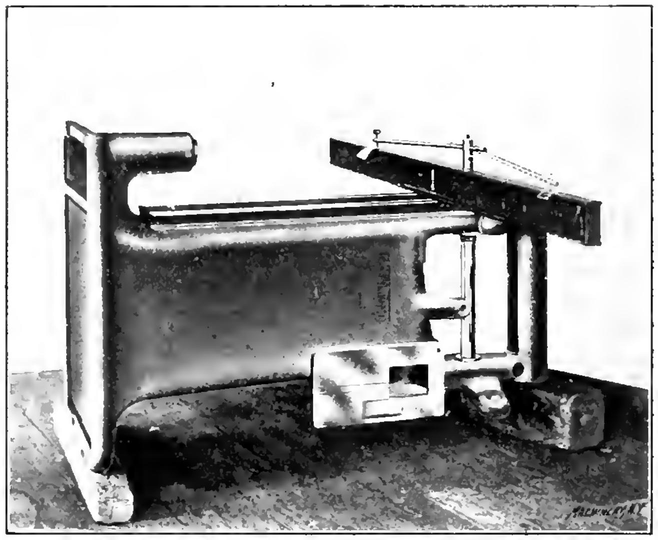

Fig. 4. Aligning Test made when Scraping Boxes Square with Face of Column. Same Test as in Fig. 3, except that Straight-edge is Laid across Column.

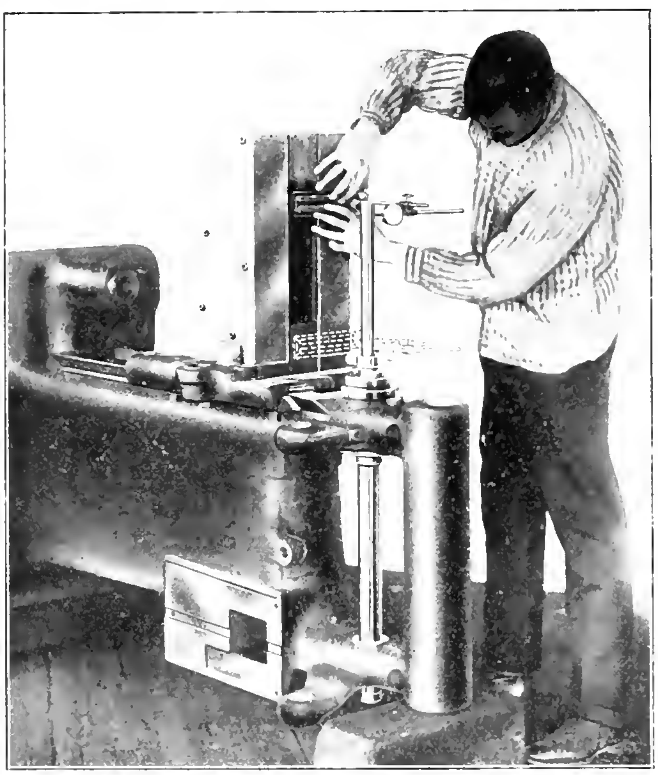

Fig. 5. Aligning Test used in Scraping Knee to Column, to determine the Alignment of the Side Bearing Surface of the Knee with the Spindle

Fig. 6. Aligning Test used in Scraping Knee to Column, to determine the Parallelism of Top of Knee with Spindle.

It is one thing to design a jig for boring holes at right angles to a given surface and perfectly parallel, and quite another thing to get the desired result, especially in the case of a milling machine column casting. Eternal vigilance is necessary to keep the tool equipment in order, and rigid tests are required of each casting. No ordinary jig, no matter how carefully planned, can produce an invariably correct alignment in long holes, especially in irregular castings, which are cored and shaped to save weight, and in which shrinkage strains are always present to some extent. The slight changes of shape caused by the removal of metal from the holes would in themselves require some corrective work, even if the jig always provided perfect guidance to the boring tools, and the fine touch of the experienced fitter is employed to correct these and other minor defects of important influence on the alignment. The tests to be described are employed to show where the scraper should be applied, as well as to prove that the work is finally worthy of acceptance.

The columns are scraped to surface-plates before boring. Boring-bar *A* and the bar shown in the jig in Fig. 2 are the over-arm finishing and roughing bars, respectively. The bar designated as *B* is for roughing out the back-gear bracket holes, and *E* is the finishing bar. The boring and reaming bars for the spindle bearings are *C*, *D*, *F*, and *G*, *C* being the roughing bar. This bar has extra slots for receiving larger cutters to do the counterboring, and *F* is the finishing bar. Bar *D* is used for boring the holes to the correct taper, the

cutters having their faces chamfered to the required taper of the bearings. These cutters are set opposite to each other to balance the cut. *G* is a bar with adjustable taper reamers for finally reaming both bearings true at one operation.

face of the column by scraping the bearings of the front and back boxes. No error is allowed in this alignment and the trams must show the same in the test when in the four positions shown.

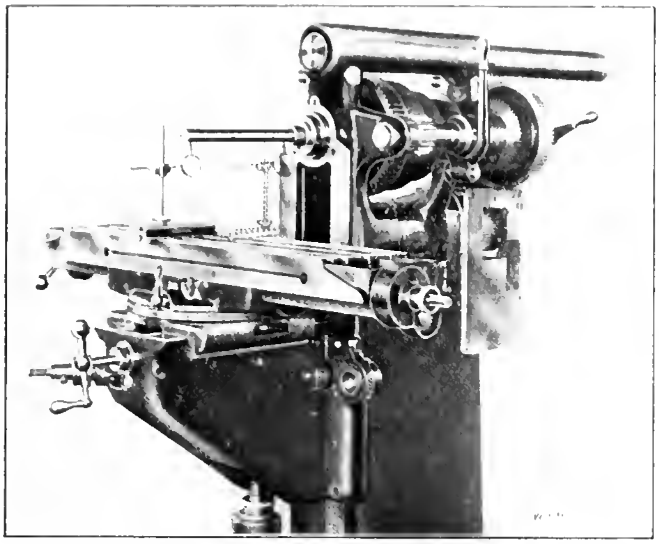

Fig. 7. Test to show Parallelism of Table with Spindle, and to indicate if Taper Hole runs True. Test is made by shifting Indicator across Table.

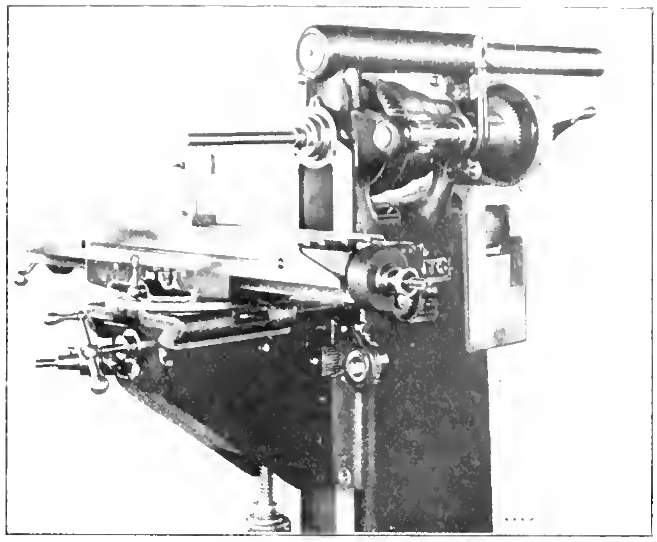

Fig 8. Test to show Parallelism of Knee with Spindle. Test is made by clamping Indicator to Table and moving Saddle across Knee with Screw.

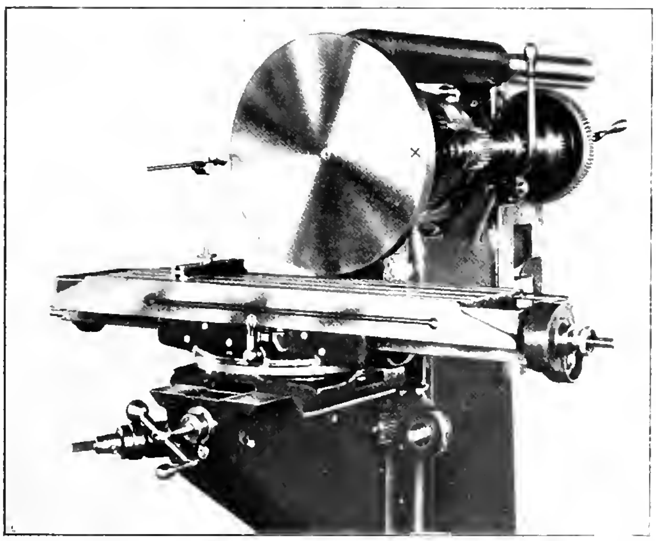

Fig 9. Testing Alignment of T-slot with Spindle. Reading taken as shown, and on other Side of Spindle at X, with Plate turned One-half Revolution.

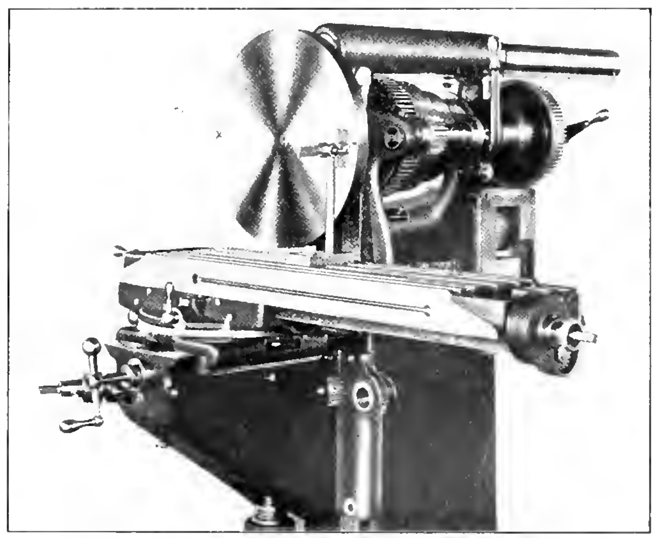

Fig. 10. Testing Alignment of Table Feed with Spindle. Indicator clamped to the Table and traversed past the Test Plate. Test otherwise made as in Fig. 9.

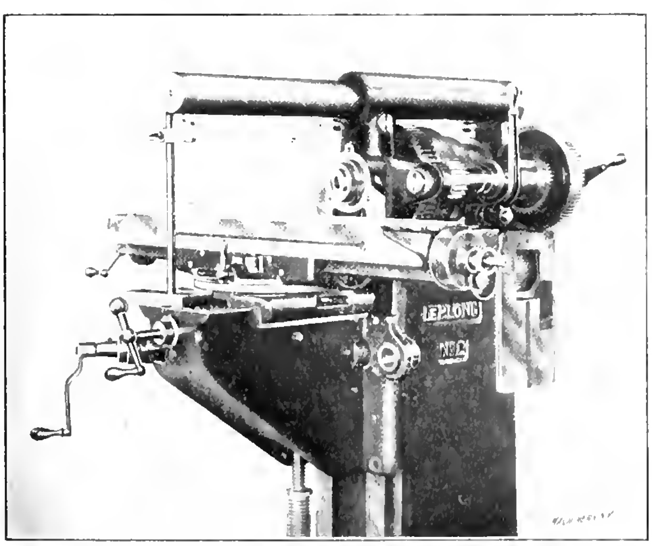

Fig. 11. Test to determine Alignment of Over-arm with Top of Knee. Indicator is passed under Arm on Each Side of Saddle.

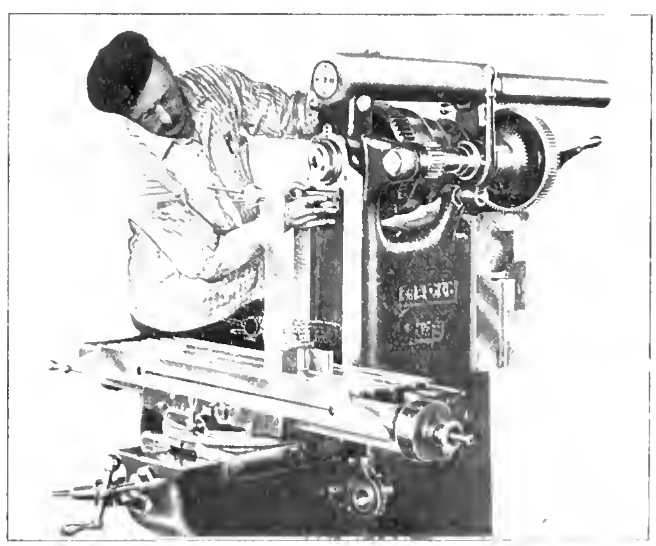

Fig 12. Testing Truth of Table Top with Side of Column. A Test for Truth with Face of Column is made with Square Clamped at Right Angles to Position shown.

The columns, as bored, come within an included error of about two thicknesses of tissue paper, or say 0.003 inch, when tested with the 18-inch trams and straight-edge, as shown in Figs. 3 and 4. The spindle is then lined square with the

Figs. 5 and 6 illustrate the test made while scraping the knee to the column. The test bar is inserted in the spindle and the knee is tested both with the face and side of the dovetail with the dial indicator. The base of the indicator has a

shoe which bears against the side of the column when making the test.

Fig. 7 illustrates testing the top of the table for parallelism with the spindle. In this case the indicator is set to the under side of the test bar and is moved across the table, the error being read in the two extreme positions as indicated in the illustration.

Fig. 8 shows the indicator clamped to the table while both the saddle and table are moved across the knee. This test proves the parallelism of the knee with the spindle.

Referring to the test card, it will be seen that the limit of error is 0.0015 to 0.003 inch high in front for No. 1 to No. 2½ machines, and 0.0025 to 0.004 inch high in front for Nos. 3 and 4 machines. The knee and table are designedly made high in front, the object being to more nearly approximate

Fig 13. Test Card giving Required Tests and Maximum Permissible Errors.

correct alignment after the machine has been in use a few months and has worn down to full bearing under the pressure of the cutters.

The testing of the alignment of table T-slots with the spindle is illustrated in Fig. 9. The indicator base has a tongue which fits into the T-slots. The indicator point is set against the test plate, screwed onto the spindle, which is then given half a turn, and the indicator is moved to the opposite side to read the error. A cross mark is made on the face-plate, as shown in the illustration, to note the testing point. Fig. 10 shows the same test as Fig. 9, but in this case the indicator is clamped to the table which is traversed across the test plate, and the difference of reading in the two positions is noted as before. This test gives the error of the table at right angles to the spindle with reference to the table dovetails. It will be noticed in the test card that allowance 0.0015 to 0.003 inch is permitted at the extreme of a 20-inch test plate in favor of the direction against the feed. This allowance is for the same reason noted before. When the machine has been in use a few months it will have worn down under the pressure of the cut until nearly perfect right angle position has been obtained.

This practice is worthy of further mention because it is of much importance to users of machine tools and to buyers of second-hand machinery. It means that a well-constructed milling machine is actually in better shape after it has been used for a short time than when new. Given data of tests made on used machines, it would be possible to plot the matter graphically and show the probable condition as regards accuracy of alignment for several years. Starting with 0.0015 to 0.003 inch inaccuracy, the conditions would be plotted probably as a reverse curve, rising from a position below the zero line in three or four months daily use, and then with ordinary good care paralleling and nearly coinciding with the zero or dead accuracy horizontal line for several years use. The departure of the curve from this zero line upward into the zone of negative inaccuracy, if we may name it so, would be relatively rapid or slow, depending on the care the machine receives and the class of work assigned to it.

The test of the aligument of the over-arm with the top of the knee is shown in Fig. 11, and in Fig. 12 two tests are indicated which are made with a 24-inch precision square to determine whether the top of the table is at right angles to the face and side of the column.

The test card we reproduce shows all the tests regularly made and the maximum permissible error allowed for the various sizes of machines built by the company. This card was made for machine No. 315 and is the one from which the photographs here reproduced were made.

* * *

An interesting kink in hack-sawing was shown to the editor in the shop of the National Tool Co., Cleveland, Ohio, by Mr. E. A. Noll, the manager. Most users of hack-saws have trouble in sawing large diameters of stock, especially tool steel, by the saw "running" and perhaps breaking before the end of the cut is reached because of becoming cramped. Mr. Noll has found that the saws will run dead true if they are slightly twisted when tightened up in the saw frame. Milford saws are used on hard tool steel stock and the blade is twisted very slightly in the frame when tightened up. Twisting a hack-saw to produce a straight cut is contrary to all preconceived notions, but the explanation seems logical. The explanation is that the saw being slightly twisted to begin with resists any tendency to deflect it from its plane of action much more strongly than it would if it were put perfectly straight in the frame. The initial twist given is so little as to have little or no effect on the cut, but it is sufficient to prevent the saw being twisted out of its plane by slight differences in the hardness of the material and other influences which tend to cause a saw to run out.

In the March, 1908, issue of MACHINERY we described the Automobile Club of America's dynamometer for testing automobiles, and mentioned that the mechanical efficiency of automobiles in general was rated at 75 per cent, but many of those tested on the dynamometer showed less efficiency. The consensus of opinion is that mechanical efficiency should be higher than 75 per cent, if anti-friction bearings were used, and it is interesting to note the results of efficiency tests made by the H. H. Franklin Co. recently. The car tested was the Franklin model G standard touring car. It gave on direct drive for 15.75 H.P. developed by the motor, 14.75 H.P. delivered at the ground. On intermediate drive the figures were 15.75 H.P. and 14.40 H.P. The loss in transmission between motor and rear wheels was 6 2/3 to 8 1/2 per cent, thus making the efficiency for the total mechanism 93.5 per cent on direct drive and 91.5 on intermediate gear.

* * *

No experienced mechanic needs to be told that the universal milling machine is a complete machine shop in itself. With the various attachments now provided it is possible to produce circular, plane and helical surfaces and combinations in almost every conceivable arrangement. Milling, turning, slotting, spur, spiral and bevel gear cutting, forming, cam cutting, drilling, reaming, boring, splining, knurling, thread cutting, thread milling, originating jigs, hobbing, etc., are all readily accomplished. Instead of being called a universal *milling* machine, it should be called the *universal* machine.

GEAR-CUTTING MACHINERY—6.

RALPH E. FLANDERS.*

As explained in the last installment of this article, in the May issue of MACHINERY, the molding-generating principle is the only one for accurately forming the teeth of worm-wheels. The principle involved is shown in Fig. 111. The forming worm (or hob) is connected by gearing with the plastic worm-wheel blank to be formed, in the same ratio as given by the finished worm gearing. While the blank and the forming worm are rotated together in this ratio, the latter is fed into the blank slowly, its threads forming the proper shaped tooth in the wheel. As the worm revolves, an axial section would give the appearance of a rack like that shown in section *A-A*, of Fig. 109, moving continuously and forming suitable gear teeth in the wheel below it. Any other section, such as *B-B* in Fig. 109, would also act as a distorted rack, forming correspondingly distorted gear teeth in that portion of the worm-wheel in the same plane. The process is thus seen, as previously explained, to be identical with that in Fig. 7.

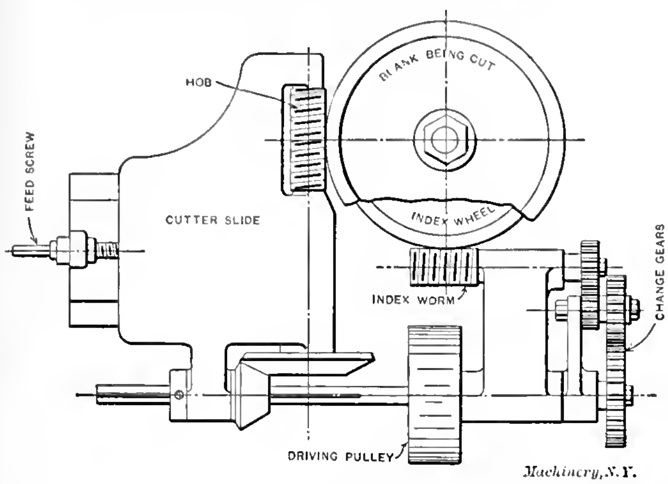

Fig. 111. Diagram showing the Principle of the Hobbing Process for Cutting the Teeth of Worm-wheels.

Of the various methods of operation, shaping or planing is of course impracticable. Milling is the method generally employed. Grinding or abrasion is used to a limited extent, it being sometimes employed in the case of "grinding in" a worm with a wheel already roughly cut to shape. In this operation the worm and wheel are run together in place under considerable pressure, the teeth of the gear being liberally supplied with oil and emery, which acts as an abrasive and forms the teeth of the gear and worm to fit each other.

In the commonly employed milling operation, the process is that known as "hobbing," and the milling cutter or tool used is a "hob," of which an example is shown in Fig. 112. The hob (barring modifications required for relief or clearance, and allowance for regrinding) is practically a replica of the worm which is to be used, but with grooves cut in it so as to form teeth. This hob is rotated in the proper ratio with the work, exactly as shown in Fig. 111, and fed slowly down into it, cutting out the tooth spaces in the wheel as it does so. When it has reached the proper depth, the teeth are all formed to the proper shape.

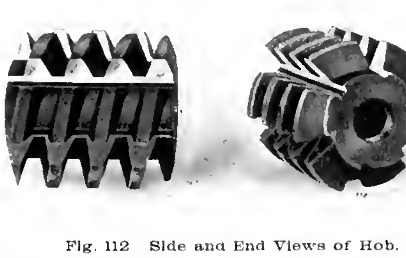

Fig. 112 Side and End Views of Hob.

Hobbing Worm-wheels in the Milling Machine.

The simplest method of rotating the hob and the work in the proper ratio with each other is that in which the work is first gashed, as shown in Fig. 110, and then finished with the hob in such a way as to be driven by the latter, the work and the hob thus furnishing their own driving mechanism. The same wheel which is being gashed in Fig. 110 is shown having its teeth finished to the proper shape with the hob in Fig. 113, the hob driving the work as described. The latter is mounted so as to revolve freely on dead centers. This is the simplest method of making correct worm-wheel teeth. It does not require special appliances of any kind, being done in an ordinary milling machine with a gashing cutter and a hob.

In cases where it is desired to hob worm-wheels directly from the solid without preliminary gashing, it is necessary to provide some special device for rotating the hob and the work in unison as in Fig. 111. Such a case is shown in Fig. 114, which illustrates the worm-wheel hobbing attachment built by the Wanderer Fahrradwerke, Schonau, bei Chemnitz, Germany. This attachment, which is self-contained, is clamped to the table of the milling machine. The device carries a vertical work spindle, driven by a worm and worm-wheel which are connected by change gearing with a horizontal shaft carrying a gear meshing with a gear on the spindle of the machine. The hob, which is carried by the spindle of the machine, is thus positively connected through the change gearing with the work in the same way as in Fig. 111. Change gearing is set to give the proper ratio between the hob and the work. The hob is fed to depth in the work by the operation of the regular table feed-screw.

In Fig. 115 is shown a hobbing attachment applied to another form of miller, in this case a horizontal spindle machine of the planer type made by the Newton Machine Tool Works, Philadelphia, Pa. The attachment consists primarily, as in the previous case, of a base provided with bearings for a vertical spindle, which is revolved by a worm-wheel enclosed within the base. The worm is connected by change gearing with a splined shaft, driven through a train gearing from the spindle. The machine is set to the diameter of the work, and the hob is fed to depth by the operation of the regular longitudinal feed-screw. A special feeding mechanism is provided, operated from the attachment instead of from the regular feed cones.

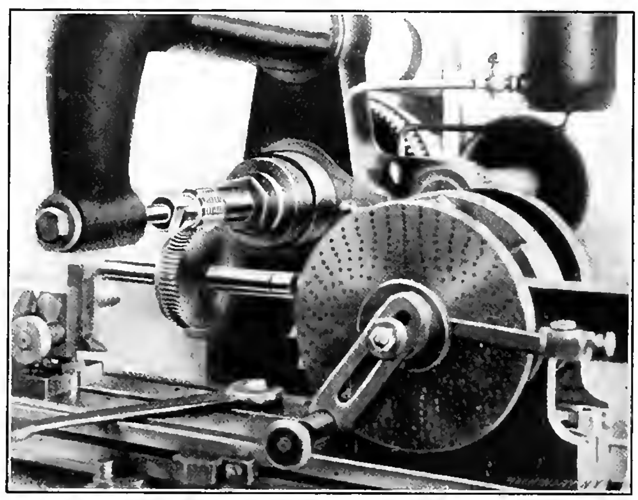

Fig. 113. Hobbing a previously Gashed Worm-wheel on Dead Centers in the Milling Machine.

Hobbing Worm-wheels in Machines Designed for Cutting Other Forms of Gearing.

With slight changes, the orthodox spur gear cutting machine can be adapted to hobbing worm-wheels. An example of such an adaptation is shown in Fig. 116, the machine adapted in this case being an automatic gear-cutter made by Eberhardt Bros. of Newark, N. J. In this machine the indexing mechanism is operated from the same splined shaft by which the spindle is driven, so that, to obtain the proper ratio of movement between the hob and the work, it is only necessary to connect the index gearing positively with the driving shaft, instead of using the intermittent indexing motion ordinarily employed. With the index gearing thus permanently connected with the spindle driving mechanism, proper change gears may be selected to give the required ratio of movement between the worm-wheel to be cut (which is, of course, mounted on the work arbor) and the hob, car

* Associate Editor of MACHINERY.

ried on the cutter spindle in place of the regular spur gear cutter. Another provision that has to be made is that for feeding the cutter into the wheel as the work progresses. This is effected in this case by lugs on the arms of the index wheel, which, rotating continuously, act on a link mechanism which operates an adjustable ratchet motion for the vertical

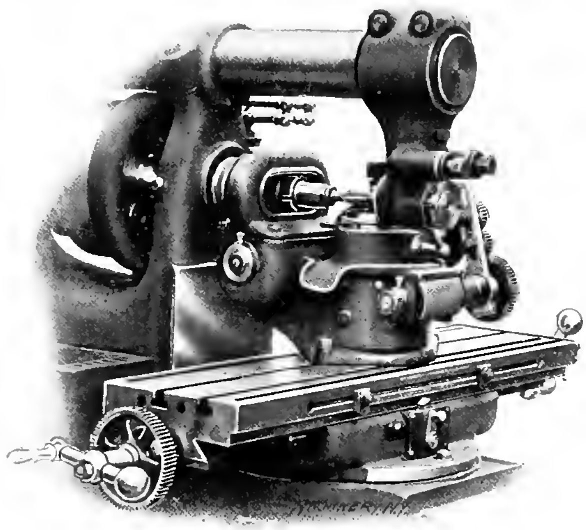

Fig. 114. Hobbing a Worm-wheel without Previous Gashing, in a Positively-driven Attachment in the Milling Machine.

feed shaft. This ratchet motion may be varied to give any rate of feed desired. By this means the work is fed down into the cutter as the operation progresses.

In Fig. 117 is shown a gear-cutting machine, made by Gould & Eberhardt, Newark, N. J., arranged for hobbing worm-wheels. In this case, also, the hob and the work are connected by means of the splined driving shaft and the index gearing, so that they revolve in unison and in the proper ratio. It will be seen that the work in the machine is so heavy as to make it advisable to support the outer end of the work arbor by means of the outboard bearing regularly pro-

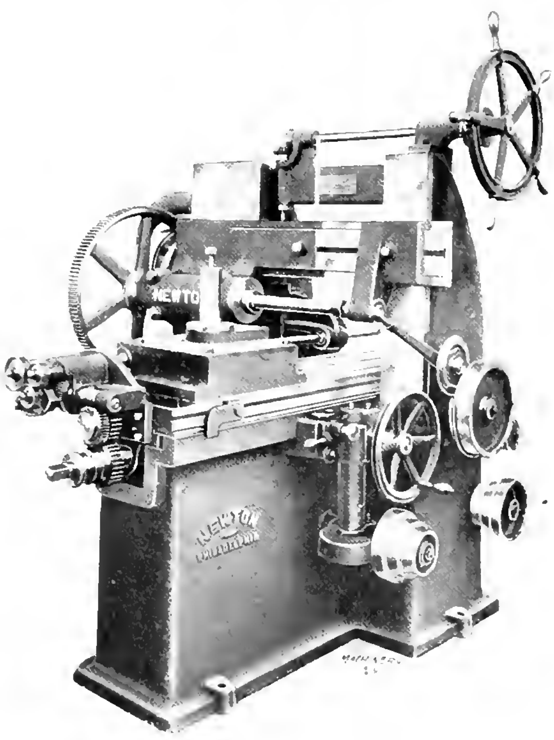

Fig. 115. Positive Hobbing Attachment used in the Newton Milling Machine.

vided for that purpose. To permit the downward feeding of the wheel, necessary to sink the cutter in to depth, the adjusting screw of this outboard bearing and the elevating screw of the work spindle head are geared together, so that they work in unison. The feed movement is applied to these two screws in such a way as to gradually lower the work into the cutter as the two revolve together.

All of the various gear-hobbing machines we have shown in Figs. 51 to 57 and 98 to 108 are adapted to the hobbing of worm gears without requiring special attachments of any kind. The only requirements in addition to the mechanism needed for hobbing spur gears, is the provision of a feed mechanism for sinking the cutter in to depth. The work saddles or tables of all these machines are, we believe, provided with this feed movement. The gearing for revolving the work and the hob in proper ratio with each other is of course embodied in the design of this type of machine. In Fig. 118 is shown one of these hobbing machines (the Grant-Lees machine of Fig. 104) engaged in hobbing a worm gear.

In addition to the machines we will describe later in which, though the hobbing process may be used, different movements are involved than in the cases we have been considering, special hobbing machines have been built from time to time, identical in their action with the various machines shown in Figs. 114 to 118. Most of these machines have been specially

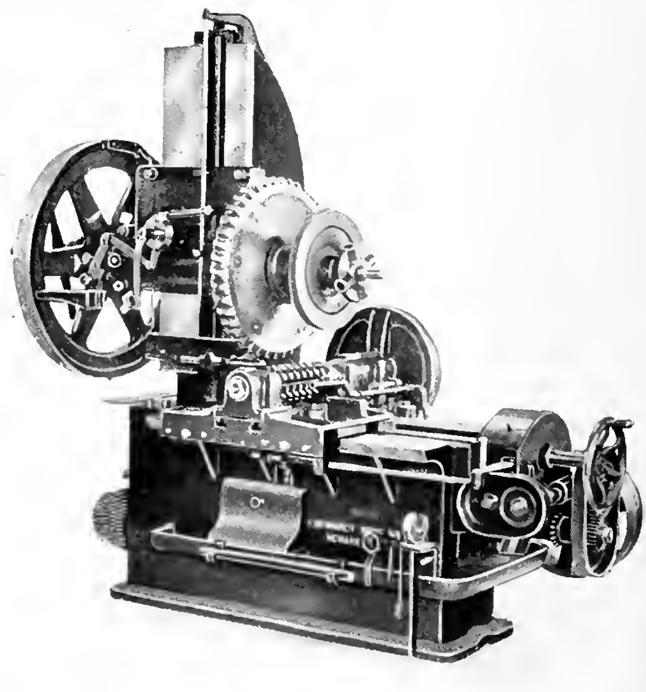

Fig. 116. Eberhardt Bros. Gear-cutting Machine arranged for Hobbing Worm-wheels, with Rachet Feed operated from Index Wheel.

built to suit the requirements of the user, without conforming to any settled type or design; very few of them have been built as a commercial product to be placed on the market.

The Fly-tool Method of Cutting Worm-wheels.

By providing suitable driving and feeding mechanism, it is possible to use a simple fly-cutter for forming the teeth of worm-wheels in place of the expensive hob used in the operations previously described. The movements required for this method will be understood from a study of Fig. 119. Here is shown in dotted lines a worm meshing with a worm-wheel, a portion only of whose periphery is seen. As previously described in referring to Fig. 109, such a worm, properly located with reference to a plastic blank and rotating with it in the proper ratio, will form accurate teeth in the latter by the molding-generating process. As we have also previously described, gashing this worm makes of it a cutter by means of which the same form may be given to a blank of solid metal. The teeth of such a gashed hob coincide with the outlines of the thread of the worm.

In Fig. 119, in full lines, is shown a cutter bar with a blade T_1 of the same outline as the thread of the worm and the tooth of the corresponding hob. In order to permit this single cutting tool to perform the function of the worm as it molds the plastic substance, or of the hob as it cuts its shape in the metal, it must be fed helically as the bar and work revolve, following the outlines of the imaginary worm from one end to the other as the cutting progresses. Beginning at the left, for instance, the blade may be fed helically in the line of the thread, passing through positions T_1 and T_3, until the feed finally runs out at the extreme right.

The methods of giving this progressive helical change of position to the fly-cutter are various. It would be possible, for instance, to so connect the feed-screw by which the cutter-bar is advanced with the rotating mechanism for the bar, through differential and change gearing, that a rotating movement due to the axial feeding of the latter would be added to or imposed upon the rotation due to its connection with the work, just as, in Fig. 97, the rotation due to the downward feed of the cutter slide is combined with that due to the connection with the cutter spindle for rotating the work. If the proper change gears were selected so that, with the spindle- and work-driving mechanisms stationary, the feeding forward of the cutter bar would rotate the latter at the proper rate to give the lead of the work, the blade would evidently follow the path of the thread of the imaginary worm, as shown at T_1 and T_3 in Fig. 119. Owing to the action of the differential

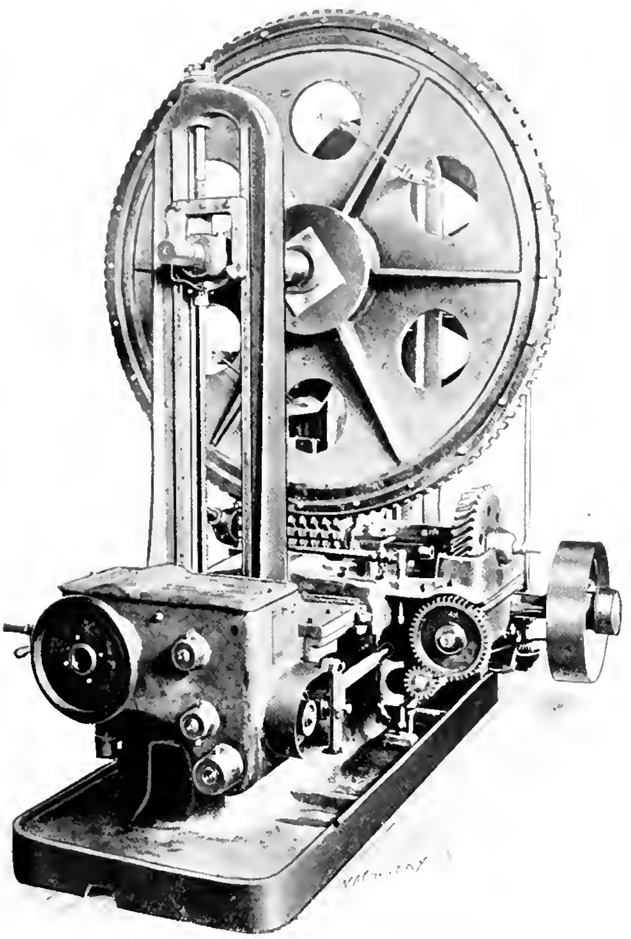

Fig. 117. Gould & Eberhardt Gear-cutting Machine arranged for Hobbing Worm-wheels.

mechanism, it would still follow the thread of the imaginary worm, even if the latter, with the spindle- and work-driving mechanism, were in motion.

Another method consists in combining in the work, also by differential gearing, a rotation due to the revolving of the cutter with a rotation due to the axial feed of the cutter bar. That this produces the same effect as the previous arrangement will also be understood from Fig. 119.

First, let the rotation of the cutter be arrested. If the cutter-bar with a worm mounted on it, such as shown by the dotted lines, be now fed axially in the direction of the arrow, the positive connections between the feed and the work spindle through the change gearing and the differential gearing, will cause the work to rotate uniformly with it. If the feed is arrested after a time, and the bar is started revolving, the imaginary worm mounted on it will still be kept in proper mesh with the work, owing to the change gear connections between the cutter-bar and the work spindle, acting through the differential gearing. As we have previously explained, the office of the differential gearing is to combine in the work the rotation due to the feeding and that due to the rotation of the worm, in such a way that they can take place simultaneously as well as separately; so that it will be seen that if the connections are properly made, the worm may be fed endwise and revolved at the same time, always keeping in perfect step with the work.

Now, the imaginary worm and the fly-tool are both firmly fixed to the cutter bar, so that the fly-tool must always follow the movements of the imaginary worm. Being set to coincide with the outlines of the worm thread at the start, it must always coincide with those outlines, and since the worm is never out of step with the work, the fly-tool will never be,

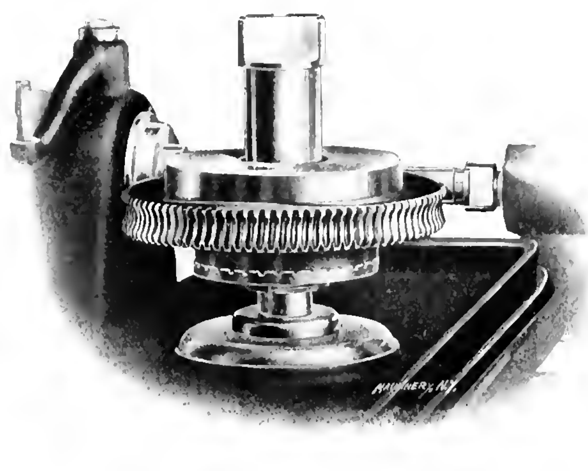

Fig. 118. Worm-wheel being finished in Grant-Lees Gear-hobbing Machine.

either. It will thus be seen that it will always follow the helical path of the dotted lines in Fig. 119, in moving, for instance, from T_1 to T_3. Revolving in the position T_3, T_4, T_2, etc., the work, as shown in the dotted lines of T_2, will always be in proper relation with the fly-tool, as it is with the imaginary worm.

With this arrangement, if the change gearing connecting the driving mechanism of the cutter-bar and the work were disconnected while the bar was fed through from left to right, the rotary motion given by the connection of the feed of the bar with the work would shape one tooth. If, on the other hand, the gearing connecting the feed of the bar with the rotation of the work were disconnected while the connections between the drive of the bar and the work were in operation, the cutter would partially shape each tooth of the work. By combining the two movements in the differential gearing, the cutter perfectly forms all the teeth.

Machines for Cutting Worm-wheels by the Fly-tool Method.

The first machine we show employing the progressive fly-tool principle was also, so far as the writer is aware, the first

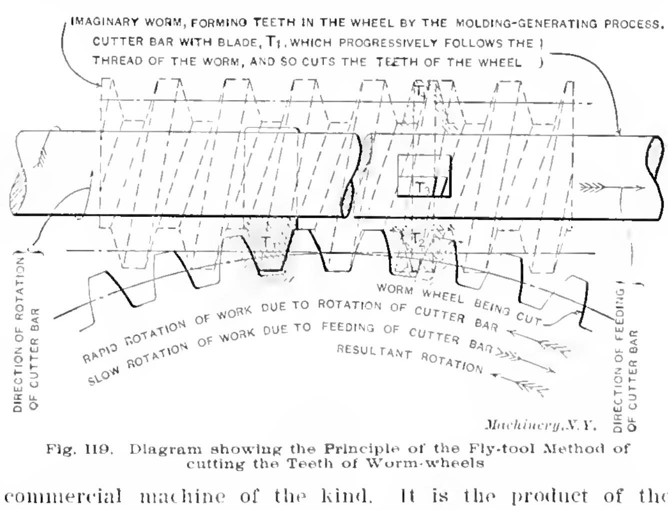

Fig. 119. Diagram showing the Principle of the Fly-tool Method of cutting the Teeth of Worm-wheels

commercial machine of the kind. It is the product of the Nya Aktiebolaget Atlas, of Stockholm, Sweden. This is the same machine that we have previously described, and illustrated in Fig. 34; in Figs. 120 and 121 it is shown set up for cutting worm-wheels. The machine is driven from cone pulley *A*. Shaft *B*, to which this pulley is keyed, is connected by the bevel gearing shown with vertical splined shaft *C*, from which, through change gears *D* and driving gear *E*, the fly-cutter arbor *F* is driven. Gearing in case *G* connects shaft *C* with horizontal driving shaft *H*, which rotates the worm

for revolving the work table and the work. Change gears D thus furnish the means for rotating the work and the hob in the proper ratio with each other.

Pulley J is connected inside the frame to the feed shaft K, seen in the end view. K is connected through change gears L and M with shaft N, which also leads to casing G. Change

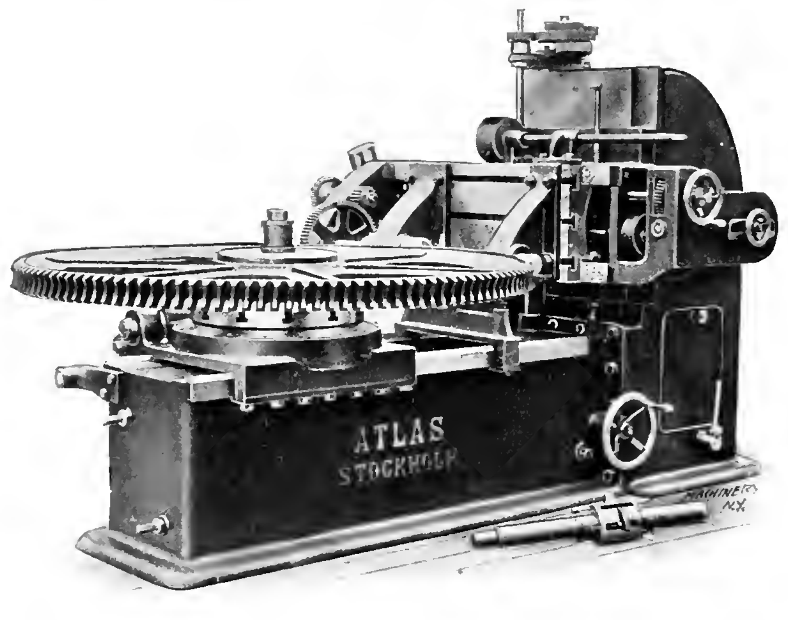

Fig. 120. The Atlas Gear-cutting Machine, also shown in Fig. 34, arranged for Cutting the Teeth of Worm-wheels by the Fly-tool Process. Note Quadruple Fly-tool on the Floor opposite the Machine.

gears M are not altered for cutting worm gearing, being employed for indexing in the case of spiral and spur gears. Change gears L, however, are set to the lead of the worm. Shaft K, besides being thus connected to shaft N, drives, through suitable shafts and gearing, feed screw O, by means of which is traversed on the cross rail the slide on which the fly-cutter arbor is carried, this arbor F being driven by a spline in the hub of gear-wheel E. Casing G contains differential gearing which combines the movements of shafts C and N in shaft H. It will thus be seen that by setting change gears D the work will be given a rotation to correspond with

throughout, being of pleasing design and simple construction, considering the variety of work it is intended to perform. This work includes, as we have before mentioned, the cutting of spiral, internal, spur and worm gears.

Another machine of the same class (which we have previously described in MACHINERY*) is shown in Figs. 122 and 123, built by Eberhardt Bros. Machine Co., 66 Union St., Newark, N. J. In this tool the work table is stationary as to its position on the bed, while the column carrying the cutter slide is adjusted in and out to suit the diameter of the work, thus reversing the conditions that obtain with the Atlas machine in Fig. 120. Another change in the construction is in the provision for the axial feeding of the cutter-bar. In the case of this machine, instead of supporting the cutter on a slide which is fed along the cross-rail, as in Fig. 120, the supports for the bar are stationary, the latter being fed through them by a sliding head (P in Fig 123) at the outer end of the cross slide. By this means, the cutter-bar is brought much closer to the face of the column, and one of the sliding joints between it and the column is eliminated. Both of these features tend toward rigidity and consequent increase in output.

The mechanism will be easily understood from a study of the diagrams of Fig. 123. Driving pulley A is connected by gears B (which are changed to give the desired spindle speeds) with shaft D, which, by means of bevel gears C, in turn drives vertical splined shaft W, by means of which connection is made with the worm and worm-wheel E which drives the cutter-bar. Shaft D is continued along the bed to change gears F, which are changed to give the proper ratio between the rotation of the cutter and of the work. These gears drive one of the members of the differential gearing X.

Feed cone J is connected by gearing K with shaft Q. The latter, through two sets of worm gearing and vertical shaft L, drives horizontal shaft M on the cross rail. From here, through gears N, the movement is led to feed-screw O by which head P is traversed to feed the cutter bar axially. Q

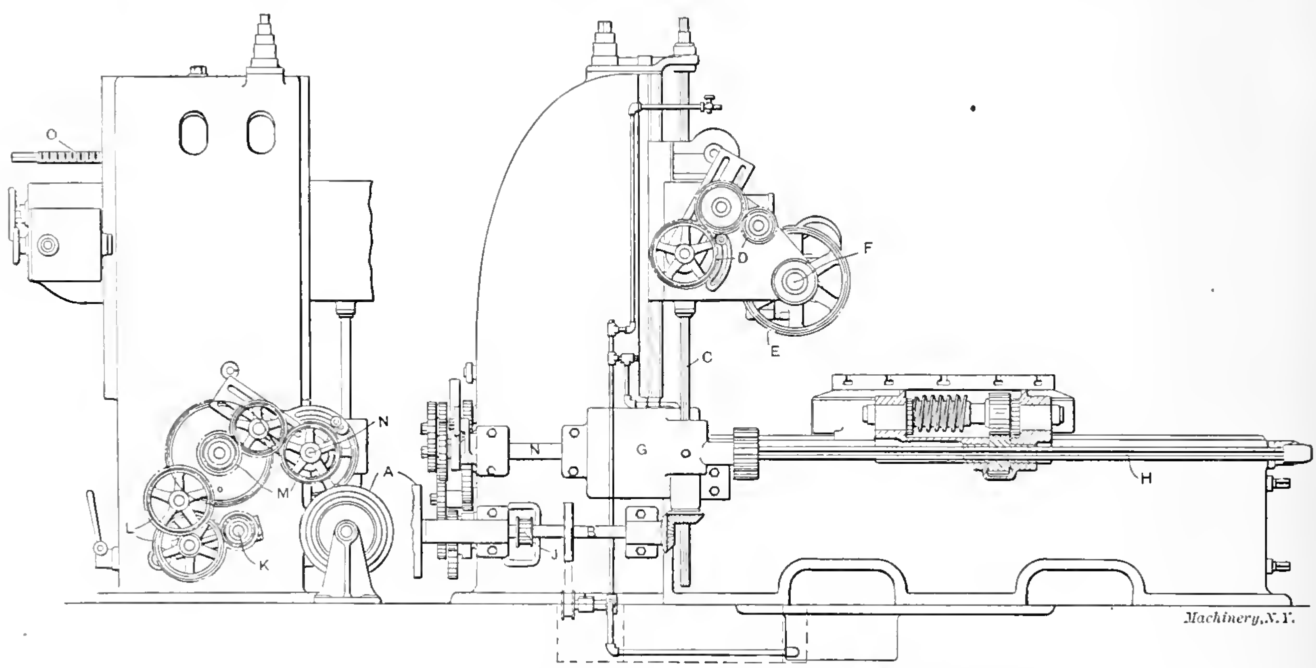

Fig 121 Diagram of the Driving Connections of the Atlas Gear-cutting Machine shown in Fig. 120.

the ratio of the number of threads in the worm and the number of teeth in the gear, while by setting change gears L properly, the work will be rotated in unison with the axial feeding of the cutter-bar as in moving T_1 to T_2 in Fig. 119, thus filling the necessary conditions.

Aside from the ingenuity of the mechanical movements thus described, this well-known machine is carefully planned

is also connected by change gears R and the worm gearing shown with differential gearing X; gears R are selected to agree with the pitch diameter of the work. In differential gearing X, motions from shafts D and Q are combined to rotate the work table and the work in the same way as in the

* See article "Generating a Large Worm-Wheel" in the October, 1907, issue of MACHINERY, Engineering edition; and "New Tools of the Month" in the December, 1904, issue of MACHINERY.

Atlas machine, and as required in Fig. 119. For small blanks, the spindle is rotated through spur gearing at H. For heavy work, however, a driving pinion is directly connected with

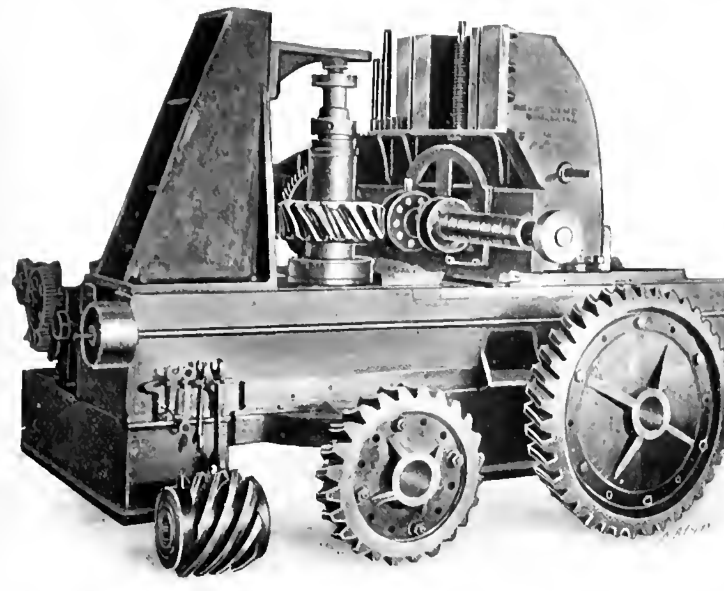

Fig. 122. Eberhardt Bros. Fly-tool Worm-wheel-cutting Machine, with Samples of Work.

teeth on the inner rim of the work table, so that a very powerful drive is obtained.

This machine can also be arranged to use the ordinary cylindrical hob, in which case the feed of head P is thrown out, and the column U is fed inward on the bed by means of screw V, so that the hob enters the blank in the same manner as for the machines in Figs. 113 to 118.

In Figs. 124 and 125 are shown half-tone and line engravings of a fly-tool gear-hobbing machine built by Henry Wallwork, Ltd., Redbank, Manchester, England. The action of the fly-cutter on the work is identical with that in the machines previously described. The work is carried by the face-plate and vertical spindle A, while the fly-tool B is mounted in the cutter spindle C. This latter is supported in slide D which is adjustable on the top of the bed for the diameter of the work, and is fed by screw E. The fly-tool starts in at one side of the work and feeds longitudinally through it, the work and tool revolving together, as in previous cases. A peculiarity of this machine, however, is that no differential mechanism of any kind is employed. The way in which this is avoided may be explained thus:

Suppose that in the Eberhardt machine in Fig. 123, the fly-cutter be engaged in hobbing a worm-wheel of 100 teeth, to mesh with a single threaded worm. If, then, the fly-cutter makes 100 revolutions per minute, the worm will make one revolution per minute. If now the cutter spindle be fed longitudinally with a certain definite feed, the differential mechanism will modify the rate of rotation of the worm, making it slightly more or slightly less than one revolution per minute, depending on the rate of the feed, and its direction as compared with the direction of rotation of the work. We may say, then, that if the cutter revolves at a certain number of revolutions per minute and feeds at a certain fraction of an inch per minute, the work will rotate at a certain number or fraction of a number of revolutions per minute. Where the gearing required with the Eberhardt machine would give a ratio of 100 to 1 between the hob and the work, as modified by the feed this ratio might be 100.0073 to 1, for instance. It will thus be seen that since these conditions remain constant until the work is completed, the differential mechanism may be dispensed with entirely, if we select the change gears connecting the hob and the work to agree with the new rate of turning of the work, as modified by the feeding of the hob.

This is what is done in the Wallwork machine. The driving shaft F is connected with the driving cone G either directly or through back gears, as may be required. This shaft, through worm-wheel H and change gears shown in Fig. 124, drives feed-screw E. It also has keyed to it worm J, meshing with the indexing worm-wheel by which the work on the vertical spindle A is rotated. At the extreme right in Fig. 125 this driving shaft is connected with cutter spindle C by change gears K, mounted on a sector which is provided with a worm-wheel adjustment at L for setting it, owing to its great weight. It will thus be seen that the feed, the work, and the cutter-bar are all connected by positive gearing. For setting up the machine, suitable change gears for connecting screw E with the driving-shaft mechanism are used to give the desired rate of feed. Then change gears K are selected to give the

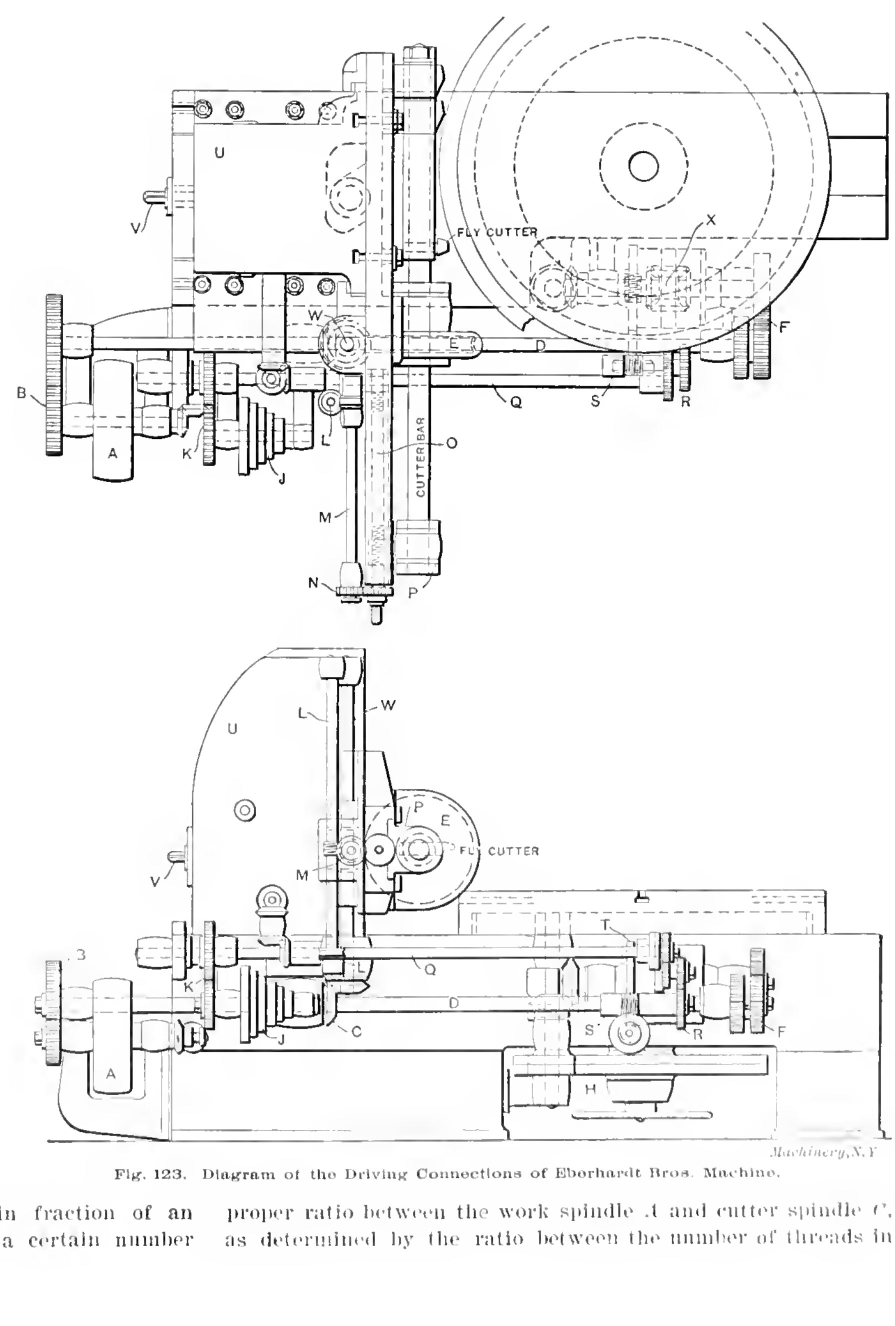

Fig. 123. Diagram of the Driving Connections of Eberhardt Bros. Machine.

proper ratio between the work spindle A and cutter spindle C, as determined by the ratio between the number of threads in

the worm and the number of teeth in the worm-wheel, modified (as explained) by the rate of feed. These change gears K are calculated by a formula which is somewhat puzzling to derive, but not difficult to use.

This arrangement would seem to possess both advantages and disadvantages as compared with the differential scheme. It results in a much simpler mechanism, but it makes it impossible to change the feed without changing, as well, the gearing connecting the work spindle and the hob, so that changes of feed are not easily made.

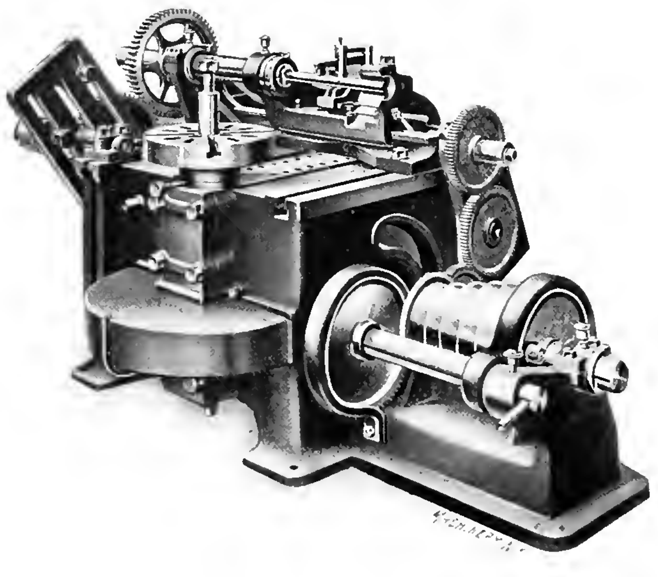

Fig. 124. The Wallwork Machine, which cuts the Teeth of Worm-wheels with a Fly-tool without using Differential Gearing.

Cutting Wheels for Multiple Threaded Worm by the Fly-tool Process.

The method of cutting multiple threaded worms was not described in discussing the principle of the fly-tool process. At the base of the machine in Fig. 120 is shown a form of tool which may be used for cutting wheels to match with multiple threaded worms. In this case, in which a quadruple thread has to be provided for, a cutter head is provided in which four blades are carried, spaced equidistant. The feeding through of these four blades simultaneously finishes the worm-wheel complete in one operation. An alternative method would be to index the cutter bar with relation to its driving gear, giving it three positions for a triple-threaded worm, four for quadruple threads, etc. This could be done by a notched index plate and locking bolt, or by unmeshing the gearing from engagement at some point in the driving train, and shifting it the required number of teeth before re-engaging it.

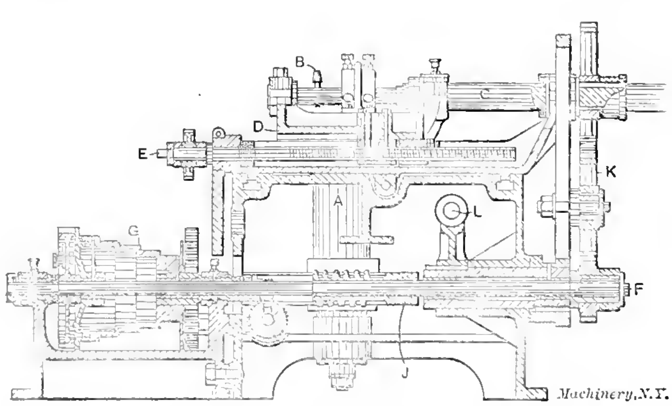

Fig. 125. Vertical Section through Wellwork Worm-wheel Generating Machine.

The Tapered Hob for Cutting Worm-wheels, and Machines for using it.

In Fig. 126 is shown a gear-hobbing machine built by J. E. Reinecker, of Chemnitz-Gablenz, Germany. This machine has the movements required for performing the work of the Atlas and Eberhardt machines, since it combines in the rotation of the work a movement due to the longitudinal feed of the cutter spindle and a movement due to the rotation of the cutter spindle. It is ordinarily used, however, with a hob instead of a fly-cutter, the hob being of the special form shown in Fig. 127. This hob, as shown, is tapered. It is placed on the cutter spindle and fed axially past the work in the same way that the fly-tools in the previous cases are fed. The combined movements cause the hob to follow spirally in the path of the thread of the imaginary rotating worm. The small end of the hob first commences to work and as the cutter spindle is fed forward, the cut is taken successively on larger and larger diameters until finally, when the tool has passed clear through, the full-sized teeth at the rear end of the hob complete the work. The machine is practically identical with the universal gear-cutter by the same maker, previously shown in Figs. 85 and 86, it being adapted, as there shown, to cutting worms by the same process. The differential mechanism used is the same as in Fig. 86, the axial feed of the cutter spindle being applied to shaft M, while the rotative movement of the cutter spindle is connected with shaft H, the two being combined in gears J, L, and N to rotate the indexing wheel G.

The original machine for this purpose, built by Mr. Reinecker, employed a different form of combining or differential movement. It is shown diagrammatically in Fig. 128. In this case, the tapered hob is connected by change gearing with the worm driving the indexing wheel, as before. The worm, however, is mounted on a slide, allowing it a considerable range of axial movement. This axial movement is controlled by a screw and nut, as shown. This screw is connected by change gearing with the screw by which the taper hob is fed. It will thus be seen that the feeding of the hob rotates the work by shifting the index worm lengthwise, while the rotating of the hob rotates the work through the rotation of the index worm and worm-gear. The two movements are independent of each other, but are combined with the same effect as produced by the "jack-in-the-box" differential gearing previously described. With this arrangement, the ratio of table movement and lengthwise worm movement should be proportioned in the ratio of the pitch diameters of the worm-wheel being cut, and the index worm-wheel. The reason for abandoning this construction was doubtless its limited range of movement, which, though enough for the hobbing of worm-wheels, was not enough (when applied to the universal gear-cutting machine) for cutting spiral pinions of great helix angle.

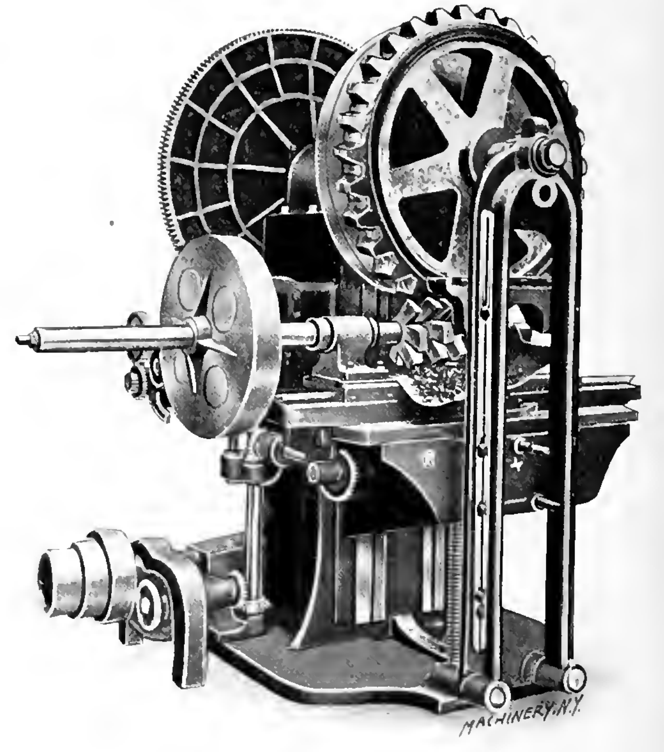

Fig. 126. Machine for Generating Worm-wheels with a Taper Hob; built by J. E. Reinecker, Germany.

The tapered form of hob and the method of using it are of course as applicable to the Atlas, Eberhardt, and Wallwork machines as to the one we have just been describing, and it has doubtless been used on all of them.

The Various Methods Compared.

Each of the various methods of cutting worm-wheel teeth which we have described has its field of usefulness. Gashing, as we have seen, is applicable either to cheap, rough-and-ready work on the one hand or, on the other hand, to the cutting of worm-wheels which are not required to transmit a great amount of power, but in which the highest degree of accuracy is required. The process of hobbing previously gashed blanks requires the least degree of specialization in the machinery used, the ordinary milling machine having all the movements and adjustments required. This process is perhaps the one followed in most shops in making worm gearing of small size. The arrangement (such as shown in Figs. 114 to 118) in which the work and the hob are positively geared together so that previous gashing is not required, is quicker than the last mentioned method, but requires special machines or attachments. The fly-tool method requires a still more elaborate machine, but is the least expensive of all in the matter of cutting tools. A large hob is an exceedingly costly appliance, and raises the cost of production to an alarming degree, particularly when but one worm-wheel has to be cut. The use of a simple fly-cutter, which may be ground accurately to size after hardening so that all inaccuracies are avoided, is thus the cheapest as well as the most accurate means of cutting a large worm-wheel. Where many large wheels of the same size are to be cut, the taper hob method would seem to be a most satisfactory one. A high degree of accuracy could be maintained, as the full size teeth at the back end of the hob do not come into play until the finishing cut is reached, so that they tend to preserve their shape indefinitely. Another item that tends to accuracy in this method of hobbing is the fact that the distance between the work arbor and the cutter spindle, is fixed at exactly the distance between the axis of the worm and the worm-wheel in the finished gearing. This is a refinement of greater importance than is usually realized, and one that is not always looked out for in hobbing operations in which the cutter spindle is fed in toward the work. Hobbing by this method is, of course, more rapid than by the fly-tool process employed on the same machines, though the latter is not a tedious operation by any means, as a solidly supported and powerfully driven tool can be given a heavy feed, taking off chips of respectable thickness.

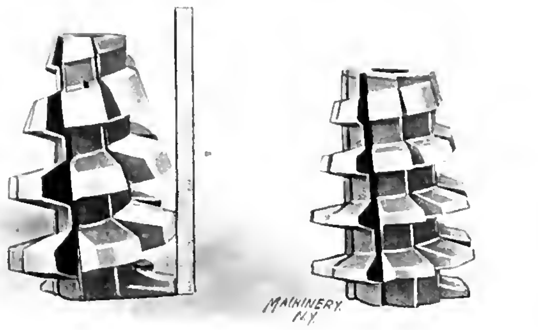

Fig. 127. Style of Hob used for Machine shown in Fig. 126

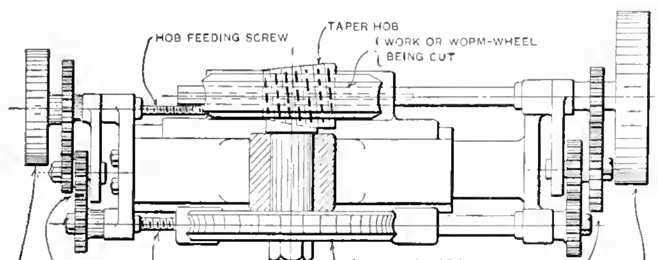

Fig. 128. Diagram of Original Form of Mechanism for Generating Worm-wheels with Taper Hob.

The methods followed in cutting the other member of this form of gearing, the worm, have already been described in connection with the machine for cutting helical and herringbone gears.

The Manufacture of the Hindley Worm Gearing.

A form of gearing which has come into extensive use of late years in elevator service and other applications in which considerable power has to be transmitted, is shown in Fig. 129. This is commonly known as the Hindley "worm" gearing, though it is not worm gearing at all, being entirely different in its action. It should properly be classed as "globoid" gearing, a term which, so far as the writer knows, was first employed by Prof. Reuleaux. The characteristic feature of its action is the fact that contact takes place on or near the axial plane of the worm, as shown in the engraving. Unlike other forms of gearing, neither member of this pair has a pitch line or a pitch diameter. The form of gearing is an old one, but it has only recently come into practical use.

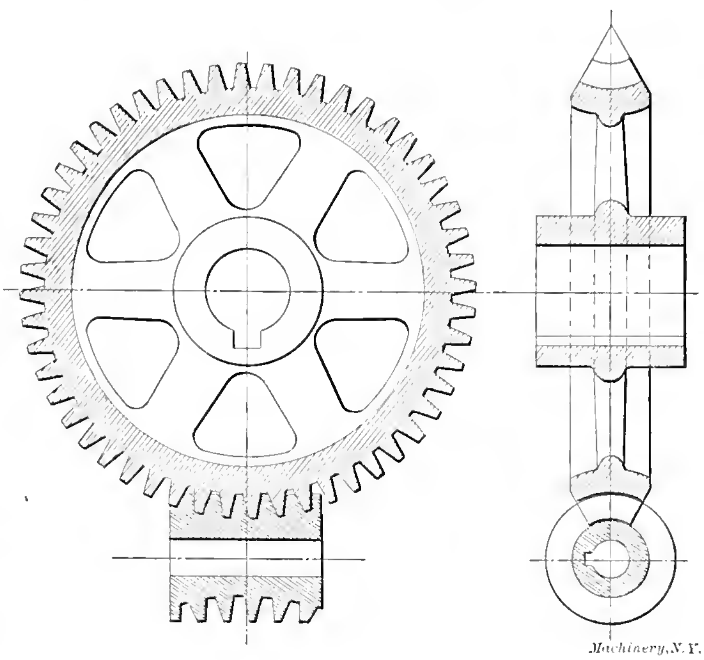

Fig. 129. The Form of Globoid Gearing generally known as Hindley Worm Gearing.

It is often stated that this style of gearing gives surface contact, but this statement can scarcely be true. The impression doubtless arose from a consideration of sections on the two planes shown in Fig. 129, in which it may be seen that the wheel is curved to fit the worm, and the worm is curved to fit the wheel, thus giving the appearance of intimate contact over the whole face of the tooth. It is probable that the surfaces more nearly match than in ordinary worm gearing, giving a nearer approach to surface contact.

Any positively operated worm-wheel hobbing attachment or machine, such as shown in Figs. 114 to 118, may be used. The manufacture begins with the cutting of the worm, which is effected as shown in Fig. 130. The blank is mounted on the spindle of the machine ordinarily occupied by the hob, while a large diameter disk provided with cutting tools clamped to its face is mounted in place to represent the worm-wheel. The cutting tools mounted on this disk each represent a tooth of

the wheel, being of the same shape and cutting on the same diameter. They are clamped to the face of the disk in such a way that the whole arrangement represents accurately a central section of the worm-wheel, of which (in this particular case) only every other tooth is used. This cutter and the worm to be cut are geared together, and slowly fed toward each other as when hobbing worm-wheels. The teeth, cutting deeper and deeper into the blank, finally form it into the characteristic "hour-glass" shape of the Hindley worm.

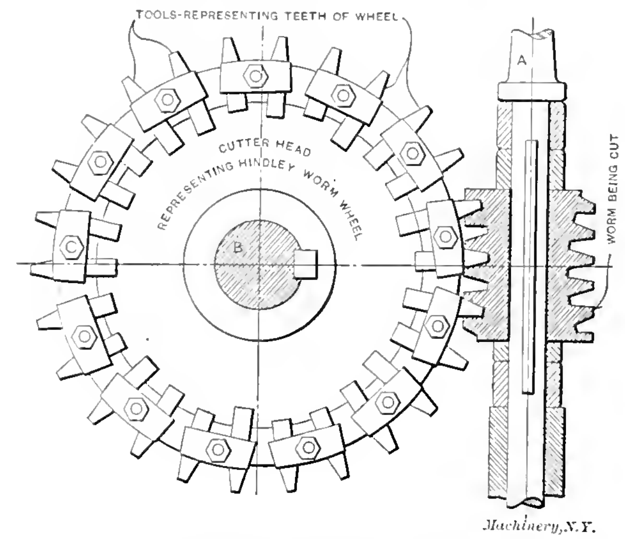

Fig. 130. Method of Cutting Hindley Worm with Rotary Cutter having Teeth corresponding with those of the Wheel.

In cutting the wheel, the process is reversed, as shown in Fig. 131. A hob cut in the same way as the worm in Fig. 130, but with its teeth relieved, is fed into the wheel blank and cuts the teeth in a way exactly identical with the method followed in hobbing worm-wheels, the only difference in the process being the difference in the shape of the hob and in the shape of the teeth produced.

The actual operation of hobbing the worm and the gear is a little more complicated in practice than is indicated here, as certain corrections have to be made for interference that require cutting the worm first with a cutter head of the same diameter as the wheel in the way we have shown, and a second time with a head of somewhat larger diameter. The necessity for this it would take too long to explain in an article which deals particularly with machines and tools, rather than with the theory of gearing.

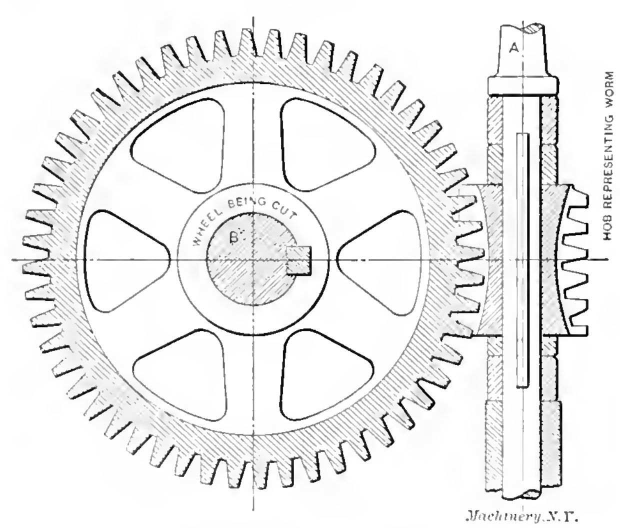

Fig 131. Cutting the Teeth of the Wheel with a Hob corresponding with the Worm.

This concludes a discussion of machines and methods for cutting the teeth of worm-wheels. The next installment will deal with bevel gear cutting processes.

On page 592 of the May installment of the series of articles on gear-cutting machinery, a record was given for hobbing spur gear teeth in which it was stated that the time for cutting a cast iron wheel of 84 teeth, 4 inches circular pitch and 2½ inches face, was 1 hour and 21 minutes. There was an error in this statement in that the pitch should have been given as 4 *diametral*. This, of course, makes the achievement somewhat less spectacular.

It should also be noted that a misprint occurs in the title of Fig. 103. The word "Pfauder" should read "Pfauter."

* * *

RELIABILTY OF MOTOR DRIVES FOR MACHINE TOOLS.

The reliability of the individual motor drive for machine tools is indicated by an item in the *American Engineer and Railroad Journal*. Probably a greater proportion of the machine tools in the McKees Rocks shops of the Pittsburg & Lake Erie Railroad are equipped with individual motor drives than in any other railroad shop in this country. During the year 1907 the average delay to tools, due to motor troubles, was about seventeen minutes. There are 84 motors in use for driving machine tools, and during the year there were only 93 delays, or an average of 1.1 per motor per year. The longest delay was 1¼ hour. The total time of all delays during working time was 26½ hours. Assuming an average rate of 27½ cents per hour for the machinist's wages and a surcharge on each machine of 50 cents per hour, would bring the total loss due to delays to only about $20.00 for the year. These delays include all time lost due to the failure of electrical apparatus at the machine. As a matter of fact the greater part of the time lost was due to trouble with the controllers and not with the motors themselves. When it is considered that these motors operate on the multiple voltage system, the controllers furnishing 21 speed steps over a range of about 3 to 1, it is remarkable that so little trouble occurred, especially as these controllers were among the first of this type that were placed in operation.

VACUUM BRAKE EXPERIMENTS.

Extensive experiments have been carried out on the Austrian government railways with automatic vacuum brakes on freight trains. A long train, composed of 70 cars loaded with coal and weighing 44,000 pounds each, was fitted with automatic brakes. Numerous trials were carried out with this train on lines having different road conditions, and, in order to ascertain the effect on steep grades, the trials were repeated on a line with gradients of from 3 to 3.1 per cent. In this experiment the train was composed of 70 freight cars and 5 passenger cars, interspersed for observation purposes. Twenty-nine of the total 75 cars carried load, and 46 carried no load. The weight of the train including locomotive and tender amounted to 1,201.7 metric tons (1,322 short tons) and the total length of the train was 2,620 feet, or nearly half a mile. To enable observations and simultaneous readings to be taken, the locomotive and each of the 5 passenger cars were fitted with telephones and measuring apparatus. The results are said to have been very satisfactory, and will form the subject of a publication shortly to be issued by the Austrian government railways. Considering the length of the train, the brake valve on the last car came in action very rapidly, only 2.2 seconds being required for the brakes to be applied on the last car after they had been applied on the locomotive. This corresponds to a brake speed of 1,191 feet per second.

* * *

The old, time-honored division of the study of mathematics into algebra, analytic geometry, and differential and integral calculus has been discarded by the Massachusetts Institute of Technology, and the whole field of the science of mathematics will be covered simultaneously. The principles of each of the old subjects are to be introduced, and all subjects developed, together. This change has been deemed advisable in order to give the students a better grasp of mathematics as a whole, and an adequate idea of the interdependence of the various branches, and also in order to accustom the students to the use of judgment in the selection of methods best adapted to the problem in hand. Undoubtedly this early introduction of calculus and analytic geometry will be found very advantageous. The whole system is intended to develop a more thorough study of mathematical principles and to do away with that kind of mathematical study which consists in mere mechanical training of the use of formulas.

MAKING WATCH PARTS IN THE COMMERCIAL AUTOMATIC SCREW MACHINE.*

Watchmaking by automatic machinery is essentially an American development. Previous to the inaguration of the industry in Waltham, Mass., Switzerland held the lead in the manufacture of watches on a large scale. The hand processes there followed are the result of long experience and careful study, and the work is highly organized so far as the division of labor is concerned, separate workmen specializing on single operations, which they repeat day after day, as long as they live and work. Swiss watches are not hand-made in the sense in which we apply that term to custom-made footwear, for instance. Of course, lathes, presses, gear- and pinion-cutters and other power-operated machines are used in the various operations required. These tools have, however, been largely operated by hand in the same way that ordinary engine lathes are operated, as distinguished from the mechanically controlled movements of the automatic gear-cutter or screw machine.

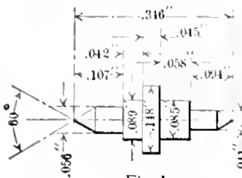

Fig. 1. Blank for Watch Pinion made by Forming, from Tool Steel Stock.

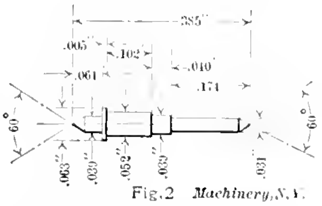

Fig. 2. Blank for Watch Wheel Staff made by Turning, from Tool Steel Stock.

In American watchmaking practice the automatic principle has been developed to an extent that is little short of marvelous, the parts not only having complicated operations performed on them in single machines, but even being transferred from one machine to another automatically, through a long series of operations. The various manufacturers of watches in this country have, as a rule, each developed their own machinery, employing competent designers and mechanics for the purpose.

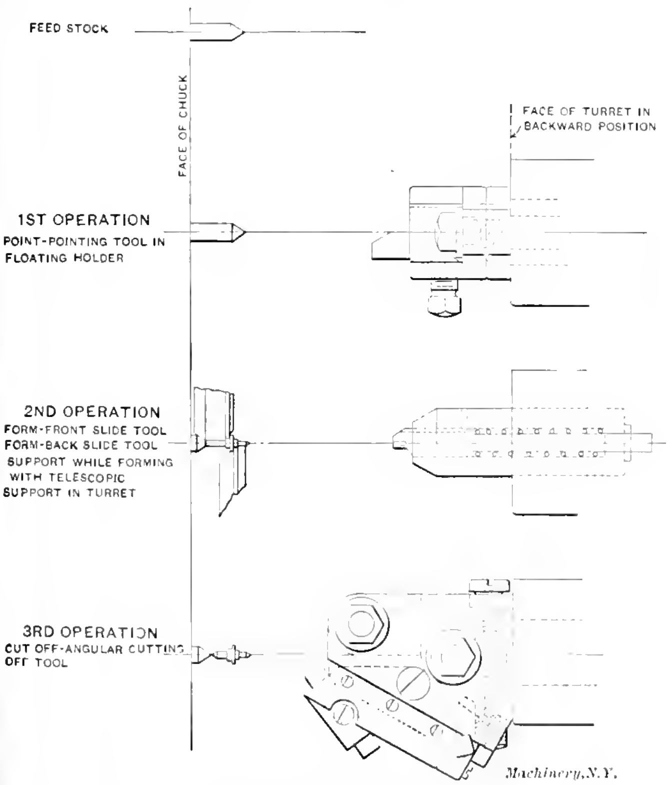

Fig. 3. Tools Used and Order of Operations Followed in making the Pinion Blank shown in Fig 1.

A notable exception to this general rule, however, may be instanced in the case of the automatic screw machine made by the Brown & Sharpe Mfg. Co., of Providence, R. I., which has been invading this highly specialized field of watch making, and has been very successful in the work it has been called on to perform. Curiously enough, considerable favor has been met with by this machine in the Swiss watchmaking field, committed though it is by years of precedent, to the use of the hand-operated machine. This interest in the American automatic screw machine may therefore be taken as an evidence of the inroads of American ingenuity on Continental conservatism.

The Work for which the Machine is Used.

The particular work for which this tool has been applied is in the turning of the larger pinion blanks and staffs (the slender shafts or spindles on which gears and pinions are mounted). These parts have to be made, it goes without saying, with a high degree of accuracy, both as to their dimensions and as to their concentricity, or the trueness with which they run on centers. Accuracy of dimension is largely a matter of careful, close fitting of the machine, so as to have all the slides and their movements accurately aligned and moving freely, yet with the smallest possible allowance for lubrication. This matter is carefully looked out for in the tool under consideration, though it is probable that for the most minute of the minute work used in watches, it would be impossible to make the fitting close enough on so large a machine. The space required for oil for the journals, for instance, would involve inaccuracy which could not be permitted. For work, however, of the size shown in Figs. 1 and 2, this machine has been found eminently satisfactory. We will illustrate and describe the methods and tools used in producing these pieces, these matters being fully as important as the design and workmanship of the machine in producing the accurate results required.

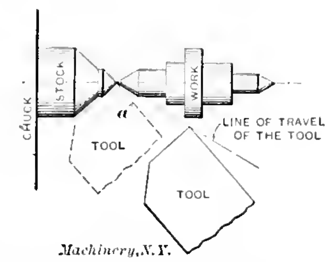

Fig. 4. The Cone Point Turning and Cutting-off Operation.

Tools and Operations for Making a Pinion Blank.

We will first follow the tools and operations used in making the part shown in Fig. 1. This is one of the larger pinion blanks used in a Swiss watch. In making it by the old-fashioned methods, a blank is cut off and formed at each end with the cone points shown, which are supported in female centers in the lathe, where successive cuts are taken to bring it to the required dimensions, the same as would be done for much larger work in the engine lathe. This operation is practically duplicated in the automatic screw machine, so far as turning on centers is concerned.

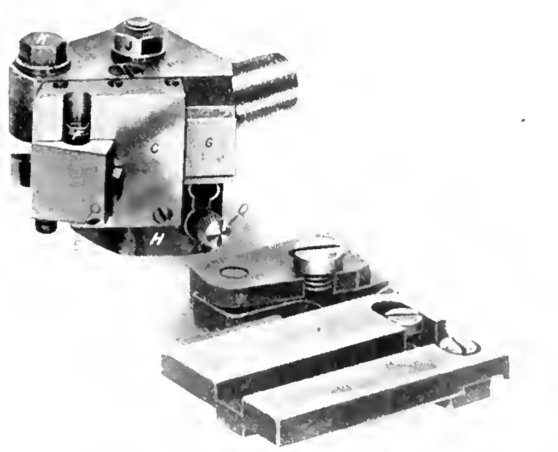

Fig. 5. Cone Point Turning and Cutting-off Tool for Pinion Blanks and Staffs, and the Pusher by which it is operated from the Cross Slide

The order of operations and the tools used for each of them may be followed from Fig. 3, which is a reproduction of the operation sheet furnished to the purchaser of the machine. The first thing that is done is the feeding of the stock. No stop is used for the stock to feed against, the feeding mechanism being accurate enough to always leave a few thousandths of stock for the first operation, which is that of pointing the end of the bar to form the outer cone-shaped pivot

* For a description of this machine see the article published in the September, 1903, issue of MACHINERY, on "Directions for Camming the Brown & Sharpe Automatic Screw Machine."

point of the work. This is done by a tool mounted in a "floating" holder, which may be firmly clamped in the proper position for forming an accurately pointed pivot each time the machine is set up. With this tool the accurate alignment of the turret with the axis of the spindle is not absolutely necessary; in fact, no alignment accurate enough for this purpose could be permanently maintained.

This piece of work is short enough and stiff enough so that it can be turned entirely by circular forming tools

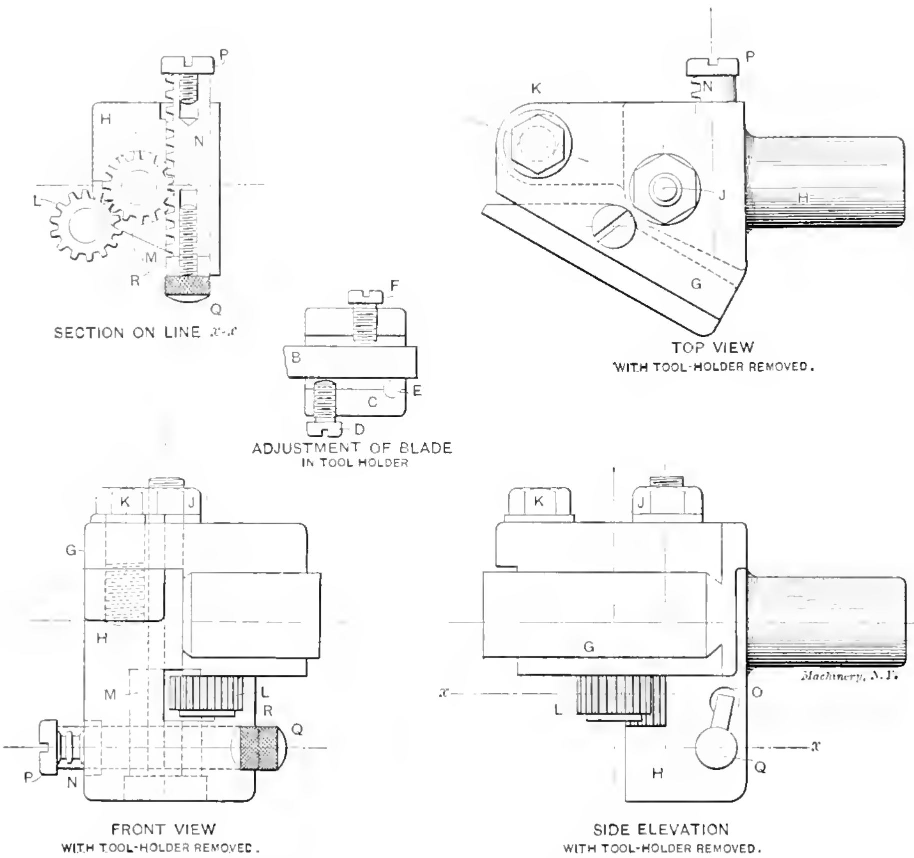

Fig. 6. Details of Construction of the Cone Point Turning and Cutting-off Tool shown in Fig. 5.

mounted in the cross slide. These forming tools are shown at work in the second operation in Fig. 3. The one in the front cross slide turns the two diameters forward of the largest diameter on the work, while the rear cross slide turns the two diameters on the other side of the collar, and rough turns the projecting end of the stock for the cone point of the next part to be made. While these operations are in progress, the outer end of the work is supported in a delicate female center, in a spring plunger held in the turret.

It was stated that this part is practically turned on centers. The significance of this statement will be understood by studying the second operation, and the succeeding or third operation. Since the outer end of the work is supported by the center while the forming is in progress, the diameters thus turned must be true with that center. In the third operation the center at the other end of the work is formed. The forming of this center, as shown in Fig. 4, is done by an operation which has been previously described in MACHINERY (see "Methods of Delicate Turning," in the September, 1907, issue of MACHINERY). The blade follows a diagonal line of travel, so that the center is turned to the right angle. Face *a* is beveled so that it clears the work entirely, and the point is quite sharp. The cutting action is thus entirely on the face of the stock, and the work is not subject to any pressure whatsoever, but remains attached to the stock until the tool has progressed so far that it separates and falls off by its own weight, leaving the point so sharp as to be for all practical purposes a perfect one. We have already seen that the outer center is true with the turning. The center formed in this operation is also true with the turning, as the work is, at this point, so close to the chuck that the operation must be concentric. The outside diameter of the piece is left stock size. This large diameter has the pinion teeth cut in it and runs true enough for all practical purposes.

Cone Point Turning and Cutting-off Tool.

The construction of the point turning tool can be readily followed from Figs. 5 and 6. The cutting-off blade *B* is held in a slot in tool slide *C* resting on adjusting screw *D* and pin *E*. It is clamped in position by screw *F*; by adjusting screw *D*, the blade is rocked about pivot *E* to bring the point higher or lower as may be required to accurately center it with the axis of the work. Slide *C* is gibbed to a dove-tail guide on slide carrier *G*. This member is pivoted to the body of the tool *H* about the axis of bolt *J*, and is clamped by screw *K* in the proper location to guide the slide *C* in forming the desired angle for the pivot of the work.

Tool slide *C* has attached to it a rack which meshes with the 32-pitch pinion *L*, pivoted to the under side of *G*. Pinion *L* meshes with a similar pinion *M*, pivoted in a hole in the body of the tool about the center of bolt *J*, so that the correct relations between them are preserved whatever the angular adjustment of *G* on *H*. Pinion *M* is lengthened and at its lower extremity meshes with rack teeth cut in the side of plunger *N*. This is best seen in the section on line *x x* in Fig. 6. This plunger, as may be seen in the side elevation, has at its front end a projection extending upward bearing against a plunger *O* in a hole above it, which is pressed outward by a spring. By this means, *N* is normally kept at the outer end of its movement, being limited in this direction by the seating of screw *P* in the recess provided for it in the body *H* of the tool. In this position the tool slide is withdrawn so that the blade clears the work.

The front end of *N* is provided with knurled screw *Q* and lock-nut *R*. These are so located as to be in line with the pusher *S*, attached to the front cross slide of the machine, when the turret has brought the tool to the proper position for cutting off. The cutting off is effected by the movement of

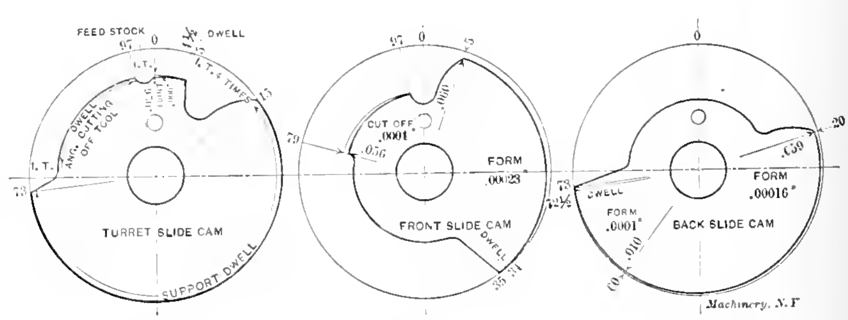

Fig. 7. Turret and Cross Slide Cams used for Making the Pinion Blank shown in Fig. 1.

the cross slide and pusher *S*. This bears on screw *Q*, presses plunger *N* inward, revolving pinions *M* and *L*, which, in turn, acting on the rack attached to the tool slide, move cutter *B* inward, severing the work from the bar and forming the pivot point, as shown in Fig. 4. The length of the inward travel of the tool is adjusted by screw *Q* and lock-nut *R*. The swiveling adjustment shown for *S* is not needed for this job.

The operations can be further studied from Figs. 3 and 7. In the latter figure are shown the cams by which the feeding

movements of the machine are effected. As is well known, the Brown & Sharpe automatic screw machine has a front and a back cross slide and a turret slide, each controlled by its own separate plate cam. In Fig. 7 the various radial lines are figured to show their distance from the starting point 0, in hundredths of a circle. The various acting surfaces of a cam have legends on them indicating the operations performed by them. The material used for this pinion blank is tool steel. The spindle revolves 1,320 revolutions per minute, giving a surface speed to the work of about 58 feet per minute, which is suitable for the material used with the heavy flow of oil directed on the cutting edges of the tools. It takes 770 revolutions to make a piece, so that each hundredth of a revolution of the cam represents 7.7 revolutions of the spindle. Knowing this, the various feeds can be

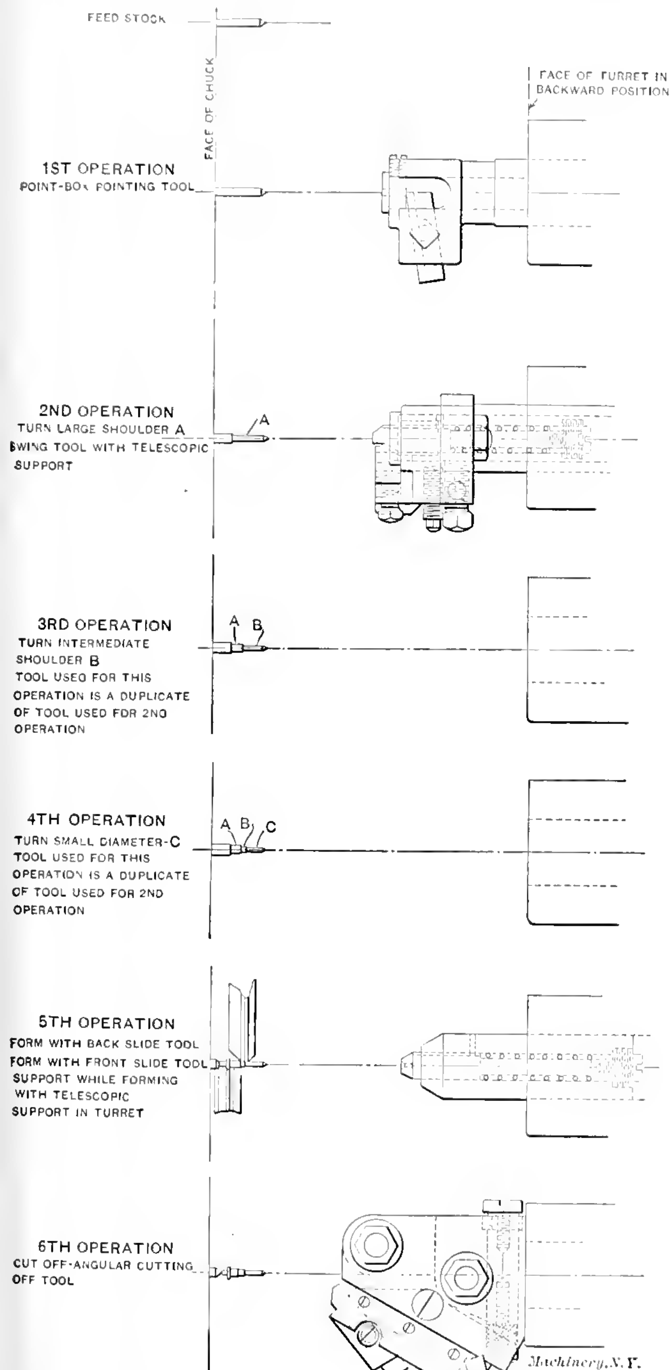

Fig. 8. Tools Used and Order of Operations Followed in making the Staff shown in Fig. 2.

readily figured out. It will be noticed that on the back slide cam, which takes the wider of the two forming cuts, a finer finishing feed is used between positions 60 and 72½ than for the first portion of the forming between 20 and 60. This is done to produce the finer finish which the finer feed gives. It will also be noticed that in all forming operations, such as those performed by the two cross slides, and by the turret slide in pointing the work in the first operation, the cams are provided with "dwells," or resting places where the periphery of the cam is, for a short space, a portion of the circumference of a circle, so that the slide is allowed to rest at this point while the chip runs out. This produces a smooth final finish. The net production is 900 per day, allowing time for sharpening tools, etc.

Tools and Operations for Making a Watch Staff.

The part shown in Fig. 2 has to be handled somewhat differently from the one we have just been considering. It is much longer and more slender, so that forming it by cross slide tools is out of the question. This part will have to be turned. The order of operations is indicated in Fig. 8.

The stock, having been fed to length, is pointed by the turret tool shown in the first operation. In this tool the stock is supported by a bushing while the end is being pointed, the work being too slender to support itself, as in Fig. 3. In the second operation, shoulder *A* is turned. This is done by a "swing tool," which will be described later. The pointed end is supported in a female center, a turning cut is taken over the shoulder of the finished diameter required, the cutting blade is released so that it is not dragged over the work on the return, and then the turret is revolved for the next operation. Operations 3 and 4 are also performed by the same kind of a tool and in the same way, shoulders *B* and *C* being each finished in turn. It will be noticed that the smallest diameter is finished last. This is obviously necessary. If shoulder *C* were turned first to its finished size, it would not be stiff enough to support the succeeding cuts *A* and *B*, and give assurance that they would be true with the cone pointed end.

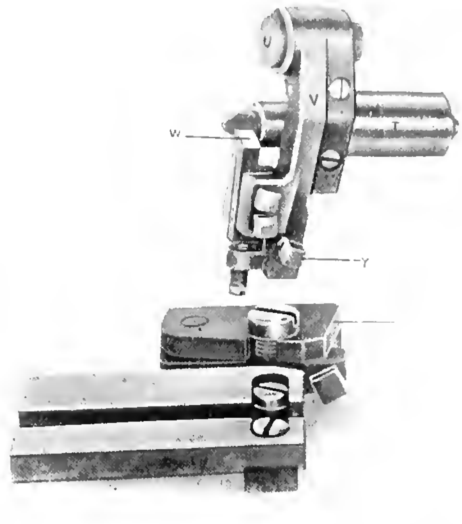

Fig. 9. Swing Tool used for Turning the Staff shown in Fig. 2, and the Pusher by which it is operated from the Cross Slide.

In the fifth operation, the work is supported in a female center (as in Fig. 3, second operation) while formed tools in the front and rear cross slides square up the shoulders already turned, and remove the burrs thrown up by the turning tools. The front cross slide tool forms the small diameter to the left of the collar and squares up the sides of the collar itself. As will be seen from a study of the cams of Fig. 11, the front cross slide tool does not commence to cut until the one in the rear has completed its work. The stock is too slender to permit of too much work being done on it at once. In the sixth operation, the same angular cutting-off tool as shown in Figs. 5 and 6 is used for severing the work from the bar and forming the cone point at the same time. It will be seen that in the operations just described, as in the previous case, the various diameters will be as concentric with the pointed centers of the work as if they had been turned on them.

Description of the Swing Tool.

The swing tool used in operations 3, 4, and 5 is shown in Figs. 9 and 10. To the body *T* of the device is pivoted (about stud *U*) the tool-holder *V*, carrying blade *W*, which is adjusted vertically and clamped by the square-headed screws shown. In a hole drilled into the body of the tool, is contained a plunger *Z* pressed outward by a spring. The opening of this hole is closed by a screw, as shown. A pin *X* driven into the side of tool-holder *V*, projects through a side hole into *T*, and bears on the face of plunger *Z*. By this means the spring keeps *V* swung outward, the movement being limited by the bearing of *Z* on the headless set-screw. Abutment screw

Y, in V, is in position to bear against pusher S, carried by the cross slide in the same manner as in Fig. 6.

In turning shoulders A, B and C (see Fig. 8), the movements of the front cross slide and turret slide cams, as may be seen in Fig. 11, are so arranged that the swing tool is brought up to the work; the cross slide is next moved in to set the tool W to the diameter desired, as determined by the adjustment of screw Y; then the swing tool is fed forward the proper distance for the shoulder desired. The front cross slide is next withdrawn, allowing tool W to swing outward under the influence of the spring and plunger Z. The turret

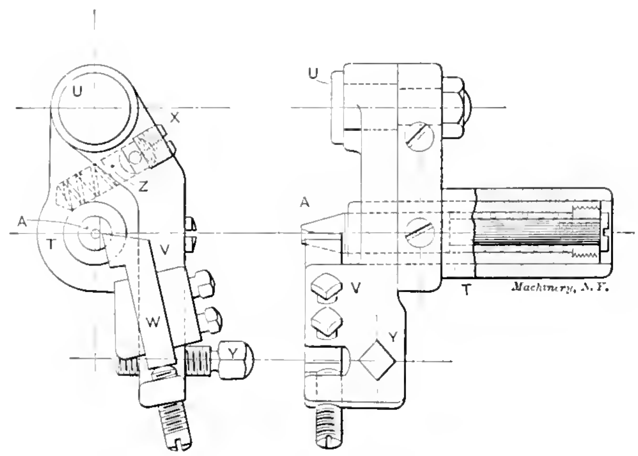

Fig. 10. Details of Construction of the Swing Tool shown in Fig. 9.

slide then retreats, drawing the blade out of the way without allowing it to drag on the work. The swivel adjustment on plate S allows either straight or taper turning to be done, as required.

The cams, shown in Fig. 11, for making this part, look somewhat complicated, but the operations may be easily followed. All the various lobes of the three cams being marked for the operations for which they are intended. Legend "I. T." means "index turret." As before, the legend "dwell" indicates a concentric portion of the cam, where the slides are at rest.

In making this piece the spindle revolves at 2,400 revolutions per minute. As shown in Fig. 2, the stock is 0.063 inch in diameter. This gives a surface speed of about 40 feet per minute, the material being tool steel as in the previous case. The net production for these pieces was 1,500

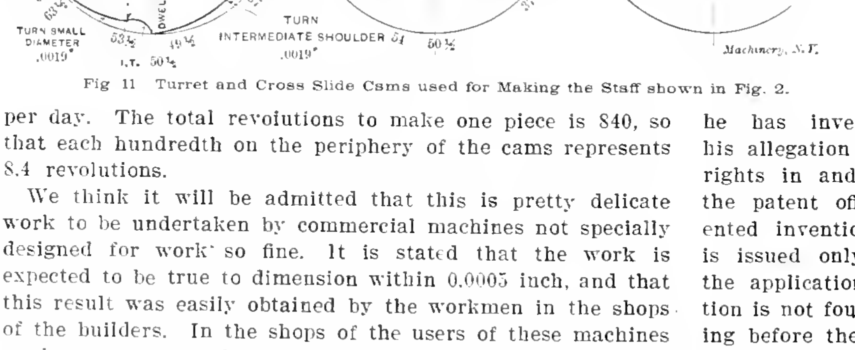

Fig. 11. Turret and Cross Slide Cams used for Making the Staff shown in Fig. 2.

per day. The total revolutions to make one piece is 840, so that each hundredth on the periphery of the cams represents 8.4 revolutions.

We think it will be admitted that this is pretty delicate work to be undertaken by commercial machines not specially designed for work so fine. It is stated that the work is expected to be true to dimension within 0.0005 inch, and that this result was easily obtained by the workmen in the shops of the builders. In the shops of the users of these machines workmen accustomed to watch machinery have been able to do much better than this, showing that the limitations of the machines were not reached in the builders' trials.

For particulars relating to the tools and operations here described, we are indebted to Mr. F. E. Anthony, head tool designer for the automatic screw machine department of the Brown & Sharpe Mfg. Co.

PATENTS AND INVENTORS.*

E. C. SMITH.†

It is written, "a man's foes are they of his own household." Equally true is it that the tribulations of the inventor arise too frequently from causes within himself—usually from insufficiency of knowledge or inadequacy of apprehension. An experience of several years in charge of a corporation patent department brought me in touch with different inventors, and indicated to me that many did not understand what constitutes an invention, or the nature of a patent. To establish an exact definition of invention, that shall serve under all conditions to distinguish invention from mere resource or skill, is practically impossible. The problem has taxed our best jurists, who have been unable to deduce a formula universally applicable under all conditions. In general, however, pure or genetic invention is creation. The phonograph, air brake, "universal" system of winding, are all good examples of genetic invention—the products of the inventor's creative genius.

Subordinate to this is what may be termed constructive invention, or the invention of development and improvement. One man conceived and reduced to practice the mechanism for reproducing human speech—a genetic invention. He and others have made contributory inventions of constructive revision. The origination of the talking machine has stimulated constructive thought in an entirely new field of activity, and thereby the original device has been modified by changes and additions which may or may not have been improvements. Unfortunately, too much of constructive invention is not stimulated by a desire to better an existing invention, but arises from predatory motives and is directed to "getting around it." Because of this fact, such inventive acts were best termed "circumventions," which word best expresses their piratical spirit. As stated by Mr. Johnston, in the March issue of MACHINERY, an inventor may secure proprietary rights in and to his invention by conforming to certain prescribed requirements. I do not agree with Mr. Johnston that the inventor's title to his invention is essentially coextensive with a land title. Land is "real" or tangible property, susceptible of explicit definition as to its boundaries, while an invention is intangible, its boundaries are not so easily defined, and it is more subject to qualifying modifications. The relation of tangible and intangible property is too extensive a subject for discussion here, but it is well to bear in mind that the land-holder and miner secure their property only because the government sees fit to grant the title, just as it sees fit to grant a title to an invention. In short, both are matters of government prerogative, and there must essentially be a wide divergence of opinion as to how the prerogative should be exercised. It does seem inconsistent, however, to propound perpetual title to invention as inherent, and in almost the same breath approve an enforced limitation of tenure.

A patent is a contract between the public, by its representative, the government, and the patentee; and the patent document is evidence of proprietary rights, duly recorded. The applicant alleges that he has invented something new and useful; provided his allegation is true, the public will accord him exclusive rights in and to his invention for a period of years. At the patent office are maintained extensive records of patented inventions, both domestic and foreign, and a patent is issued only after due investigation and comparison of the application with these records, and provided the invention is not found in the prior act or in some application pending before the patent office, and provided that no fraud has been detected in the preparation or proescution of the application. Having secured his patent, the inventor has attained two things, *viz:* a more or less uncertain asset on which he may or may not raise money, and a status or basis for suit

* For additional information on this subject, see the article "On the State of the Patent Office," published in the March issue of MACHINERY.

† Address: R. F. D. No. 4, Attleboro, Mass.

before the courts. The law provides no guarantee of the validity of the invention, nor does it, as Mr. Johnston avers, provide any penalty for infringement. It provides means for securing just treatment and damages in case of injury by infringement. Judge Colt stated the position of patent litigation very clearly in Boston several years ago. Speaking for the Appellate Court, in a refusal to entertain discussion of some "legal precedents," he said, in substance, "Cases of this character (patent causes) are not matters of law, but of equity; and equity, in plain English, is simply that which is right and just between parties."

Probably the most disconcerting experience to the inexperienced inventor is the securing of a patent with its crisp parchment, ribbons and seal, and attendant cost, only to find that the invention, though "new and useful," cannot be practiced because dominated by some existing patent. Possibly the dominating patent was disclosed among the first references cited by the examiner, but because it did not show precisely the same form of construction as his own, and he did not find the broad, basic claim, and because he did not understand the law of equivalents, the inventor proceeded with his case supposing he could use his own peculiar construction. An exceptionally clear illustration of the principle of "domination" appeared in a little advertising pamphlet issued by an attorney several years ago. Assume that percussion firearms are unknown. X invents the first percussion device comprising a hammer. He applies for a patent and secures, by broad, basic claims, the sole right to make, use or vend firearms that have hammers. Y sees the disadvantage and danger of employing only a hammer, and invents the trigger, and he likewise secures, by patent, sole rights, title and privilege in the manufacture, use and sale of firearms of which a trigger is a component. But the trigger is dependent on the hammer for its usefulness, and as X has sole right to the manufacture of guns with hammers, Y's invention is useless to him unless he can sell his patent to X, or induce him to use the triggers on a royalty basis, or can secure on a similar basis the right to make guns with hammers, under X's patent, or can manufacture trigger attachments for use on guns manufactured by X. Unaware of this, many would-be inventors, unacquainted with a given field of activity, attempt, without any canvass, to devise some supposed improvement, and proceed to seek a patent.

Again, there are some who waste time with what they wrongly dignify as an invention, by applying a device invented for one purpose to some other purpose. This is done many times in a belief that the various classifications in the patent office are distinct fields of enterprise, and that the importation of an invention from one to another is as patentable as the original creation and development. Generally speaking, a patent protects its invention in all its uses, though there are exceptions when the work of adaptation involves distinct inventive ability, which is recognized. For those who study and analyze, securing information regarding the field in which they propose to work, there is ample opportunity in the realm of constructive invention. The field of purely genetic invention is becoming rapidly more limited, and patent values are differentiated on narrower margins of constructional difference. This is as it should be, because minor constructional variations are frequently productive of large commercial results. As a matter of fact, the inventor has exceptional privileges and opportunities under our patent system. If he elects to prosecute his own patent application, he may do so, bound by no fine technicalities, and, for his guidance, provided gratuitously with one of the most complete, and clearest compilations of rules and directions, clearly illustrated and supplied with skeleton forms for any and all possible actions. One of your correspondents implies that no particular erudition is required to prosecute a patent application. It is true that many inventors successfully prosecute their own cases, and it is likewise true that many professional attorneys are pitifully incompetent. Nevertheless it is also true, that just as some individuals find best expression for their abilities in mechanical conceptions, some in mechanical construction, and some in the commercial exploitation of mechanical products, so others, peculiarly able because of their command of language and resourcefulness of apt expression, can best reduce the inventor's conceptions to record form. If, however, the inventor would exercise the same diligence in delving into the realm of invention that the average business man exercises in his conduct of affairs, he would avoid many pitfalls, and his passage through what is usually pictured as a veritable slough of despond would be more expeditious and less gloomy.

Regarding the patent office, there is much to be said. That the funds earned by it are not available for its own use seems wrong. That there are deficiencies and abuses appears inevitable; they are to be found everywhere. Judged by the commissioner's report, his department seems to be doing all it physically can, as at present constituted. To me the showing is not one of incompetency, but of exceptional merit under adverse conditions. The commissioner states that the work of some of his force is frivolous, and otherwise lacking in essential qualities. What can be expected when men's work is demanded in exchange for boys' pay? It has been my good fortune to meet one or two of the examiners personally, and these were keen, clear-headed and able men. One must remember that they have little access to the concrete embodiment of the inventions on which they pass. Their knowledge of the technical ground they must cover is derived chiefly from the text and illustrations of the patent records and applications in their hands. It is always more difficult to understand a written description than to understand the embodiment of an idea. Does the inventor who desires to negotiate capital, content himself with sending a written description to his prospective financier? No, he wants *him* to see the *machine*. Whether he will see it or not is a matter of volition, and whether or not he will "back" it, likewise. With the examiner, this is not the case. He may not have opportunity to see the machine, yet he must grasp the spirit of the invention and apprehend its advantage with, too frequently, insufficient description to guide him. It is charged that examiners sometimes make immaterial and irrelevant references. Whether this is as flagrant a wrong as might appear on the surface is questionable. If actually done under stress of extreme congestion, it keeps things moving in the patent office, and may throw unexpected light on the subject in hand. Sometimes a reference is declared immaterial because it relates to a distinctly different class of articles from that which includes the subject of the application. But it may be material, nevertheless, under the doctrine of a patent protecting an invention in all its uses. The real danger arises, not from citing irrelevant material, but from failure to perceive that which is vitally relevant and liable to cause trouble to the patentee should he secure a patent and attempt to practice his invention.

In regard to delays, no one can view with complacence the proposition to delay action on the cases of those who desire delay. On the other hand, due deliberation is better than undue haste. Mr. Johnston would have us believe that a multitude of inventors are suffering from lack of funds, due to non-issuance of patents. I will venture a guess that for every one individual in such a plight, there are ninety-nine who hold issued patents and still similarly suffer. Indeed, reasonable delay is not without its advantages. Sometimes, in course of delay, an inventor finds that while he has produced the invention of his application, his analysis is at fault and his original claims inadequate. He may then be able to fortify his case, whereas, had it been immediately acted on, pushed through the office, and a patent issued, the insufficiency might have passed unnoticed until too late, resulting in reissue for correction, or what is worse, a disclosure of the weakness by which some pirate could profit and depreciate if not annul the value of his patent.

Referring again to reference patents, one fact which disposes me leniently toward the examiner is the fact that the inventor himself frequently encounters difficulty in discerning the relation of a cited patent to his own invention. Mr. Johnston suggests one action which, to say the least, seems of dubious utility, *viz:* to penalize the deferment of a request for division until after several actions. What difference does it make to the applicant when he is asked to divide his application? If he must divide it, he must pay two fees; so why throw the second fee on the examiner for any cause?

If there are any penalties to be meted out, they are due the man who wastes time in needlessly dissecting the punctuation and phraseology of an application. It has been officially decided that such criticism is ill-judged and misdirected.

The essentials of an adequate application are simply clear, intelligible composition in the English language, according to prescribed forms. The suggestion that the commissioner be made general manager, with unlimited credit, seems untimely, when Congress is holding onto the funds earned by the patent office. It seems essential that something be done, however, and the most feasible move would appear to be a concerted action to impress Congress with the needs of the situation. The realm of invention touches every phase of our industrial welfare and development. It is not local in any aspect, but reaches and affects the uttermost parts of our land, and indeed, of the world. It should be an easy matter to convince Congress that something needs to be done and must be done.

It must be realized, of course, that we have passed through extraordinary times. The demand for skilled labor has exceeded the supply. Several engineers have graduated from the Panama Canal work. Our military establishment is depleted because men can find better inducements in the industrial world than in army life. Works managers at large have bewailed the scarcity of help. Is it any wonder that examiners resign from the patent office at the rate of one a week? As for commercial firms and their business methods, there are some from whom we purchased our supplies who didn't know the nature of a promise, and beside whose methods those of the patent office could shine with the effulgence of perfection. It is easy to make invidious comparisons, but the instability of the premises on which such comparisons are based has made be a cynic.

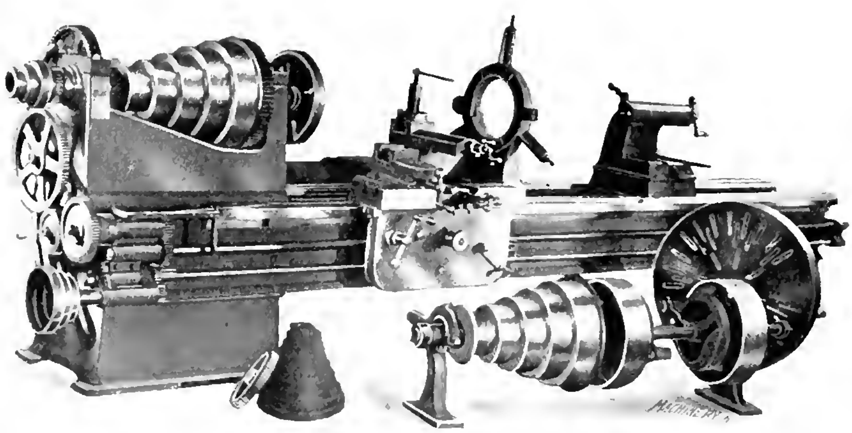
AN OREGON LATHE.

The accompanying illustration shows an engine lathe built by the Eugene Iron Works (G. N. Frazer, proprietor), Eugene, Ore. This shop, we believe, is the only one on the Pacific slope that builds lathes for sale. The lathe illustrated is 30 inches swing and takes 10 feet between centers. The spindle is hollow, having a $2\frac{1}{2}$-inch hole. The tail-stock is of the well-known cut-away pattern which permits the compound rest to be swung around parallel with the ways without interfering with the tail-stock. This lathe is not the first lathe built by the Eugene Iron Works. We are informed that several others have been built, one of them being 44 inches swing and 12 feet between centers. This example was built twenty-eight years ago, and is still doing good work. It was made in sections that could be planed on a 22 x 6-foot planer, and it has the much-talked-of double plate apron, now pushed as a comparatively new feature by many prominent lathe builders. We are indebted to Mr. Ed. B. Eby, of Eugene, Oregon, for the above information.



A 30-inch Lathe built by the Eugene Iron Works, of Eugene, Ore.

The English turbine-driven torpedo boat destroyer *Tartar*, during her official trials, developed a speed of 35.672 knots as a mean of six runs.

A POWER-PRODUCING PLANER.

GREBO.

I often think it is a great pity that some of the wonderful achievements of machinery, as related by certain accomplished traveling men, do not agree with the fundamental laws of mechanics. These stories sound so well that it seems they ought to be true, and if they were true, what a different world this would be! It really would be a pleasure to run a machine shop. For example, having a certain tale in mind, we would grow richer day by day by simply running a shop and selling power to our neighbors. Now you think this sounds "fishy," and I will explain how it could be done (?) much simpler than has ever been proposed before. You, of course, have heard of steam engine and boiler installations that were equipped with various improved appliances, some of which saved 10 per cent of the fuel, others 15 per cent, and still others as much as 25 per cent. By using enough of these wonderful affairs the point was reached where instead of consuming coal the plant was able to turn out half a ton of coal a day for some other fellow to burn. Now this was a very clumsy affair, not really worth the while of an up-to-date factory economist. You always have a feeling that a salesman will come along some day with a smoke-consumer or an ash-burning compound that will make all your previous economies look like thirty cents. Real improvement is in the direction of simplicity, and that is what I am going to tell you about.

I knew a salesman who sold planers—rather big planers, heavy and clumsy-looking affairs, but wonderful machines for all that. Of course his "spiel" was that these planers were better in all working points than any other planer built, or that ever would be built. But customers had heard these stories before and discounted his talk 66 2/3 & 25 & 10 & 10 & 5 per cent in approved commercial style. They would look at his pictures and his specifications and ask him about the power required to drive the big machine. Right here is where our salesman made a claim that firmly fixed his reputation. He admitted the planer would need something like 20 horsepower to start it, but when once it was started, why he had known of a great many cases where the planer ran so easily that instead of the engine running the planer, the planer was actually helping out the engine!

Now this proposition is more attractive than may be realized at first. Most manufacturers do not care for a few horse-power more or less. Power is a small part of their expenses, anyhow, but when you had bought one of these planers you had a very useful machine. It not only required no power after it was once started, but actually contributed to running the other tools in the shop. With a sufficient number of these planers running you could run your entire shop and have a surplus to light it; or, if enough planers were operated, you might run the street car lines of the town!

It is painful to record that the rosy prospects an active imagination might conjure from the unqualified statements made by our salesman did not excite the imagination of his prospective customers. They listened coldly to his eager words and his sales fell considerably below those of his fellow salesmen. Finally he was called home and asked to explain the "becauseness of the why," and his customary "spiel" was poured into the astonished ears of the general manager, who could scarcely believe what he heard. Finally, when the manager got his breath, he let out a few wrathful comments punctuated with exclamation points, on the asininity of the power claim and the ridiculous position that our smart salesman had put himself into. The salesman learned more about the conservation of energy and the limitations of machines as power producers in those few hot minutes than most of us learn in several years of schooling.

If there is any particular point to be impressed by this foolish tale it is that manufacturers should employ salesmen only who know what they are talking about.

ADVANCED DESIGNS OF GERMAN DRILLING MACHINES.

OSKAR KYLIN *

The accompanying half-tones show a few types of the extensive line of drills manufactured by the Dresdner Bohrmaschinenfabrik, A.-G., Dresden, Germany. This firm manufactured originally, in accordance with the common practice of nearly all German machine tool builders, all types and sizes of machine tools, without specializing in any; but, learning of the success of the specialization of the American machine tool makers, and clearly seeing the advantage of this, and with how much less amount of labor an equally large amount of work could be produced by systematizing the output, as compared with the old method, this firm discontinued the making of all kinds of machines except drilling machines, and devoted itself exclusively to this one line.

Figs. 1, 2 and 3 show some of the small sizes of drills, of the single spindle as well as the multiple spindle type, intended for ordinary light or medium grade work, and equipped only with hand feed. There is nothing startling in the design of these machines, as they follow the general line of design which for years has been brought out by many different machine tool builders, and proved to fill the requirements. It will be noticed, however, that in many features these machines are different in their appearance from common American types, and that the multiple spindle drills, in particular, are of a heavy and substantial design. The drills shown in Figs. 2 and 3 are also built with a greater number of spindles, if required.

In Figs. 5, 6, 7 and 8 are shown the large types of drills manufactured by this company, equipped with power feed and designed for heavy duty. The machine in Fig. 8 is equipped with a pump and arrangement for water cooling of the drill, while at work. It will be noticed that all gearing is very carefully covered with guards, forming integral parts of the machine. The radial drill shown in Fig. 7 is of particular interest. It will be seen that the design is unusually rigid and that the column as well as the arm is very heavy. The column is mounted on a base-plate provided with T-slots, which serves as a support for large work, when the small table is swung aside as shown in the half-tone. This machine is provided with single pulley, all-gear drive, the speed changing mechanism being operated by the handle shown at the back of the column. In this machine also it is noticeable how carefully all gearing has been covered. The design, in general, is clearly shown in the engraving, and may be studied directly from this without further comments.

In Fig. 4 is shown an interesting type of turret drill, which is radically different from anything else hitherto presented in drill press design. This machine is of an exceptionally heavy and rigid design throughout, in accordance with the work for which it is intended. It is provided with a single pulley, all-gear drive, the speed changing device being operated the same as in the radial drill press, Fig. 7. Power is transmitted to the top of the drill by means of bevel gearing and a shaft located centrally in the column. The drill spindles are driven through shafts connected at one end through bevel gears to the central shaft, and at the other end by bevel gearing to the drill spindles, these shafts being arranged radially, one for each spindle. There are five spindles in the turret arranged around the central column, but power can be transmitted to only one at a time; that is, to the one directly above the table of the machine. This prevents undue consumption of power, and unnecessary wear of spindles, gearing and bearings. The engaging and disengaging of the power to and from the spindles is effected by a cam and clutches, brought into operation as the turret is being slowly revolved by hand around the column. The clutches are located on the radial shaft near the outer bevel gear. The cam by which the

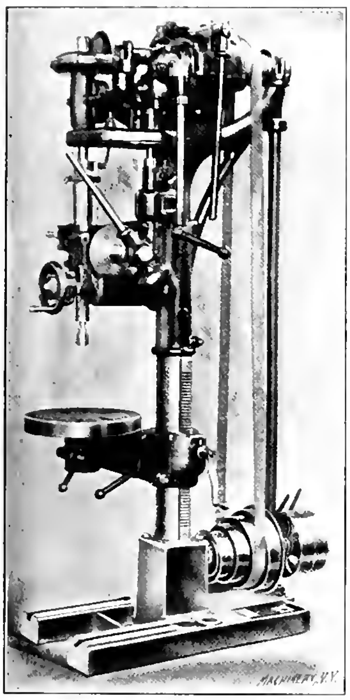

Fig. 1. Regular Type Upright Drill built by the Dresdner Bohrmaschinenfabrik.

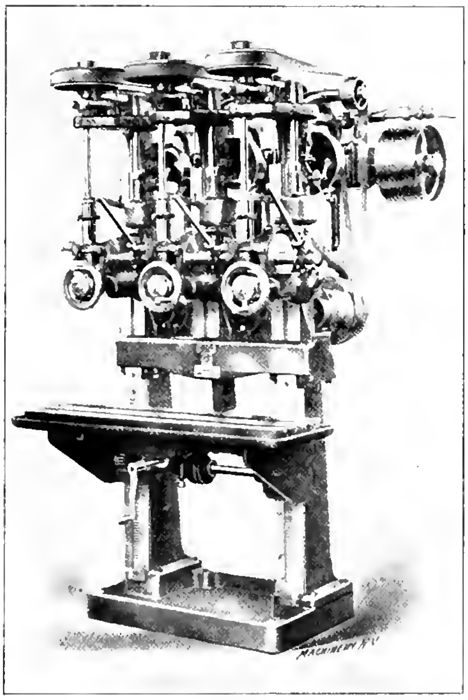

Fig 2. Three-spindle Drill, of Heavy and Substantial Design.

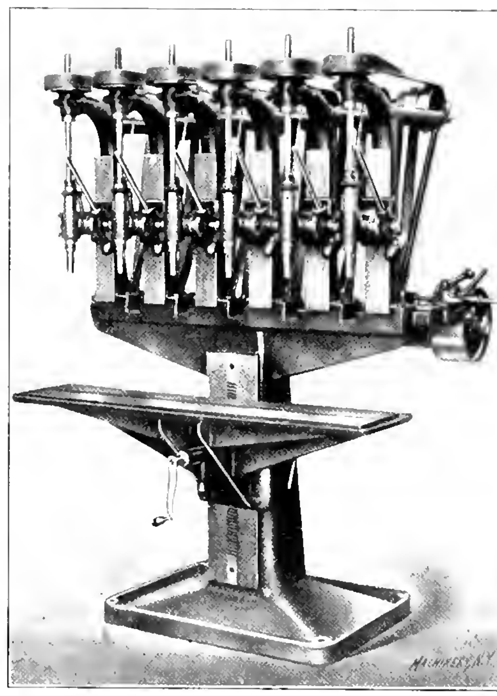

Fig. 3. Multiple Spindle Drill for Light and Medium Grade Manufacturing.

clutches are engaged and disengaged is located below the gear mechanism at the top of the drill, and immediately on the top of the column, as can be plainly seen in the half-tone. When the spindle is moved into position the respective clutch is being engaged, and when again moved out of position, the clutch is thrown out of mesh. In order to make it easy to revolve the turret, this rests on ball bearings. Attention should be called to the rigidity of the design, and to the construction of the drill table, the features of which can be seen plainly from the half-tone. This drill is equipped with pump and arrangement for water cooling. As the five different spindles are intended for different kinds of work, drilling, reaming, tapping, etc., they can be run at different speeds suitable for each kind of work. These different speeds are obtained by different sizes of bevel gears for driving the different spindles.

A feature that will be noticed in all the designs brought out by the Dresdner Bohrmaschinenfabrik is that the unit system of design is employed to the largest possible extent. One unit, as, for instance, the heads and the gear boxes, will be found to be the same on many of the different types of the machines represented in the accompanying half-tones. Many times a new type of machine is brought out by simply making new

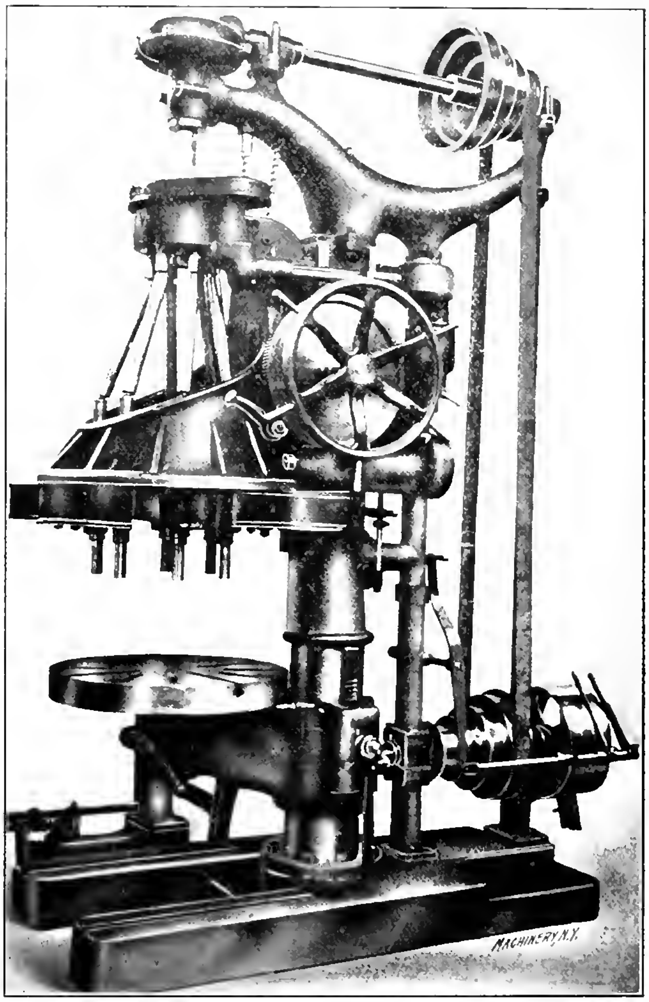

Fig. 5. Heavy Multiple Spindle Drill of Universally Adjustable Type.

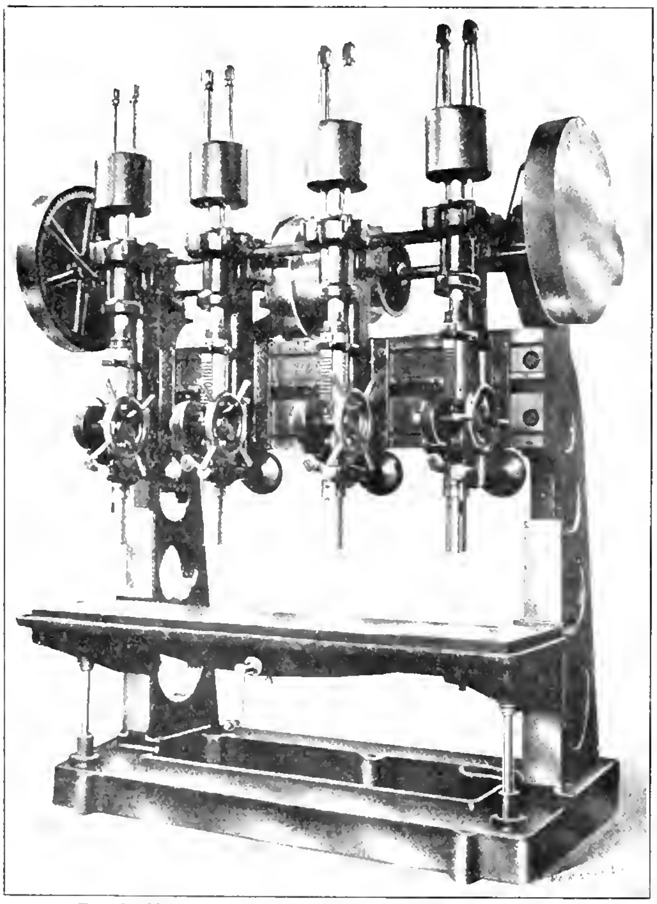

Fig. 6. Multiple Spindle Drill of Linear Adjustable Type

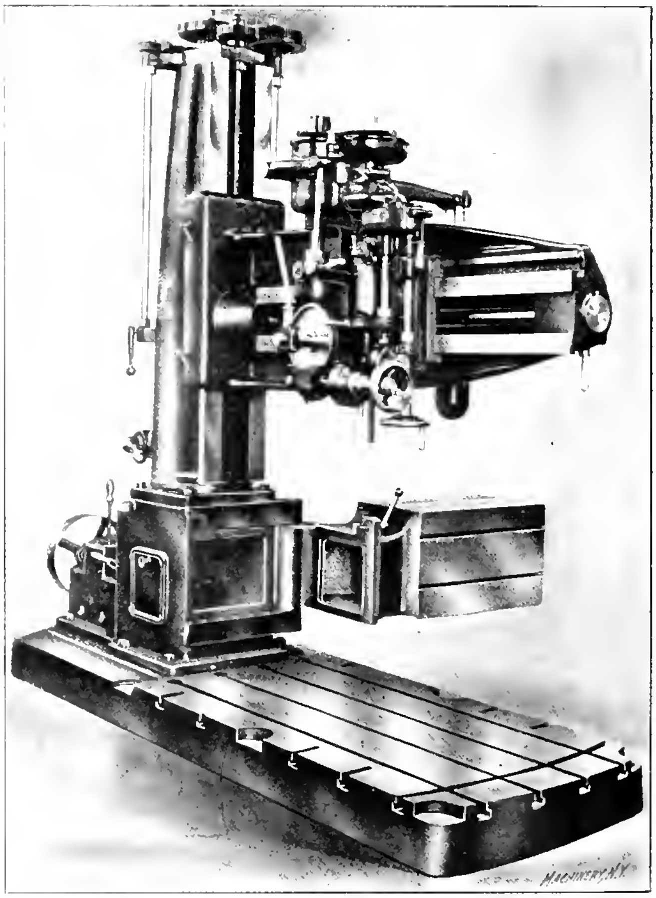

Fig. 7. Dresdner Bohrmaschinenfabrik Radial Drill, with Hinged Table.

main castings and then employing the units used for other types. Thus, a manufacturer of a special line of machine tools can afford to carry a large number of types, and still have the advantage of specialization. Various details and whole units can be made in very large numbers and kept in stock, and the building of a new machine may simply mean bringing out

and machining the main castings, and assembling the various units for making up a complete tool.

All the machines provided with power feed for the drill are provided with feed changing mechanism. This feed changing arrangement is shown best in Fig. 4, on the side of that spindle which is in position over the table, and is operated by the small handle shown. Three different feeds for each spindle speed are obtainable. A small matter, which, however, is well worth noting, is that all the nuts on the machine, which occasionally need to be loosened for the sake of setting the table or adjusting some other part, are provided with handles. This, many a time, means a great saving, as compared with having the ordinary hexagon nuts, which have to be unscrewed and tightened by a wrench, because it is well known that entirely too much time is lost in shops by hunting for wrenches.

In order to reduce the power consumption and also the wear of the machines, all principal bearings are made with

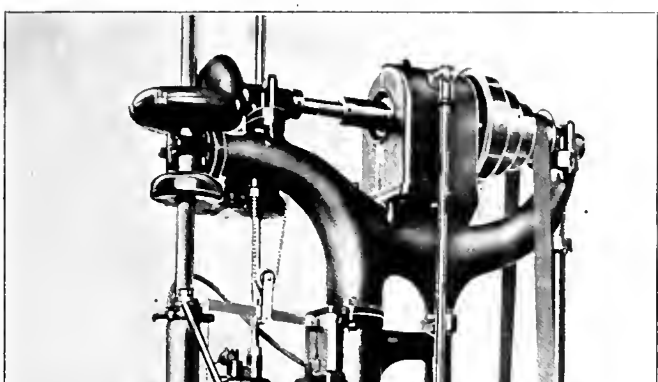

Fig. 8. Heavy Design of Upright Drill Press.

ringed oiling devices or ball bearings. It is very noticeable in many German shops that more attention is paid to the power consumption of the machine tools than is done in the average American shop. Thus, in the Dresdner Bohrmaschinenfabrik's shops, all ordinary sized and large drills are tested in regard to power consumption before being placed in the stock room, or delivered to customers, the power consumption being noted when the drill is running idle as well as when performing work.

A special and rather unique feature employed in the manufacturing of these drills is that after having been once assembled in one department, they are taken apart and re-assembled in another department by entirely different men. This is done, the company claims, in order to find all possible defects in the machines, and secure nice running conditions everywhere in the finished drill press.

JIGS AND FIXTURES—3.

EINAR MORIN.*

LOCATING POINTS.

The locating points in a jig usually consist of finished pads, bosses, seats, or lugs, cast solid with the jig, as illustrated in Fig. 18. In this engraving the surfaces marked *f* are the locating points, which bring the piece to be machined in right relation to the bushings guiding the drills, or to the gages to which other cutting tools may be set. This way of locating the work is satisfactory when the work done is finished in a uniform way, and where there is very little variation in the parts inserted in the jig.

Another commonly used means for locating the work in jigs is by means of dowel pins, as shown at *A* and *B* in Fig. 19.

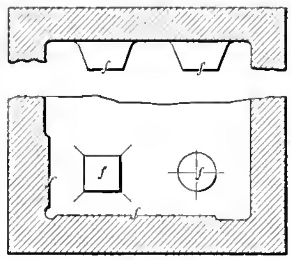

Fig. 18. Locating Pads in Jigs.

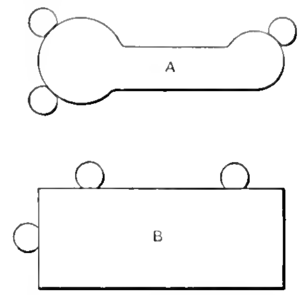

Machinery, N.Y.

Fig. 19. Pins used for Locating Work.

The sides of the dowel pins which rest up against the work are usually flattened, as indicated, so as to give more bearing than a mere line contact with the pins could give, and, at the same time prevent too rapid wear on the locating pins, as would be the case if the work should bear against the pins along a line only.

Sometimes pins or studs are inserted in jigs to act as locating points, instead of having lugs cast directly on the jig, as shown in Fig. 18. A case where a pin is used for this purpose is shown in Fig. 20, where *B* is the body of the jig, *A* the pin inserted to act as a locating and resting point, and *C* the work located against this point. Locating pins of this character should always be provided with a shoulder or collar,

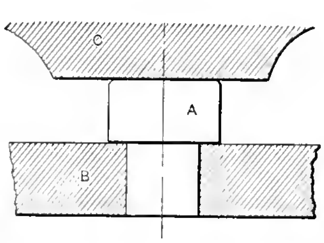

Fig. 20. Inserted Pin used for Locating and Supporting Work.

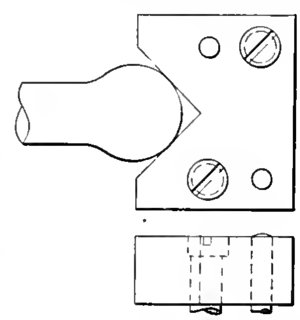

Machinery, N.Y.

Fig. 21. V-block for Locating Round Work or Cylindrical Surfaces.

so that there is ample security that they will resist the pressure of the work they support, without possibility of moving in the hole in which they are inserted.

A common method of locating cylindrical pieces or surfaces is that of placing the cylindrical surface in a V-block, as shown in Fig. 21. This V-block as a rule is stationary, and is held in place by screws and dowel pins, as indicated in the engraving, but sometimes these V-blocks may also be made adjustable, in order to take up the variations of the pieces placed in them, and also in order to act as clamps. A V-block of this character is shown in Fig. 22. In this, *A* is the adjustable V-block, having an oblong hole *B* to allow for the adjustment. The block is held down in place by a collar-head screw *C*, which passes through the elongated hole. The under side of the block is provided with a tongue *D*, which enters into a slot in the jig body itself, the V-block being thereby prevented from turning sideways. The screw *E* passes through the wall of the jig, or through some lug, and prevents the V-block from sliding back, when the work is inserted into the jig. It

* Address: 833 W. Sixth St., Plainfield, N. J.

is also used for adjusting the V-block, and, in some cases, for clamping the work. The V-blocks are usually made of machine steel, but when larger sizes are needed, they may be made out of cast iron. Little is gained, however, in making these blocks out of cast iron, as most of the surfaces have to be machined anyway, and the difference in the cost of material on such a comparatively small piece is very slight.

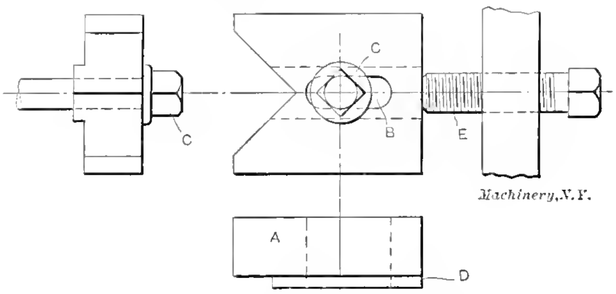

Fig. 22. Adjustable V-block used for Locating Purposes.

When it is essential that a cylindrical part of the work is located central either with the outside of a cylindrical surface, or with the center of a hole passing through the work, good locating means are provided by the designs shown in Figs. 23 and 24. In Fig. 23, the stud *A* is countersunk conically to receive the work. The stud *A* is made of machine or tool steel, and may, in many cases, serve as a bushing for guiding the tool. In Fig. 24, the stud is turned conically in order to enter into a hole in the work. These two locating appliances are always made stationary, and are only used for locating the work, never for binding or clamping.

Screw Bushings and Sliding Bushings Used as Locating Means.

Screw bushings of the type which has already been shown in Fig. 14 (May issue), may be used for locating and clamping purposes by making them long enough to project through the

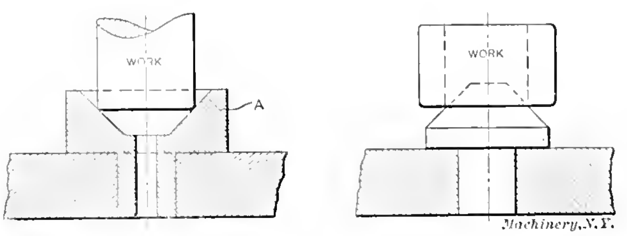

Fig. 23 Recessed Stud used for Locating Round Work.

Fig 24 Conical Stud used for Locating Work in Relation to the Center of a Hole.

walls of the jig, and by turning a conical point on them, as shown in Fig. 25, or by countersinking them, as shown in Fig. 26.

Another type of bushing which serves the same purpose as a screw bushing is illustrated in Fig. 27. This bushing, together with the forked lever *D*, and clamping bolt and wing nut shown, will serve not only to locate but also to clamp the work in place. This sliding bushing gives very good results and is preferable to the screw bushing in cases where accurate work is required, but, as a rule, where extreme accuracy would be required, this kind of bushing is not used.

In Fig. 27 the sliding bushing *A* has a close sliding fit in the lining bushing *B*. In the head of the bushing *A* there are two screws with hardened heads, which fit into elongated slots in the forked lever or yoke *D*, which, in turn, swivels around pin *E*. The eye-bolt *F* fits into a slot *G* in the yoke, and the wing nut tightens down the bushing against the work as clearly indicated in the engraving. A comparatively long bearing for the bushing is required in order to produce good results. On work that varies considerably in size this arrangement works somewhat quicker than does a screw bushing, but it is clearly in evidence that it is a rather expensive appliance, and that the construction of the jig does not always permit of its application.

In some instances it is necessary to have the screw bushing movable sideways, for instance, when the piece of work to be made is located by some finished surfaces, and a cylindrical part requires to have a hole drilled exactly in the center of a lug or projection, the relation of this hole to the finished surfaces used for locating, being immaterial. The piece of work, being a casting, would naturally be liable to variations between the finished surfaces and the center of the lug, particularly if there be other surfaces and lugs with which the already finished surfaces have to tie up, and in such a case, the fixed bushing for drilling a hole that ought to come in the center of the lug, might not always suit the casting. In such a case, so-called floating bushings, as shown in Fig. 28, are used. The screw bushing *A* is conically recessed, and locates from the projection on the casting. It is fitted into another cylindrical piece *B*, provided with a flange on one side. The piece *B*, again, sets into the hole *C* in the jig body *D*, this hole being large enough to permit the necessary adjustment of the jig bushing.

When the bushing has been located exactly concentric with the lug *E* on the work, the nut *F*, having a washer *G* under it, is tightened. It will be seen that the flanges on piece *B* and the washer *G* necessarily must be large enough to cover the hole *C* even if *B* is brought over against the side of the hole. The occasion for using this floating bushing, however,

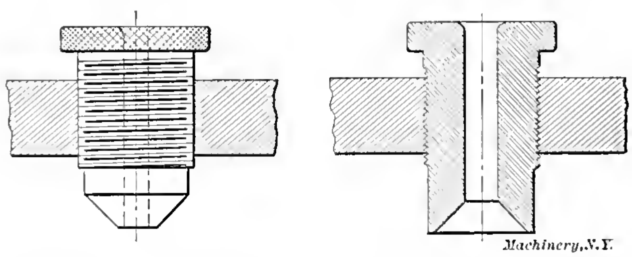

Fig 25. Screw Bushing used for Locating Work Central with a Hole.

Fig 26. Screw Bushing used for Locating Round Work by means of a Conical Recess.

does not often occur, because it is seldom that a drilled hole in a piece of work can be put in without having any direct relation to other holes or surfaces.

Adjustable Locating Points.

The most common form of adjustable locating points is the set-screw provided with a check nut, as shown in Fig. 29. The screw *A* is a standard square head set-screw, or, in some cases, a headless screw—with a slot for a screw driver; this screw passes through a lug on the jig, or the jig wall itself, and is held stationary by a check nut *C* tightened up against the wall of the jig. Either end of this screw may be used as a locating point, and the check nut may be placed on either

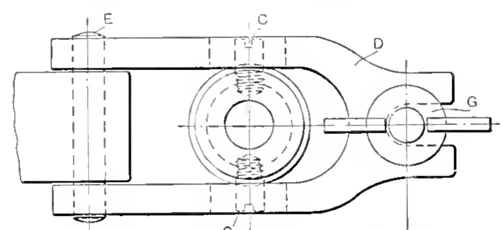

Fig. 27. Sliding Bushing for Locating and Clamping Work.

side. By using a square head screw, adjustment is very easily accomplished, but unless the operator is familiar with the intentions of the designer of the jig, locating points of this kind are often mistaken for binding or clamping devices, and the set-screws are tightened up and loosened to hold and release the work, when the intention is that these screws should be fixed when once adjusted. It is not even possible

to depend upon the check nut stopping the operator from using the screw as a binding screw. A headless screw, therefore, is preferable, as it is less apt to be tampered with.

The sliding point, as illustrated in Figs. 30 and 31, is another adjustable locating point which is used to a great extent in jig work. A flat piece of work or a plate which is not perfectly level will always rock if put down on four stationary locating points, but the difficulty thus encountered is very easily overcome by making one of the locating points adjustable, and, as a rule, the sliding point is used for this purpose.

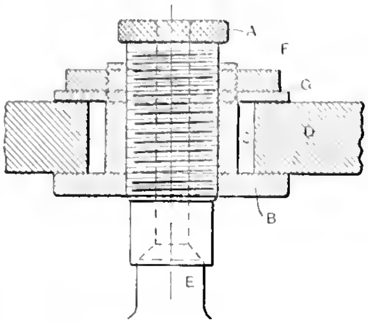

Fig. 28. Floating Bushing.

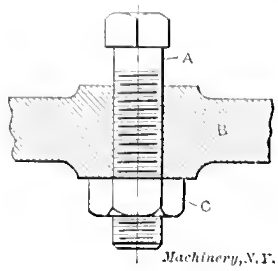

Fig. 29. Simplest Form of Adjustable Locating Point.

The design shown in Fig. 30, where *A* represents the work to be located, *B* the sliding point, itself, and *C* the set-screw, binding it in place when adjusted. The sliding point *B* fits a hole in the jig wall and is provided with a milled flat slightly tapered, as shown, to prevent its sliding back under the pressure of the work or the tool operating upon the work. This design of sliding point is frequently used, but it is not as efficient as the one illustrated in Fig. 31. In this design the sliding point *A* consists of a split cylindrical piece, with a hole drilled through it, as illustrated in the engraving, and a wedge or shoe *B* tapered on the end to fit the sides of the groove or split in the sliding point itself. This wedge *B* is forced in by a set-screw *C*, for the purpose of binding the sliding point in place. Evidently, when the screw and wedge are forced in, the sliding point is expanded, and the friction against the jig wall *D* is so great that it can withstand a very heavy pressure without moving. Pin *E* prevents the sliding point from slipping through the hole and into the jig, when loosened, and also makes it more convenient to get hold of. In Figs. 32 and 33 are given the dimensions most commonly used for sliding points and binding shoes and wedges.

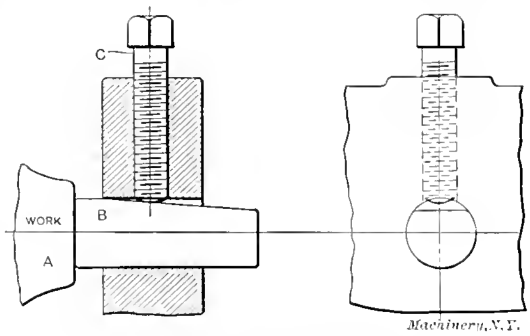

Fig. 30. Adjustable Locating Point consisting of a Flatted Stud held in Place by Set-screws.

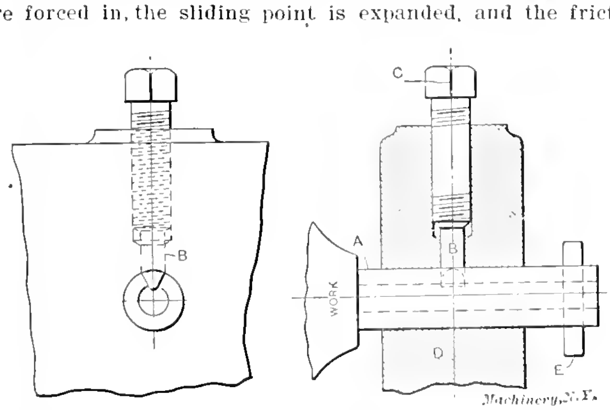

Fig. 31. Sliding Point used for Locating Work

If the work to be finished in the jig has some holes already finished, it is sometimes most satisfactory to locate the work by these holes, which may be done by means of studs or plugs similar to the one shown in Fig. 20, which then enter the holes; preferably, these studs should then be ground and hardened to the standard size of the hole. If the finished hole should be of a character that varies somewhat in size, expansion studs with bushings may be used. These studs may be of a great many different designs and styles, but, as a rule, they always work on the same principle as the one shown in Fig. 34. In this, *A* is the bushing, fitting the finished hole in the work. This bushing is split in several different ways, either by having one slot cut entirely through it, and two more slots cut to within a short distance of the outside periphery, or by having several slots cut from the top and from the bottom, alternating, but not cut entirely through the full length of the bushing. The matter of splitting, however, in every case, accomplishes the same object, that of making the bushing capable of expansion, so that when the stud *B*, which is turned to fit the tapered hole in the bushing, is screwed down, the bushing is expanded.

Locating by Keyways in the Work.

Sometimes the work to be finished in the jig is provided with a keyway or a slot, or with some other kind of a seat, by means of which it is located on its component part on the machine for which it is ultimately intended, and it is always essential that the work be located in the same way in the jig as it is to be located on the machine on which it is to go; thus, if the work has a keyway, suitable for locating, a corresponding keyway ought to be put into the jig, and the work located by means of a key, as shown in Figs. 35 and 36. Instead of a loose key, a tongue may be planed or milled solid with the jig, but, as a rule, it is more satisfactory to have the loose key, as, if it should happen to wear, it is possible to replace it; and if the width of the keyway should vary in different lots of the parts made, it is possible, with little expense, to make a new key to fit the variation, whereas, if the key is made solid with the jig, and found to be either too large or too small, the trouble of fixing this would be considerably greater.

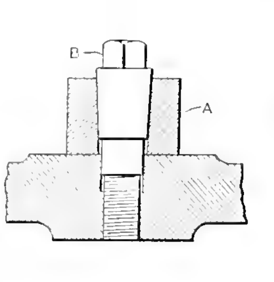

Fig. 34. Expansion Bushing used for Locating and Clamping Work.

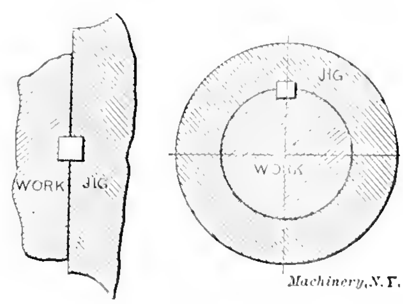

Figs. 35 and 36. Locating Work by Keyways

There are, of course, a variety of different methods of locating the work in the jig, depending upon the nature and the shape of the work, but those mentioned above are the most common, the cheapest, and those that, as a rule, give sufficiently good results for ordinary work. The principles involved in the design of the means of locating the work described above, would all be the same in any kind of locating devices, so that it would simply be a difference in application of the principles, rather than a difference in the principles themselves.

SHOP ORDER TRACING SYSTEM.

CHARLES M. POND.*

In suggesting any new system, one must first of all fully realize that the same conditions do not exist in two shops or factories. Hence, the system suggested must be broad and flexible enough to permit of being adapted to the various conditions already in existence. Moreover, the conditions permitting the use and adoption of the system should be carefully analyzed in order that the individual or corporation which is inclined to try the system, may first investigate and see if it can be maintained successfully.

CUSTOMER:

ADDRESS:

CUSTOMER'S ORDER NUMBER	SHIPPING ORDER NUMBER	MATERIAL	SHIPPED

Machinery, N.Y.

Fig. 1. Card on which is recorded Customer's Name and Address, Order Numbers, and Date of Shipment.

The system which the writer is about to present is of chief interest to the manufacturer of tools, instruments, fixtures, and the like. To all those engaged in this work, the daily mail brings its full quota of "tracers," "ticklers," and inquiries. These, in many cases, constitute fully 10 to 15 per cent of all mail received; and if the correspondence is large, their number will be proportionately great, and will require a separate department to give them proper attention and to answer them intelligently and correctly. The customer receives an answer and promise of shipment, and bases his calculations accordingly. If the promise is not kept, it may mean serious loss to him, and consequent ill feeling, and the curtailment of orders placed with the offending concern. Many times it results in cancellation, and consequent loss, if the goods are in any way special. It is therefore evident that care should be taken in replying to these inquiries. Moreover, a manufacturer who has a reputation for keeping his promises of delivery need have little fear of losing his customers, provided his product is satisfactory. That these "inquiries" or "order tracers" before mentioned are very common is evidenced by the fact that almost every concern which buys at all, has a printed form which is sent to the seller, asking that most important, and often vexing, question: "When can you ship?"

Now, having the conditions existing as outlined, it remains for the manufacturer to give an immediate and satisfactory answer; and this is where the value of a comprehensive and practical system will make itself felt. It is the writer's object to lay out such a system as can be easily adapted, and will not require much outlay to install.

First let us see where and under what conditions this system may be used. It will be of chief value, as has been said before, to the manufacturer of small articles such as drills, tools, fixtures, and the like, where a great variety of stock is kept constantly on hand, and for which there is a steady demand. It will also be of most value to the factory having its machines grouped in departments according to kinds of operation. It can readily be seen that, in the case where the complete tool is made entirely in one department under the direct supervision of one foreman, the time of completion of any article or order is readily determined. But this manner of dividing machinery is gradually being replaced by the modern and vastly more economical method of having machines of one type grouped together in one department. This department is under the supervision of an expert in that line, and but one operation is performed under his jurisdiction. For example, we can assume that a concern makes twist drills of a great variety. It would be entirely possible to have one department make the common drill complete; another department, the high speed drill; still another, the wire drill, etc. But the proper way is to have it so arranged that one department cuts off the stock, another does the milling, another the turning, another the grinding, and so on. It is because of the almost universal adoption of this latter arrangement of machinery that it is often difficult to estimate with accuracy the exact date of completion of any order, especially if it must pass through many departments, and take its turn. Hence a follow-up system is necessary, and every manufacturer will find it to his advantage to have one on which he may rely.

Of course, the financial question comes up: "Can I afford to install and maintain a system?" The writer has considered this phase of the question, and has outlined a method that may be readily handled by two men in a shop employing about four hundred hands. With but two hundred men, only one man will be required, and the same proportion holds where the number of men is larger than four hundred.

The first item which comes up for attention is the customer's order. This, as a rule, has a number by which it is known in all future correspondence between the manufacturer and customer. This number is given to it by the customer, and we shall designate it hereafter by the term "customer's order number." Sometimes the date of the order is its only identification as far as the customer is concerned, but this is generally in the case of small concerns.

This customer's order now becomes a definite factor to the manufacturer, and he must keep a record of it in various ways. For this purpose he gives it another number by which he identifies it for his own records. This number may conveniently be called the "shipping order number." In some concerns the customer's order is taken directly to the storeroom and there filled, if possible. Other manufacturers make it a practice to transcribe the order to a regular shipping order form, which has the advantage of uniformity in size, and can be more easily understood by store-room and shipping clerks. This form will have the same shipping order number as is given to the customer's order. If the order (which we will hereafter call the "shipping order") can be filled from stock on hand, the material is immediately boxed and sent to the customer, and the shipping order is filed away after all necessary records are made. But suppose for some

SHORTAGE OF:

ON WORKING ORDER NUMBER:

SHIPPING ORDER NUMBER	NUMBER OF PIECES	SHIPPING ORDER NUMBER	NUMBER OF PIECES	SHIPPING ORDER NUMBER	NUMBER OF PIECES

Machinery, N.Y.

Fig. 2. Card on which Pieces not in Stock, but which are required to fill Orders, are recorded.

particular reason the stock necessary to fill the order is not in the store-room, but is in the process of manufacture somewhere in the shop. It then becomes necessary to place the shipping order in a temporary file, and wait until the material in the works is completed, before making shipments. Again, let us suppose that the customer requires something out of the ordinary, that has to be made up especially for him. Then a special working order must be issued to the shop, and the shipping order filed away temporarily until these special goods are completed. Hence it is evident that there will be in the factory two general classes of orders, namely, the orders for stock goods, and the orders for special goods.

* Address: 49 Tremont St., Hartford, Conn.

These working orders should all be numbered for reference, and when a special working order is made out for any shipping order, the working order number should be noted on the shipping order, and *vice versa*.

We now have the following papers to deal with:

1. Customer's orders.
2. Shipping orders (which may be the same as No. 1).
3. Special working orders.
4. Stock working orders.

Next let us see what printed forms and card indexes are necessary for the follow-up system.

First we must have a card index consisting of cards, as shown in Fig. 1. After the customer's order has been given

DAILY REPORT.

Fig. 3. Foreman's Daily Report Card.

a shipping order number, or transcribed to a shipping order form, a record should be entered on this card. At the top of the card is the customer's name and address, and the cards are filed alphabetically, according to the name of the customer. In the first column is entered the customer's order number, in the second column, the shipping order number, and in the third column may be entered, if desired, a short description of the goods. When complete shipment is made, the date of such shipment should be stamped in the last column.

The next card index required is a "shortage list." This is complied from a shortage sheet of any convenient form, made out by the store-room clerk. The cards may be printed as shown in Fig. 2. When any stock article is required to fill a shipping order, and this article is not in stock, the store-room clerk makes out a slip or list showing what is needed and for what shipping orders. These data are then classified and entered on the cards, so that upon receipt of the stock, the number of pieces required for various shipping orders may be correctly distributed. It is well to place on the card the shop working order number on which the stock is being made, in order to readily locate the goods in the shop.

A daily report sheet is necessary, as shown in Fig. 3. These should be made up in pads, and every department supplied. Each day the foreman or his clerk enters in their proper columns the working order numbers which he sends away, and the number of the department to which he sends them. These reports should be dated and turned in every night to the head of the follow-up system. From them the "follow-up man" enters a report on his tracer cards. (See Fig. 4.)

These cards are filed numerically according to the working order numbers, and may be used either for special or stock orders. Of course, in the case of stock orders the customer is "Stock," and there is no shipping order number. These tracer cards are made out from the working orders before they go out into the shop. If kept up to date, it is possible to tell at a glance where any particular working order is located, and on what date it went to the department where it then is.

We are now in a position to assume a case and see the working of the system in detail.

1. A customer sends in an order, duly numbered, for some stock article. This order is first examined to see if everything is clear, and is then given a shipping order number. If customary, a regular shipping order form is made out. The order should then be entered on the proper card in the customer's card index, Fig. 1. The customer's order number is placed in the first column, and the shipping order number in the second column, as explained before. If a regular shipping order form has been made out, the customer's original order may be filed away, otherwise it must go to the store-room to be filled. We will suppose the goods ordered are on hand and that the shipment occurs immediately. The following day all shipments are stamped on the customer's cards in the last column opposite the proper number. Now, as often happens, the customer sends in his inquiry directly after his order. This inquiry comes to the "follow-up man," and he turns to the correct customer's card and sees that shipment was made on such and such a date.

2. Now let us suppose an order was received for some special goods. The entries are made exactly as before, but shipment cannot, of conrse, be made directly. A working order is now issued for the goods wanted, and its number is noted on the shipping order, and this latter is filed away temporarily according to its number. Now comes the inquiry. The "follow-up man" turns to his customer's card and sees that shipment has not been made. He then notes the shipping order number on the inquiry, and gets this shipping order from its temporary file. Then he can readily see that the goods are special, and are in the process of manufacture. By means of the working order number he can locate the tracer card for that particular order, and this tracer card has a complete record to date of the order in question, and shows in which department it is. It is now necessary for him to make out a card as shown in Fig. 5. In the column headed "last reported" he enters the latest report as shown by his tracer card. The working order number, shipping order number, customer's name, and a short description of the goods are also entered in the spaces provided. This "estimate card" may then be clamped to the order and inquiry, and when the "follow-up man" is ready, he takes these inquiries and looks up the work in the department in which it was last reported. From the foreman of that department he obtains a promise as to when his work on the goods will be done. He must enter the date of this promise on his estimate card in one of the "promised" columns opposite the name of the department making the promise. This promise should also be recorded by the foreman in a book suitably indexed for the purpose of enabling the foreman to lay out his work in such a manner as to be best able to keep or anticipate his promises. When he has obtained all the promises desired, the "follow-up man" may return to his desk and enter in his "estimate" column the dates on which he estimates the work should leave the various departments through which it has yet to go. From the estimated date of delivery of the goods to the store-room he makes a promise which he enters on his estimate card, on the customer's inquiry, and also on the tracer card for that particular order number.

Machinery,N.Y.

Fig. 4. Tracer Card which gives the Location of any Particular Order.

The "estimate card" is now filed in a specially prepared index as shown in Fig. 6. It is filed under the date promised and under the sub-division of the department making the promise. Each day the cards filed under that date are taken out, and the "follow-up man" goes from department to depart-

ment, ascertaining if promises have been kept, and if so, getting a new promise from the next department. This will prevent an inquiry from ever being forgotten, and it is easy to see whether a promise to the customer will be lived up to or not.

3. Last of all we have the case where the customer orders regular goods, but these are not in stock at present. After the usual preliminaries, the store-room clerk makes out his shortage list, which is afterwards transferred to the shortage card file, the shipping order being placed in the first column, and the number of pieces wanted in the second column. The inquiry now comes in and goes, as usual, to the "follow-up man." As before noted, he obtains the correct shipping order

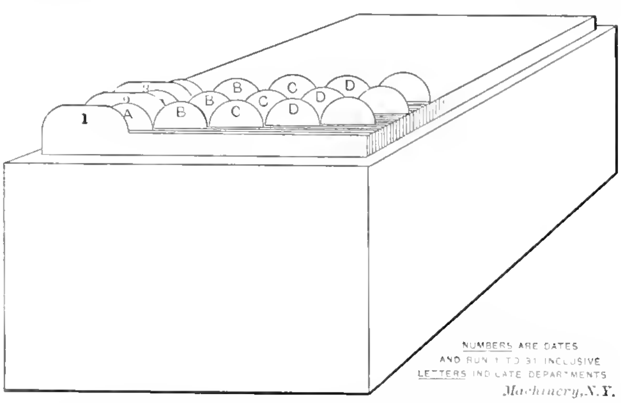
by means of his customer's cards and then notes what stock is needed to complete the order. Next he looks to his shortage list, where he finds the particular shortage in question duly entered, together with the working order number on which the stock goods are being produced. He will then make out his estimate card and treat this stock order just the same as a special order. A promise once made on a stock order will answer for all inquiries for these particular goods. In other words, there is a record of the probable time of completion of certain stock goods, and these goods are being systematically hurried through the shop by means of the estimate card, which comes up automatically at the time the goods should leave any department.

It has been found that a typewritten list of all stock orders needed to complete shipping orders is a most valuable detail, and should be distributed to the various departments, as it will enable the foremen to direct their work in the proper



Machinery, N.Y.

Fig 6 Estimate Cards filed under promised Date of Shipment, and under Sub-division of Department doing the Work.

channels, and get the goods well under way before an inquiry is received. This list can be made out at regular intervals, say once a week. Another helpful little adjunct will be found in a small paster of any form or wording desired, which should be attached to all orders that are being followed. This paster may simply have the word "Rush" or "Promised" printed upon it in large type. It will facilitate the progress of the work, and give no excuse for its being laid aside because it was not thought to be urgently needed.

Another paster having the word "Shortage" printed upon it can be supplied to the various foremen to paste to any orders in their department which are not being followed, but which, according to the weekly shortage list, are needed to complete shipping orders. Some form of paster is also desirable to attach to the customer's inquiry, on which to enter the shipping order number and the promise. In the accompanying engraving all cards are shown half size.

With these few forms it is easy to answer inquiries in shops receiving fifty to a hundred orders daily. Where fewer orders are received, the number of forms can be cut down slightly. The system is capable of infinite expansion for very large shops.

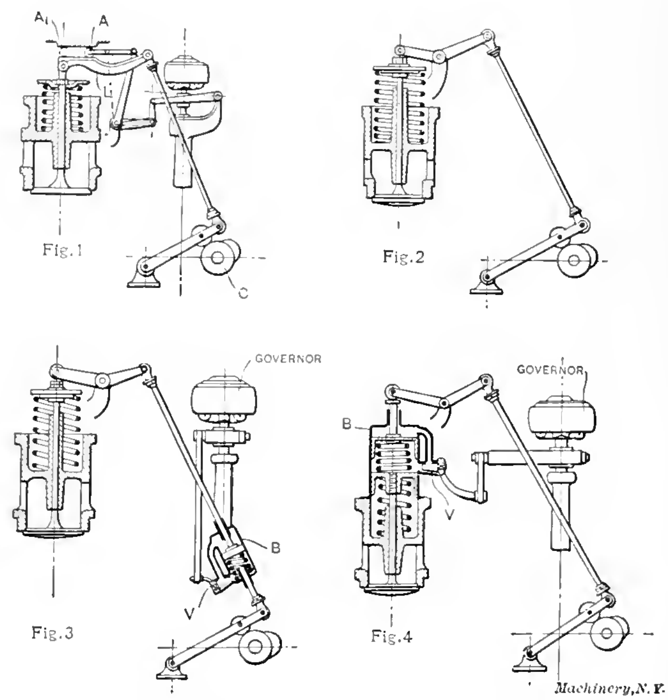
To any manager whose mail contains complaints which are annoying, a remedy such as above suggested will not only give him immediate rest from the annoyance, but tend to increase his business.

* * *

A PRACTICAL PROBLEM FOR ENGINE DESIGNERS.

We take a great interest in your valuable journal, and as we have noted that you encourage your readers to send problems which they want solved, we wish to propose the following for general consideration.

The problem is to design a new method of controlling the movement of poppet valve reciprocating steam engines. Fig. 2 shows the ordinary plain construction of poppet valve, operated by a cam on a longitudinal lay shaft. This valve has a fixed movement, always opening to its maximum extent. Fig.



Machinery, N.Y.

1 illustrates a method for obtaining a variable movement, the variation extending from the maximum to zero, and the operation being controlled by the governor. The construction is quite plain. The little roller *A*, whose position is controlled by the governor through suitable linkage, acts as a pivot on which the lever *L* rocks. When the engine is running slow, the position of the roller *A* is as indicated in the full lines. When the engine is running above full speed, the position of the roller is as indicated at A_1, the result being that the poppet valve is not opened at all by the action of the cam *C*.

In Fig. 3 is shown the "extensible bar" method, the construction being that of a cylinder and piston in the valve connecting-rod with suitable by-pass valve *V* controlled by the governor. The piston is under pressure of a coiled spring and both sides of the cylinder are filled with oil. Fig. 4 shows a variation of the same construction.

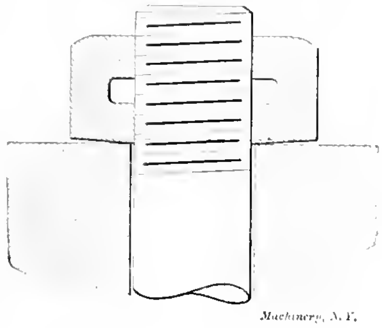
Now, who can get up a different construction which will give variable opening of the valves with delicate governor control?

Societe Anonyme des Moteurs a Gaz A Bollinckx.
Huyssinghen, Belgium.

ITEMS OF MECHANICAL INTEREST.

SIMPLE FORM OF LOCK NUT.

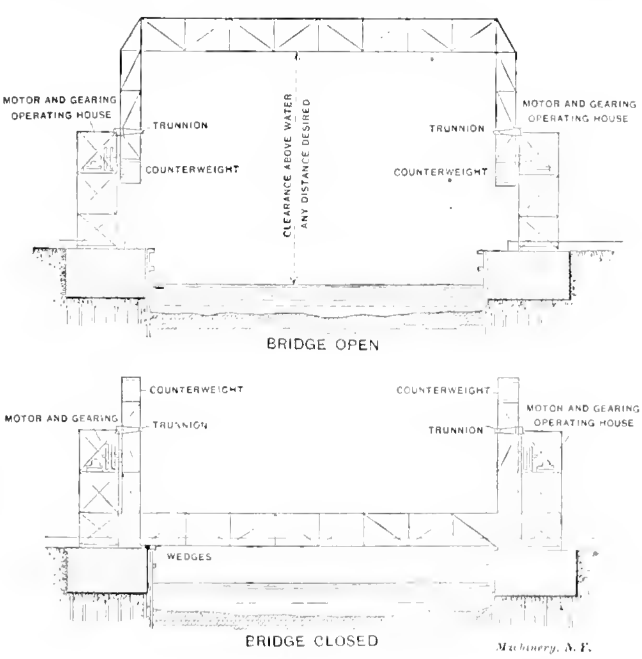
A new form of lock nut, interesting chiefly on account of its simplicity, was illustrated in the February 7 issue of the *Practical Engineer*, and is shown in the accompanying engraving. This construction of lock nut has recently been proposed by some English inventors, Messrs. R. R. Wellbury, T. Harle and G. Mackie. Most of the lock nuts patented from time to time, though fulfilling their purpose successfully, have been expensive to manufacture, and have been accompanied by difficulties in fitting. The nut shown here is free from these objections. The lower face of the nut is faced slightly conical, as shown, and an annular groove is formed inside the threaded hole, allowing a certain amount of elasticity between the upper and lower portions of the nut. When used, the inside area of the lower conical face is the first part to come in contact with the work, and, owing to the elasticity allowed by the annular groove, further tightening forces the lower threads of the nut into close frictional contact with the threads in the bolt, thereby preventing any slackening back or shaking loose of the nut. It is stated that a number of these nuts have been applied to high speed steam engines, traction engines, motor cars, etc., and have proved very satisfactory.



Inexpensive and Simple Form of Lock Nut.

AN INTERESTING DRAW-BRIDGE.

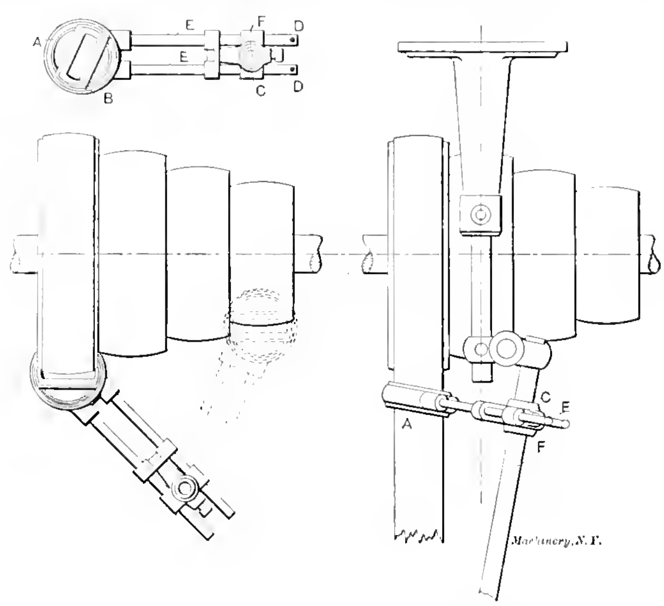
A draw-bridge of novel type has recently been designed by Mr. Eric Swensson, of Minneapolis, Minn., with the intention of applying the design to a bridge across the "Narrows" on Lake Minnetonka. The principle of the construction is shown in the accompanying engraving, taken from the *Engineering News*. The construction is so peculiar that a brief description may be of interest. The bridge consists of a truss or plate girder span, suspended by trussed hangers from trunnions bearing on towers at each abutment. The draw is opened by revolving the truss in an arc around the horizontal longitudial axis through the center of the trunnions, as is clearly indicated in the engraving. The upper portion of the trussed hangers carries counterweights equal in weight to the suspended structure, so that the friction and the wind pressure are the only forces which the machinery has to overcome in opening the bridge. When the bridge is in its normal condition wedges are placed under the extreme ends, so that the weight is carried directly by the abutments, and not by the trunnions.



A Draw-bridge of Unique Design.

GERMAN TYPE OF BELT SHIFTER.

An interesting, and for its purpose, well adapted belt shifter, which has been in use in Germany for some time past, is shown in the accompanying engraving. This belt shifter is made by the Berlin-Anhaltische Maschinenbau-A.-G., Berlin, and is known by the trade name "Bamag." As shown in Fig. 1 this belt shifter consists of a casting *A*, into which the belt guide *B* is fitted so that it can turn freely in the hole in *A*, in order to adapt itself to the belt in the various positions of the shifter. Into the casting *A* are inserted two rods or shafts *E* of such a length as to accommodate the required motion of the belt guide *B*, in relation to the holder *C*, in which the two rods *E* have a sliding fit. The small stop pins *D* prevent the shafts *E* from entirely sliding out of the holder *C* when the device is in operation. Through the hole *F* in the holder *C* the shifting rod, which is made of cold rolled stock, is passed, and the shifting is accomplished by turning this rod, a pin or handle being attached to it at the lower end for this purpose. When the shifter is applied to cone



Figs. 1, 2 and 3. German Type of Belt Shifter.

pulleys, the belt guide *B*, containing the belt within it, will adapt itself to such a position that the belt will run freely, the adjustment of the part *A* containing *B* being accomplished by the sliding action of the studs *E* in the body *C*.

The engraving, Fig. 2, shows a plan view of a case where the belt shifter is applied to a cone pulley. Fig. 3 shows the connection of the belt shifter with a bracket on the ceiling and shows the general arrangement of the device. The connection with the ceiling bracket support is a universal joint, permitting perfect freedom to the motion of the shifter rod and shifter. It is difficult to judge from the engravings to what extent this shifter is practical, but we understand that as many as 14,000 are in use on the European continent, and the Krupp works alone use over 600. This would indicate that the device has proved to be thoroughly practical. The Brown & Sharpe Co. employs in its shops a belt shifter working on a similar principle, although even somewhat simpler; this shifter gives entire satisfaction.

* * *

In the construction of a battleship, the exact weight of every part, and of every accessory, from a doily on the captain's table to the heaviest piece of armament or mechanism, is ascertained and recorded, thus making it possible to determine the weight of the ship at any stage of the construction. The importance of weighing everything will be appreciated the more when it is known that the weight of the paint alone, used on the battleship *Connecticut*, amounted to 210 tons.

Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JUNE, 1908.

PAID CIRCULATION FOR MAY, 1908, 22,426 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

HUNTING FOR WORK.

During the present depression thousands of men, skilled and unskilled, are engaged in the almost hopeless task of looking for work. They spend money and energy in about the most discouraging task a human being can engage in. Rebuffed at every turn, there is great danger of a man's moral fiber being so deteriorated that his former good habits are lost. Such periods make tramps and hoboes, and a skilled man should be very careful how he starts out in an aimless search for employment. It is hard, of course, to sit quietly at home when want is staring you in the face, but what is the use of making a bad matter worse? The cheapest and generally the most profitable way for a skilled man to find out where employment is to be had is to write letters to all the concerns within a radius of, say, one hundred or two hundred miles, stating his experience and asking for employment. When no work is to be had, such letters, of course, cannot bring employment, but they will most likely be placed on file and referred to when openings do develop. A personal interview is always preferable, but when "nothing is doing," superintendents will not entertain applicants, or even go to the trouble of taking their names. The letter puts on file the very data that may give you a job long before the other fellow, who depends on a personal canvass, gets one. It is better, nine times out of ten, to stay at home and help the wife clean house, tend the baby and do the cooking. You will have time also to study mechanical drawing and other matters connected with your trade, knowledge of which may advance you rapidly when good times come.

* * *

BUILDING SHOPS FOR GROWTH.

It is a matter of first importance in building a machine shop to arrange for future growth. We recently visited an old shop which had grown to considerable size by repeated addition made in piece-meal fashion, the result being a shop having no system of arrangement, and which is poorly lighted and badly arranged for the manufacture of its product. It was impossible to provide adequate overhead appliances for handling the work, and in consequence this shop, although well located in many respects, cannot compete advantageously with other shops having modern equipment, so that it has become necessary to put up a new structure having cranes and handling appliances. It is, of course, needless to say that the new shop will be constructed with an eye toward possible extension which can be added in harmony with the original plan.

The saw-tooth roof shop is admirable in this respect, it being possible to add to it indefinitely in harmony with the original unit, and still have a shop that is well lighted in all parts. A monitor roof shop with saw-tooth roof wings can be extended indefinitely, also, and the combination is well adapted to both heavy and light constructions. The monitor roof shelters the heavy traveling crane and heavy erection, while the saw-tooth wings shelter the machines and small erection floors, these latter being provided, desirably, with light hand traveling cranes.

* * *

FOREIGN MACHINE TOOL COMPETITION.

With apparent good reason, many of our American machine tool builders have felt that foreign trade was largely a matter of the past. Europe has an army of educated engineers—men who rank higher in technical attainments and training than the same class here. They have highly developed powers of analysis and are quick to grasp the fundamentals of a given proposition. They excel in the metallurgical arts and are most thorough in general application. Europe's manufacturers are long-established, and the inherited skill of many generations of workmen is at command for moderate wages. With all these resources available in a country where trade is keenly sought, it would seem that the machine tool business must go back into the hands of the native builders.

There is another theory, however, that gives us a crumb of comfort, and it is one that is quite important to consider. It means much to all American manufactures, for, if sound, it may result in giving us the markets of the world. Whether it was developed by a high tariff man we know not, but it does have a measure of plausibility.

The theory is that the machine tool builders of England and Germany cannot develop into strong competitors of the United States for the simple reason that *they have a restricted market*. The rampant militarism in Europe and the trade jealousies fostered thereby, discourage Germans from buying English tools, and *vice versa*. The same holds good with the other European countries all along the line. The colonial trade of none of these countries will call for a large number of machine tools for years to come. Without a large market the machine tool builder cannot specialize, and if he cannot do this he cannot compete with us. The majority of the foreign machine tool builders are "engineers"—that is, they build anything under the sun that will make a penny of profit. If this condition must continue because of the reason we have given, we have a hold on foreign business that cannot be shaken off until military domination is done away with.

However, the influence of militarism and political prejudice is waning, and we are inclined to take the view of Winston Churchill, who started in life as a Tory, but who is now the leader of the younger democratic group in the Liberal party of England. He believes that economic and not political policies will dominate in the future. "The world has become acutely conscious of the fact that political freedom, however precious, is utterly incomplete without a measure, at least, of social economic independence. All over the world the lines of cleavage are ceasing to be purely political, and are becoming social and economic." In trade intercourse, political prejudices will be cast aside, more and more, and the progressive German manufacturer will have no more hesitation in buying machines from English or French makers, which will be money-makers for him, than from his own countrymen. Political prejudice is fostered by ignorance, and the spread of intelligence by the telegraph, telephone, the daily newspaper, the trade journal and the commercial traveler is doing much to prevent war, the bitter feelings engendered by war, and the political prejudices that hinder international trade.

SPECIALIZATION.

The tendency toward specialization in practically all branches of manufacturing develops some curious anomalies, or perhaps we should say some apparently curious anomalies. These, in most cases, are largely imaginary because of the feeling still remaining with most of us that a machine manufacturer constructs his product from the raw materials, that is, from the metals as they are received from the rolling mill, the blast furnace and the smelter. There is no good reason for such opinion, in the first place. Even if there were, a sound definition of "raw material" being impossible, it becomes very difficult to say what work a so-called builder should actually perform to have proper credit for actually manufacturing his product.

Take, for example, the manufacture of sewing machines. It is the most highly organized business in existence, yet we understand that very few sewing machine manufacturers make their own bobbins, practically all the bobbins used in the United States being made by one Chicago concern. Needles and shuttles are made by specialists cheaper, it is claimed, than they can be produced by large manufacturers, because of the ability of an individual to concentrate his powers of organization and inventiveness upon a single subject without interference. In large manufacturing plants it has been found that the development of special machinery is not desirable, and many of our best-known concerns contract with the small concerns for the invention and development of certain special machinery. They have found it more satisfactory both in the efficiency of the machines produced and the cost. This fact betrays a weakness in the organization of large concerns which perhaps means that the small concern will always enjoy certain advantages over powerful corporations.

* * *

WAGES AND THE TARIFF.

It has been often pointed out, although not quite as often, perhaps, as it should have been, that while wages in America are *absolutely* higher than in Europe, they are *relatively* lower in this country, if the amount of product turned out per capita is taken as the basis of comparison. In itself this may be considered as of small consequence; but it is highly significant and of interest to note in connection with the claims made by the defenders of our protective tariff, that it would be difficult, if not impossible, for our manufacturers to compete with European labor if this were a free market, because the wages paid to American labor are higher than those paid in Europe. This argument is fallacious, because for the same amount of product there is less paid in wages in the United States than in Europe. Mr. Clark, in the *Engineering Magazine*, issue of May, 1904, pointed out that while 21.4 per cent of the value of the product went to pay labor and the cost of power in the principal industrial countries in Europe, only 17.4 per cent of the value of the product was used for these purposes in the United States. Power, he says, can be considered as being of the same cost on both continents; consequently, the wages, in proportion to the product turned out, are lower in the United States.

Another indication of the truth of this statement is given by the returns on the coal trade given out by the British Board of Trade. It is shown that the output per person employed in the coal mining industry of the United States, is 560 tons, while in the United Kingdom, the output per person employed is only 280 tons; in Germany, the output is 242 tons; in France, 202 tons, and in Belgium, 159 tons. Now, even if the wages of coal miners in the United States were double the wages paid in Europe, it would follow that the wages as compared with the output, would be the same in the United States and in England; that for Germany the wages would be relatively much higher than in the United States; and in Belgium, in fact, 1.75 times as high. Of course, it is admitted that the coal mining industry presents a case where the difference is greater than in many other industries, but the general tendency is the same in all trades.

The American ability of systematizing and of cutting out useless expense, and the existence of a more contented and intelligent class of workers, has made it possible to produce more per person employed; but it should be distinctly understood that the wages in proportion to the product are lower, and that, therefore, there can be no reasonable fear whatever, that, even with a reduction in the tariff, the lower per capita wages of Europe would be able to force an unprofitable competition on American manufacturers.

* * *

MATHEMATICS AND PRACTICAL EXPERIENCE.

An Eastern machine tool builder, who is a broad-minded and competent mechanical engineer as well, (by no means an unusual combination) remarked the other day that it was the regret of his life that he had graduated as a young man from the technical school which was his *alma mater*, instead of from another whose name he gave, and concerning whose work he was well informed and enthusiastic. In the school he attended, the first importance was, and still is, given to mathematical analysis, the faculty believing that a thorough knowledge of this is the prime requirement for a successful engineering career. As an instance of the kind of instruction given, he mentioned the fact that his text-book on the steam engine was written by a chaplain to Queen Victoria, an estimable clergyman of great mathematical ability, who had analyzed the steam engine problem mathematically, and been rewarded for his labors by the honorary appointment mentioned. He covered the ground of steam engine design quite thoroughly for the time in which he lived, producing what is, perhaps, the most formidable array of formulas on the subject that has ever been assembled. These formulas include an appropriate supply of constants, whose values are not given, as those values can be derived only from experiment and practical experience. The necessity for saying anything about the values of these constants apparently did not enter into the head of the reverend engineer, as he probably believed that the task of instructing students was completed when the analysis and its resulting formulas had been followed and understood.

In contrast with this pedagogical idea, the second school which our acquaintance mentioned so appreciatively, lays special stress on the necessity for bringing analysis and practice into intimate relation with each other. A large share of its laboratory work consists in the commercial testing of various apparatus within its field. Its professors are largely engaged in consulting work, and its president is the head of a famous firm of engineers, and only gives half of his time to the school. Under such conditions as these, the student learns that mathematical analysis is of the greatest importance, but that its importance is the importance of a tool, useful in applying results of past experience and experiment to future design, and in suggesting methods and lines of experimental research into new fields of practice. From a standpoint like this, it will be seen that the chaplain-engineer's neglected constants assume an importance which he did not realize, and his fine spun analysis is left hanging in mid-air, as it were, without any point of contact with the solid ground of practical work.

It was probably due, in part at least, to such an implicit reliance on analysis as would be fostered by prolonged study of the chaplain's text-book, that the engineers responsible for the design of the Quebec bridge disregarded the repeated assertions of the untrained "practical" men in charge of the erection, that the great bridge was unsafe. So confident were they in their knowledge of mechanics and mathematics, that they failed to realize that the signals of distress displayed in the structure had an importance far overshadowing the results of their theoretical conclusions. The *Engineering News* has rightly remarked that perhaps the most profound lesson to be drawn from the Quebec disaster is the lesson of humility for the technically trained engineer. Not humility in the sense that he should think less of his technical training, but that he should think more of the importance of the practical behavior of the materials, structures and mechanisms with which he has to deal.

The man in charge who is missed when temporarily absent is a bad organizer.—*D. T. Taylor.*

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

In the May issue of MACHINERY we stated that helium had been solidified by a Dutch scientist, Professor Onnes. It seems, however, that Prof. Onnes had made a mistake in stating that he had succeeded in solidifying helium. He has now given out a statement to the effect that his helium contained a slight amount of hydrogen, and that this accounted for the solidification.

The Schlick gyroscope for preventing the rolling of ships at sea has been applied to a small steamer *Silvania* of the Hamburg-American line. The displacement of this vessel is 900 tons. The fly-wheel of the gyroscope is 65 inches in diameter, and will run at a rate of 1,800 revolutions per minute. The results will be watched with considerable interest by marine engineers as well as by mechanical engineers in general.

The tower of the Metropolitan Life Insurance Co.'s building, which is now in the process of construction at Madison Square, New York City, and which is to be the highest structure in the world outside of the Eiffel tower in Paris, is to have another 37 feet added to its original height, bringing the extreme top 693 feet above the sidewalk level. The new design provides for an observation balcony 662 feet above the sidewalk, and including two stories in the basement, the total number of stories will now number 50.

The horse-drawn vehicle is, says the *Horseless Age*, slowly but surely being displaced by the motor car for public transportation in all large cities. In London there were on January 1, 1907, 783 motor omnibuses and 2,964 horse omnibuses, while on January 1, 1908, the number of motor omnibuses had risen to 1,205, and the number of horse omnibuses had decreased to 2,557. The number of motor cabs had increased during the same period from 96 to 723, while the number of horse cabs had decreased from 10,492 to 9,818. There are, at the present time, 1,700 motor trucks in use in London.

An English inventor, Mr. Chas. J. Grist, London, has, according to the *Iron Age*, patented a method of hardening steel or steel alloys. By this process the steel to be treated is heated in a vessel containing mercury heated to a temperature varying for different steels from about 400 to 840 degrees F., and then an electric current is applied at from 200 to 500 volts and 25 amperes. Carbon steel twist drills treated in this manner perform nearly double the amount of work done by drills hardened in the ordinary manner. Inasmuch as mercury vaporizes at 675 degrees F., a temperature of 840 degrees would, however, not be attainable.

According to the *Berliner Lokal Anzeiger*, a course in automobile engineering will be instituted at the technical institute at Berlin. It has been decided to extend the instructions concerning automobile engineering to all its branches, and to render it practical by increasing the laboratory equipment. The cost of machines and testing equipment necessary is estimated at about $60,000, and many expensive machines will be loaned by private firms who will also bear the expense of a great portion of the experimental equipment. The department will be conducted by a professor having a staff of two assistants, two mechanics and a chauffeur.

The best record in high-speed drilling that we know of is that made lately by Baker Bros., Toledo, Ohio, on a special drill press, using a Novo twist drill 1¼ inch diameter. Holes were drilled through cast iron blocks 4¼ inches thick in 8 2/5 seconds, or at the rate of about 29 inches per minute. The drill ran at 450 revolutions per minute with a feed of 1/15 inch per revolution. A peculiarity of this rapid drilling is that the drill is not as hot when it has passed through the block with a feed of 1/15 inch per revolution as when it is run with a finer feed. Allowing that steel plate could be drilled at only one-half this rate, it is of interest to note that even then drilling would be faster than punching 7/16-inch plate on a punching machine running at the rate of 30 strokes per minute!

The highest efficiency as regards steam consumption that has as yet been obtained in any steam engine, has, according to *Industritidningen Norden*, been attained in an engine built by the J. & C. G. Bolinder's Works, of Stockholm, Sweden. This engine is of 1,000 H.P., and at official tests the steam consumption per indicated H.P. hour was only 8.58 pounds. Another remarkable feat in the design of steam engines has been attained with a 100-horse-power superheating portable engine built by R. Wolf, of Magdeburg-Buckau, Germany, which during a 7 hours official trial showed a steam consumption of 8.66 pounds per horse-power-hour, and a coal consumption of only 1.04 pound per horse-power-hour. The lowest steam consumption previously attained with any steam engine is, as far as known, 8.89 pounds, which was attained some years ago by an engine built by a Belgian firm.

In our September, 1907, issue, engineering edition, we mentioned the favorable results obtained with motor-driven fire engines in Hanover, Germany. The city of Berlin also, about two years ago, appropriated $12,000 for the purpose of carrying on experiments to determine the most suitable motive power for fire-fighting apparatus in that city, and the results obtained from these experiments indicate that a great saving can be accomplished by the use of steam and electric automobile fire engines. Gasoline engines are not recommended on account of not being considered absolutely reliable, and also because the danger of gasoline was considered objectionable. In consequence of the favorable results obtained, the Berlin city council has made an appropriation of $32,000 for the acquisition of a complete motor fire engine outfit, consisting of a chemical extinguisher, a tender, a hook and ladder, and a steam fire engine.

A circular from the United States Department of Agriculture calls attention to the significant signs of the awakening of the American people to the dangerous destruction of the forest wealth, and the necessity of a wise use of what remains of it. The question of the limitation of our supply of woods is one that is of great importance to all industries, inasmuch as this material is used in a greater or less degree in all our industrial activities. The circular calls attention to the fact that information on the subject of preserving timber from decay will be furnished to all who make request of the Forester Service of the Department of Agriculture, Washington. The fact is pointed out that it is not only possible to utilize the forests without waste, but also to prolong the service of the wood used so as to thereby decrease the consumption. The life of the wood can be considerably lengthened by the use of certain preserving methods which the department has been investigating.

The saw-tooth roof shop is a very satisfactory construction for the small manufacturer who must "pay as he goes." It is so readily enlarged in harmony with the original lay-out and so cheap in first cost that it is likely to become a very common type of machine shop architecture. The feature of uniform lighting, there being no glare or dark shadows anywhere, is in itself enough to commend it above most other types. Of course, where land is very costly the saw-tooth roof shop must give place to the factory type, having several floors superimposed. A fault of the saw-tooth roof is the difficulty of making the gutters proof against leaking. Hard rainstorms, especially when driving from the north, have caused much trouble with certain concerns, especially if the north saw-tooth windows were glazed with small panes set in the sash with ordinary putty. The remedy is to use large panes of ribbed glass without sash, the glass being set in the frame-

work of the shop, thus avoiding joints other than between the glass and the wood. The Kearney & Trecker shop in Milwaukee is built on this plan, the glass being placed in the openings without sash and set with good white lead putty.

INDICATOR FOR ASCERTAINING HARDENING TEMPERATURE.

An indicator for ascertaining the temperature of steel to be hardened has, according to *Page's Weekly*, recently come into use in Great Britain. This instrument depends on the fact that at the recalescence temperature at which carbon steel should be hardened, it becomes non-magnetic. With the aid of this indicator any kind of carbon steel, but not high speed or alloy steels, may be hardened at much lower temperatures than is commonly done when the temperature is gaged by the eye alone. The gage consists of a permanent magnet held in the hand, the poles of the magnet being prolonged by rods of special metal which remains magnetic at temperatures higher than the hardening temperature of carbon steel. If the pieces of work to be hardened are small, they are held by the magnet itself in the flame for heating the work. They will be attracted and held by the gage until they reach the hardening temperature, and at that time they are promptly quenched. This gage is said to be very accurate, so accurate in fact, that unless the steel is instantly transferred to the quenching bath when heated to the point where it loses its magnetic qualities, the loss of heat during the interval will prevent the piece of work from being fully hardened. It is also stated that it would not be difficult, when using this gage, to harden even the most intricate shapes in ordinary brine. The combined hardness and toughness secured by hardening in this manner is such that many cutting tools—in particular milling cutters—may advantageously be used without subsequent tempering. These gages are manufactured by Messrs. Taylor, Taylor & Hobson, Leicester, England, and they have used them in their tool-room for about two years, and have established a remarkable record. In all of the miscellaneous jobs that have been completed in the tool-room, not a piece has been spoiled by poor hardening, or by the very common troubles of warping and cracking.

MANUFACTURE OF SAND-LIME BRICK.

Many travelers on the New York Central lines between Buffalo and Chicago have noticed the immense sand-hills in northern Indiana, especially near Michigan City. These great moving masses, resembling the waves of the sea and typical of the great elementary force of nature, are almost irresistible in their destructive power. The engineering powers of man can not cope with the march of the drifting sand except as they are directed toward the growing vegetation. The birth of the desert can be directly attributed to the destruction of forests on a sandy tract, and one shudders to think of what the fate of large areas of the United States will be if the destruction of forests now going on is not checked. But this is not what we started to say. The moving sand has been made useful in the manufacture of brick, and brick-yards are so located in certain favored localities that the sand is blown up to them as fast as it is wanted. The transportation of this part of the raw material to the works is done by the wind without cost or effort on the part of the brick maker!

The manufacture of sandstone brick or lime brick is a German industry that has reached great commercial importance in Europe and is one that is rapidly growing in this country, there being two hundred plants that have sprung up in the past five years. A few words on the process may be of interest in this connection. The sand is ground in tube mills and is mixed with crushed lime. This mixture is moistened, pressed into bricks, and dried in large steam cylinder driers of 125 to 160 pounds per square inch, the temperature being that of saturated steam at those pressures, of course. The process is essentially the same as the natural process of forming sandstone, except that the time required is only a day or so against thousands of years by nature's method. The sand-lime bricks are made in a variety of colors, and being very strong and uniform in structure are regarded as a most desirable building material.

NEW DEPARTURE IN THE DESIGN OF HYDRAULIC PRESS CYLINDERS.

Teknisk Tidskrift, April 11, 1908.

A Russian engineer, V. Tatarinov, has designed an entirely new and interesting type of hydraulic press, as shown in the accompanying line engraving, Fig. 1. A detailed section of part of the construction is shown in Fig. 2. The fundamental principle on which the new press is designed depends on the fact that when the diameter of the cylinder is increased, the cross-sectional area increases as the square of the diameter, while the area of the cylindrical walls only increases in the

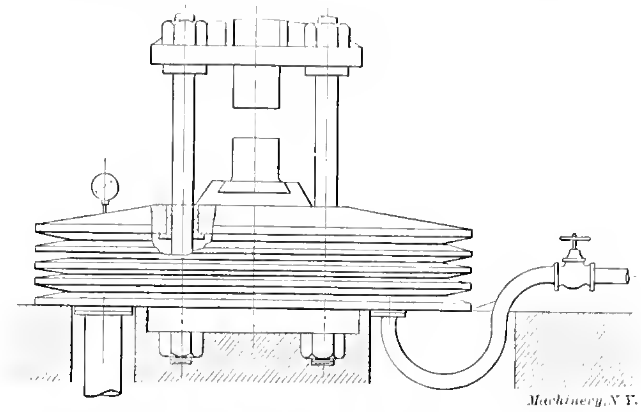

Fig. 1. General Appearance of Hydraulic Press of Novel Design.

same proportion as the diameter. Thus, for instance, if the diameter is denoted $2r$, and the height of the cylinder is supposed to be the unit of length, and the pressure assumed to be the unit of pressure, then the cross-sectional area A of the cylinder equals πr^2 and the area of the cylinder walls Y equals $2\pi r$. Tabulating the results for a few numerical values will best show the variation between the increase of the cross-section area and the area of the cylinder walls for increasing diameters.

r	$2\pi r = Y$	$\pi r^2 = A$
10	63	314
50	314	7,854
100	628	31,416

This table indicates plainly that if the diameter is made large enough, high total pressure can be attained, although the unit pressure on the cylindrical walls will be comparatively low, so that it is possible to use fairly thin walls for the hydraulic cylinders. When the ordinary hydraulic cylinder, however, is made of large diameter, the difficulty of mak-

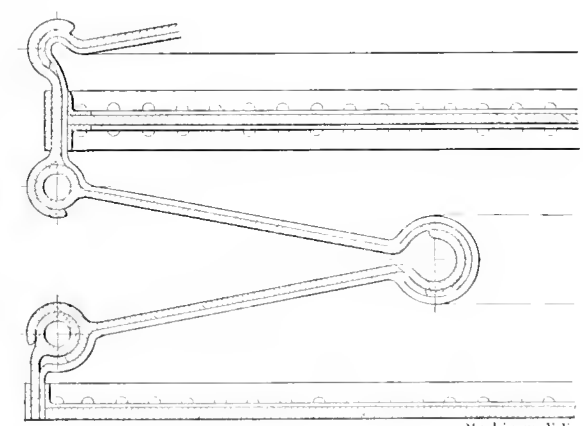

Fig. 2. Detail showing the Design of Elastic Walls in the Hydraulic Cylinder.

ing the pistons becomes very great, and it is practically impossible to make pistons that will work well, with diameters of so large a size as would be required to attain very high total pressures on the pistons without getting any considerable unit pressure on the cylindrical walls.

The next step in the mind of the inventor was therefore to find a cylinder that was so designed that it could work without pistons, the cylinder itself giving the required motions. To accomplish this the walls of the cylinder had to be made elastic in a longitudinal direction. The design of cylinders filling these requirements at first seems to be a more or less

difficult task, but the accompanying line engravings plainly indicate how the problem has been solved. The cylinder, in fact, consists of a large number of shorter cylinders, the cylindrical walls of each one of these simply consisting of plates of metal, joined together, as shown in Fig. 2. This construction permits the lengthening and shortening of the cylinder in a longitudinal direction. It is also evident from Fig. 1 that a comparatively small unit pressure in the cylinder will effect a very high total pressure at the point of action of the press, due to the large diameter of the cylinder on which the pressure acts.

In Fig. 1 the guides or supports, which hold the flexible cylinder in alignment, pass directly through the cylinder, because this permits of a less heavy construction. In a hydraulic press designed as described, it is evident that the circular form of cylinder is not as imperative as in the case of ordinary hydraulic presses, and therefore the section of the cylinder may be either circular or square.

While the present design is rather ingenious and constitutes an entirely new departure in hydraulic cylinder design, it seems that the new construction is not of very great importance, and the making of hydraulic cylinders of this type would be most likely fully as expensive, if not more so, than the making of ordinary hydraulic cylinders and pistons. Besides, the press would work rather slowly, owing to the fact that only low pressures would be used and a large volume would have to be filled with the fluid before action would take place.

FRENCH SELF-TIGHTENING AND QUICK-RELEASING DRILL CHUCK.

La Machine Moderne, February, 1908.

We show in Fig. 2 a section, and in Fig. 1 details, of an ingenious automatic chuck for drills, invented by M. Heynan. This chuck permits the insertion and removal of straight shanked drills without stopping the machine, and without the use of a key or wrench of any kind. Referring to the assembled view and the details, the gripping surfaces are a series of rollers, *A*. These rollers are each composed of three disks, formed integrally with the spindles of which

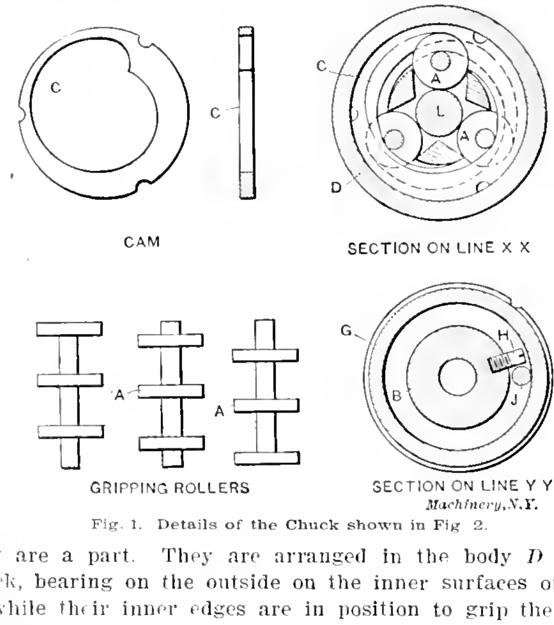

Fig. 1. Details of the Chuck shown in Fig. 2.

they are a part. They are arranged in the body *D* of the chuck, bearing on the outside on the inner surfaces of cams *C*, while their inner edges are in position to grip the work. There are nine cams in all, one in position to engage each of the three rolls of each of the three spindles. These cams *C* are keyed to a sleeve *D*, which is in turn screwed and doweled to a collar *B* on the shank *G* of the chuck. By means of the shoulders shown, parts *D* and *B* may be revolved freely on *G*. Screws *J* in *B*, and *H* in *G*, however, limit this movement. A coiled spring *F*, in the recess shown, tends to revolve *D* in a clock-wise direction. The nine cams *C* (see the upper right-hand view in Fig. 1) are keyed to *D*, so the spring tends by the action of the cam surfaces, to force rolls *A* inward. Cams *C* and rolls *A* are simply slipped into place from the bottom of the chuck, and are retained by cap *K*, which screws over the nose of sleeve *D*.

The operation of the chuck will at once be evident. As it is revolving in the direction required for right-hand drills, sleeve *D* is grasped by the hand, thus stopping its rotation until screws *J* and *H* have been brought up against each other. When this happens, the parts are in the position shown in the section on line *X X*. Centrifugal force throws the rolls *A* outward, leaving the full diameter of the chuck for the insertion of the drill. Drill *L* is then inserted and sleeve *D* released. Spring *F* revolves it in a clockwise direction, forcing rolls *A* into contact with the drill, thus holding it tightly. If the drill should slip under the pressure of the work, it will only cause rolls *A* to revolve, turning cam *C* further in the direction in which it is urged by the spring, thus holding the drill all the more tightly. Since, however, only a very slight turning moment is required to hold the drill firmly, it is easily released, even when the chuck is revolving, by simply grasping the sleeve as before, until the rolls have been loosened and screws *H* and *J* have been brought up against each other so that the parts are expanded to their fullest extent.

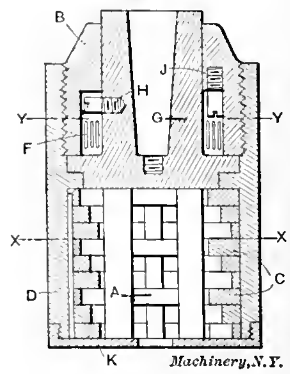

Fig. 2. A Chuck which automatically grips the Drill and automatically tightens if Slippage occurs.

ECONOMY OF HIGH SPEED PLANERS.

Times Engineering Supplement, March 18, 1908.

The first makers of planers contented themselves with giving the idle stroke a speed double that of the cutting stroke, so that, instead of 50 per cent of the time being expended in the idle stroke, as would have been the case were it speeded at the same rate as the cutting stroke, only 33 per cent of the time was so expended. In these early planers no serious amount of energy was dissipated at the time of reversing, because the rate at which the planing was done rarely exceeded 20 feet per minute for cutting and 40 feet per minute for returning. High speed steels, however, have rendered it practicable to cut at a speed of 60 feet per minute, and even if the old ratio of return to cutting speed were not exceeded, the idle stroke would be at the rate of 120 feet per minute.

The energy of a moving mass, however, increases as the square of its velocity, so that whatever dissipation of power there was in the old-time planer, having a cutting speed of 20 feet, the amount dissipated at a speed of 60 feet per minute will not be three times as much, but nine times. It is this circumstance that has made the planer a more difficult subject than the lathe to properly adapt to high speed steels. If the lathe is speeded up threefold, it takes three times as much power to drive it, and it turns out three times as much work, but the power consumed per unit of work remains the same as before. The planer, however, speeded up in the same ratio, dissipates energy at each reversal nine times as great as before, and becomes consequently seriously extravagant with power. It is interesting to note what this waste amounts to. It depends, of course, upon the number of reversals made per minute, and the masses which have to be reversed. A medium-sized planer, with table and work weighing 10 tons, consumes each time the table is stopped or started at the 60 feet per minute cutting speed, power equal to 0.3 foot-ton, and each time the table is stopped or started at 120 feet return speed, power equal to 1.2 foot-ton. This, however, does not include all the energy lost, if the table is driven by gearing revolving at high speed, which also has to be reversed. While these parts may be comparatively light, many of them run at a far higher speed, and as the energy is proportional to the square of the velocity, the power consumed in stopping, starting and reversing these parts is often twice as much as that required for reversing the table itself. If this loss is reduced by the slipping of belts or friction clutches, it is reduced at the expense of time, but if the belts are sufficiently powerful and driven by an electric motor, the

violent fluctuation in the demand made on the motor is plainly visible by the use of a suitable recording wattmeter.

Several schemes have been proposed to save this waste of power. One scheme is to use regenerative springs, which are analogous in their action to the recoil springs on a disappearing gun mounting, and these springs receive the energy of the moving parts in retarding, and restore whatever energy they receive in accelerating these parts in the reverse direction. Other schemes for solving this problem have been the use of hydraulic pressure, which stores the energy in the accumulator at the end of one stroke, where it becomes available without loss of power for imparting energy to the return stroke. Electricians have also arranged to drive planers with reversing motors, on the theory that when the currents are reversed at the reversal of the table, the motor becomes a dynamo, and aids the prime mover in mitigation of the excess of demand upon it for accelerating the motor in the reverse direction. Neither of these two last systems, however, has been carried out over as great a range of speed as the system of spring balancing. There are now a considerable number of spring balanced machines at work in Great Britain, which have return speeds as high as 180 feet, and forward speeds as low as 20 feet, or a ratio between the forward and return speed of 9 to 1. In such a case the idle time is reduced to about 10 per cent of the total time, and, if one may assume that the planing machine while cutting is 10 per cent more efficient than other machines on which the same class of work can be done, there could be no economical reason against its extended use.

It is conceded that the straight-line motion of the planer produces a truer surface than the angular motion of revolving tools, and by the use of high speed planers, there seems to be little doubt that more stock can be removed per unit of power by planing with strongly held, stationary cutting tools than with tools revolving on spindles with running fits.

HISTORY OF CRANE DESIGN.

Alton L. Smith, in the *Journal Worcester Polytechnic Institute*, January, 1903.

The lifting and transporting of great weights has from the beginning of history taxed the ingenuity of mankind. The achievements of the engineers of ancient Egypt, in moving and erecting the enormous masses of stone embodied in their colossi, obelisks, temples and pyramids, for a score of centuries, has provoked the admiration and wonder of travelers. While the methods they employed for transport may be understood from the numerous extant tomb paintings, the apparently more difficult operation of erection has never been explained. The fact that no picture of such an undertaking has been found would seem to indicate that the ancient engineers did not regard such feats as of sufficient importance for record. Plausible suggestions are that the elevation of these massive stones was effected either by the use of an inclined plane of banked earth, or by means of levers and some system of blocking.

Vitruvius, writing just before the beginning of the Christian era, describes a lifting device used by his contemporaries which is easily recognized as our sheer-legs with a primitive windlass and pulley block tackle. He also describes another device similar to our guyed derrick but without a boom. This was for lifting very heavy weights and the motive power was supplied by men walking inside a large drum or treadmill which, as it revolved, wound the rope on the windlass. An antique relief preserved in the Lateran Museum at Rome shows such a machine with an inclined guyed mast. The upper block is attached to the head of the mast and the treadmill is filled with young boys. A civil engineer, writing eighty years ago, mentions this form of motor as being recently in use and speaks of the terrible accidents which sometimes occurred when control of the load was lost. The load, descending, would cause the drum with its occupants to revolve at frightful speed.

Little is known of the details of lifting machines employed during the middle ages, but from the scanty records available it appears that the builders of this period made use of a variety of lifting jacks, sheer-legs, the derrick with swinging boom and the under-braced swing crane. The multiplication of power seems to have been obtained generally by pulley blocks rather than by gear trains.

Up to the time of the introduction of the steam engine, the principal uses of hoisting machinery were for building construction, mining, quarrying, shipbuilding, dock and warehouse purposes, naval and military engineering. The moving and mounting of heavy cannon, particularly, seems to have brought out a large number of lifting devices.

The first part of the nineteenth century teemed with industrial possibilities. During this time steam power had been applied for hoisting purposes and found to be more economical than hand power, but not until about 1850 does there appear a traveling crane actuated by steam power. This was a typical overhead traveler of 10 tons capacity with a steam engine and boiler on one end of the bridge. The various movements of lifting, traversing and traveling were accomplished by means of gearing and clutches. About this time also, Fairbairn's design of a tubular revolving dock-crane was accepted by the British Admiralty. It proved so satisfactory in service that it has persisted as a type until recent years.

While the engine-driven traveler was satisfactory for use out-of-doors and in foundries and forges, the smoke and stifling fumes from the soft coal made it unsatisfactory for other industrial works. The cost of labor, however, did not exert sufficient influence to produce a better machine until about 1861 when Ramsbottom perfected his "flying rope" system for shop cranes and applied it successfully to a traveling jib crane at the Crewe (England) Locomotive Works. In 1864 this type of drive was successfully extended to several 25-ton overhead travelers at the same works and effected an important saving.

From this date forward, power cranes began to appear with increasing frequency until twenty-five years ago they were found in great variety both as to form and motive power. Fixed cranes were operated by compressed air, steam or water pressure, while travelers were driven by high- or low-speed ropes of cotton, hemp or wire, by square shafts or by engines located on the crane itself. Capacities had also greatly increased, going as high as 30 tons for floating cranes, 50 tons for overhead travelers, 60 tons for steam jib-cranes and 70 tons for steam dock-cranes. Many of these types had reached the general form which they present to-day, changes since then having been largely due to the substitution of steel for the wood, cast iron, iron forgings and structural iron then employed. A 2½-ton wrecking crane, described by a writer in 1874 as "very powerful," throws an interesting side light on the rolling stock of that time.

The date of the advent of the first commercial electric overhead traveler is uncertain, but the first of which published record is found was in operation in a foundry at Bourges, France, about 1883. It had a capacity of 20 tons and a span of 50 feet, the power being furnished by a single motor. The various movements on these early single motor cranes were obtained by means of clutches and gearing. At the Paris Exposition of 1889 two 10-ton single-motor travelers were installed by the management, chiefly, it would seem, as objects of curiosity. There was also exhibited at this time a traveling hoist of small capacity equipped with two motors, one for lifting and the other for traveling.

Many single motor travelers were brought out in the next two or three years, but the hesitation with which they were accepted is indicated by the fact that of four 150-ton travelers put in operation at about this time in England and the United States, one was driven by an engine and boiler placed on the crab or trolley, while the other three were square-shaft driven. A three-motor electric traveling crane built at the shops of the Edward P. Allis Co., of Milwaukee, Wis., after a design by Mr. A. J. Shaw, one of their engineers, was probably the first commercial machine of this type installed in America, if not in the world. This was in 1889.

The perfecting of the series motor and its controller for street railway service soon put an end to general demand for the single-motor, square-shaft and flying-rope systems of driving. One manufacturer of electric travelers states that "within six months of the completion of our first successful crane,

inquiries for other styles of construction had practically ceased." In the square-shaft system the unavoidable use of tumbler bearings and the dependence on gravity to hold the shaft in place, did not permit a very high speed of rotation. If the capacity of the crane was large, then the driving gear had to be heavy and clumsy or else the speed for the various operations had to be slow. This method of driving has apparently become obsolete.

In the flying-rope system the troubles and expense incident to the frequent repair and replacing of the rope prevented its general adoption outside of Great Britain where conditions were more favorable to its use. While our conservative cousins buy the single-motor and flying-rope travelers to some extent, they have practically gone out of use in this country. It is recalled, however, that there is at least one manufacturer of each type here in the United States to-day.

For more than ten years the traveler employing a separate motor for each movement has demonstrated its superiority over the older types. The motor in most common use is the enclosed type direct-current series motor. The induction motor has been successfully used by German crane builders for a number of years, but while its adoption has been urged by some American engineers, it has not displaced the direct-current series motor to any extent. The latter has proved very satisfactory for crane service, and in some new installations where alternating current is employed the expense of rotary converters has been added to avoid induction motors for the cranes. If the altenating-current series motor recently introduced for railway service proves as reliable as present experience indicates, it should displace the induction motor entirely for crane work and make an alternating system just as satisfactory for crane service as is the direct current.

The maximum load capacities of power cranes have been gradually increased until at present the limits are about as follows:

	Tons.
Dock Cranes	150
Floating Cranes	150
Foundry Jib Cranes	50
Locomotive Cranes	50
Overhead Travelers	150
Wrecking Cranes	100

It is a significant fact that most of the very large cranes produced at any one period during our industrial development have been made necessary by the requirements of naval armament. Twelve-inch rifles weigh about 58 tons, while the turn-table and gear for the barbette in which they are placed will weigh about 125 tons. So, too, the machines used in the production of modern armor plate must be served by cranes which can handle ingots of 125 tons or more. But large cranes are also needed to handle what may be called peaceable material such as locomotives and parts of large stationary engines and electric generators. The boilers of the *Mauretania* weigh about 110 tons each and the weight of her low-pressure turbine rotor is 126 tons. If the competition continues between Great Britain and Germany for the domination of the Atlantic ferry, we may look for still larger cranes in the near future.

The first of the very large dock cranes was installed at Bremerhaven in 1899 Since then they have sprung up like toadstools in the shipyards of Germany and Great Britain, being mostly of German manufacture. Great Britain seems now to have waked up to the situation and during the first six months of 1907, six cranes of 150-tons capacity each have been installed at various British works. Three of the six were made necessary by the two new Cunarders.

The economy of a crane for handling material has long been recognized in Germany and France. In this respect Great Britain and the United States have been more backward. About fifteen years ago the great German industrial movement began, and their crane industry shared the general stimulus with the result that Germany probably leads all countries to-day in the diversity and capacity of her output. In 1905 the factory department alone of the Krupp Works employed 591 cranes. In the United States the principal production has been overhead travelers and in this type our manufacturers are leaders. Cantilever and Gantry cranes for handling medium and light loads over large areas has also been an important product of American genius. The powerful machines for rapid handling of coal and ore at the ports on the Great Lakes are distinctively American ideas and they have had a most important bearing on our recent industrial activity. The heavy rolling stock and frequent accidents on American railroads have operated to bring out a powerful and efficient 100-ton wrecking crane.

* * *

PIPE BENDS.

WM. F. FISCHER.*

In the modern power house steel pipe bends of large radius are nearly always used in preference to steel or cast iron fittings. There are several very good reasons for this. In the first place, using bends in preference to fittings does away with many extra joints which are liable to cause leakage, and which are, in many cases, a constant source of trouble, requiring the renewing of gaskets, etc. In the second place, in steam lines or water lines of high temperature, the steel pipe bends provide a ready means of taking up expansion and contraction, and it is customary to use special bends for this purpose, known as expansion bends. In the third place, steel pipe bends permit the elimination of many steel castings. The cost of bends is less, and they can be delivered quicker. They also give a neater appearance to the engine-room, in general, than it has when covered with fittings. The weight is also less, and owing to the large radii to which the pipes can be bent, they reduce the friction of the fluids conducted inside of them to a minimum.

The process of bending is as follows: One end of the pipe to be bent is first plugged. The pipe is then filled with sand, which is packed tightly, and the other end of the pipe is capped. The pipe is then placed in an oil-heated furnace, and the portion to be bent is heated to a red heat. It is then taken out and placed on the so-called bending table, which is made of cast iron and securely bolted to a heavy foundation. This table is flat, and is cored all over with holes, spaced about six inches apart. Circular steel pins are inserted into these holes. The pipe is clamped between two or three pins, and bent around other pins set so as to give the required radius. A rope is attached to the end of the pipe, and the bending is accomplished by pulling this rope with a winch or other suitable means.

After the pipe is bent to the required shape, it is cooled by running water with a hose over the heated portion. The purpose of the sand filling is to prevent the pipe from flattening when bending, which would necessarily occur in large pipes if they were not filled and well rammed down before bending. Should it happen that after the pipe has cooled off, it is found that it does not agree with the required measurements, it can be reheated and again pulled into shape. A man well experienced with pipe bending can, in most cases, bend a pipe to within ¼ inch, or even ⅛ inch, of the required dimensions. If the bends are made even as much as ½ inch or ¾ inch off the correct dimensions, they are quite easily drawn into position when erecting, at least if the line is of ordinary length, say 40 feet or more.

Large sizes of pipes, say up to 6 inches diameter, are very often bent by machine. A templet should first be provided by bending a round iron rod and carefully measuring it, until the right radius and dimensions are obtained. This templet is then placed over the center line of the pipe, as a guide in bending to shape.

As regards the kind of pipe to use, it should be of good quality standard steel or wrought iron pipe, full weight or extra heavy. Lap welded pipe should be used in preference to butt welded, as butt welded seam is liable to open up under the stress of bending. The welded joint should be placed directly over the center line of the pipe, along what might be called a neutral section, so that the joint will be neither in tension nor compression. This prevents the seam from being strained to any extent when bending.

Large pipe from 12 to 20 inches in diameter is liable to buckle on the compression side, especially if bent to a short radius. To prevent this, the radius when bending large sizes

* Address: 392 Second Ave., New York City.

should be made as long as possible. A suitable radius for bending all sizes of pipe from 4 inches to 20 inches diameter, inclusive, is 6 times the diameter of the pipe, and this is known as "standard radius." Bends made with a radius having this proportion to the diameter of the pipe are very satisfactory. Pipe from 4 to 12 inches, however, can be bent, if necessary, to a radius equal to three times the diameter of the pipe, and sizes above 12 inches may be bent to a radius of four times the diameter of the pipe, if required. Even smaller radii than those last mentioned may be employed, but it is not advisable to do so, as it puts heavy strains on the pipe, and is likely to cause buckling on the compression side, even in the smaller sizes.

The length of the straight portion at either end of the bend should be at least equal to the diameter of the pipe, and in pipes 10 inches diameter and upward, it is advisable to make the smallest length of the straight portion equal to 1½ times the diameter of the pipe. If the length of the straight portion is made less than one times the diameter, the pipe is liable to flatten on the ends, which will prevent the flange from fitting tightly, and is apt to cause leakage.

All threads should be cut and flanges put on and made steam tight before bending. On rolled, or Van Stone joints, the rolling, "Van Stoning," and finishing the face must all be done while the pipe is straight, as it would be a difficult task to do after the bend is made.

The Data Sheet Supplement for the present month gives formulas for four different classes of bends. The length of the pipe in the finished bend must be calculated to find out the length of straight pipe necessary. This length, of course, equals the length of the straight portions of the pipe added to the length of each of the arcs. The length of the arc is easily found from the formula:

$$\text{Length of arc} = \frac{3.1416}{180} \times \text{radius} \times \text{number of degrees.}$$

This formula, of course, will be found in this or similar form in all hand-books, and can be easily deducted by simple mathematics. In the form as here given (with the exception of that more decimals are stated for π) it will be found in Kent's Pocket-book.

* * *

CALCULATION OF FANS AND HEATERS.

CHARLES L. HUBBARD.*

The tables and formulas presented in the following, together with the tables which will be found in the Supplement, have been compiled in as concise a form as possible, and will be found very useful in determining the sizes of fans and heaters necessary for special given conditions. The article is not intended to deal with the design or construction of those apparatus; but the data given embody, of course, the fundamental principles on which the design must rest.

Centrifugal Fans.

When a centrifugal fan is in motion, the air in contact with the blades is thrown outward by the action of centrifugal force, and delivered at the outer circumference. A partial vacuum is thus produced at the center of the wheel, and air from the outside flows in to take the place of that which has been discharged. This type of fan is enclosed in a steel plate casing having an inlet opening at the center of the wheel and a discharge outlet at the periphery.

The pressure within a fan casing is caused by the air being thrown from the tips of the blades, and varies with the speed of rotation. In Table I are given the velocities of outflow from a fan outlet into the atmosphere for different pressures within the casing.

TABLE I. RELATION BETWEEN PRESSURE AND VELOCITY IN CENTRIFUGAL FANS.

Pressure in ounces per square inch.	Velocity in feet per minute.
¼	2,585
⅜	3,165
½	3,653
⅝	4,084
¾	4,472
⅞	4,829
1	5,161

* Address: 420 Boylston St., Boston, Mass.

When the outlet from a fan casing is small, the air will pass out with a velocity equal to that of the tips of the blades, and the pressure within the casing will be that corresponding to the tip velocity. The limiting area of outlet at which the velocity of outflow begins to drop below the tip velocity, is called the blast area of the fan. This, for the ordinary form of ventilating fan is approximately $0.14\,D^2$, in which D is the diameter of fan wheel.

The effective discharge outlet of a fan, in practice, is always made larger than the blast area. This, for average conditions, taking into account the contraction of vein in passing through the outlet, may be taken as 1.78 times the blast area, or $0.25\,D^2$.

Capacity Speed and Horse-power of Centrifugal Fans.

The capacity of a fan when operating under a given pressure and discharging into free air is equal to the velocity corresponding to the given pressure, multiplied by the effective area of outlet.

Example: A fan 4 feet in diameter has an effective discharge area of $0.25 \times 16 = 4$ square feet, and when operating under a pressure of ¼ ounce will deliver $4 \times 2{,}585 = 10{,}340$ cubic feet of air per minute.

When the discharge outlet of a fan is equal to the blast area, the tip velocity for any given pressure must correspond to that pressure, as given in Table I, and the speed in revolutions per minute will be equal to the required velocity of outflow, divided by the circumference of the fan wheel. When the effective area of discharge is made larger than the blast area, the pressure for a given speed will drop. Hence, when the effective area is taken as 1.78 times the blast area, or $0.25\,D^2$, the speeds as found above must be multiplied by 1.2 to maintain approximately the same pressure.

Example: A fan 4 feet in diameter has a circumference of 12.5 feet, hence to maintain a pressure of ¼ ounce under actual conditions it must run at a speed of

$$\frac{2585}{12.5} \times 1.2 = 248 \text{ R.P.M.}$$

The theoretical horse-power required to move the air which is discharged through each square foot of effective outlet area under different pressures is given in Table II. This table, however, does not take into account the friction of the fan, so that, in practice, the result must be divided by the efficiency, which may be taken as 0.40 under average conditions.

TABLE II. RELATION BETWEEN PRESSURE AND HORSE-POWER IN CENTRIFUGAL FANS

Pressure in ounces per square inch.	Horse-power per square foot of Effective Opening.
¼	0.175
⅜	0.324
½	0.498
⅝	0.695
¾	0.914
⅞	1.15
1	1.40

Example: A fan 4 feet in diameter has an effective outlet area of 4 square feet; hence, the power required when discharging into free air under a pressure of ¼ ounce is

$$\frac{4 \times 0.175}{0.40} = 1.75 \text{ horse-power.}$$

Resistance of Centrifugal Fans.

The Tables in the Supplement for speed, horse-power, and capacity of centrifugal fans have been computed by the methods given above, and apply only to fans discharging into free air. When connected with a series of ventilating ducts the effect is the same as partially closing the fan outlet, and thus reducing the volume and horse-power in practically the same proportion. In the case of schools, churches, etc., where shallow heaters are used, and the flue velocities do not exceed 800 to 1,000 feet per minute, the volume and horse-power as found in the tables for any given speed should be reduced about 20 per cent. In shops and factories where deep heaters are used and flue velocities run up to 1,800 to 2,000 feet per minute, there should be a reduction of about 40 per cent

Disk Fans.

The following data are based on the assumption that the disk fans are connected with shallow heaters or with ventilat-

ing ducts of medium length, through which the air is flowing at a velocity of 800 to 1,000 feet per minute. The tables found in manufacturers' catalogues are usually for fans running in free air without the use of connecting ducts, hence the results are much in excess of those given by the following rules, which are for the average conditions commonly found in ventilating work.

TABLE III. SPEED, HORSE-POWER AND CAPACITY OF DISK FANS.

In computing the volume of air moved, it may be assumed that each revolution of the fan moves the air in a direction parallel with the shaft a distance equal to 0.6 of the diameter, over its entire area, or

$C = 0.6\,D \times R \times A$; in which

C = cubic feet of air moved per minute;

D = diameter of fan in feet;

R = revolutions per minute;

A = area of fan in square feet.

The horse-power depends upon the velocity of the air through the fan and the resistance of the ducts. Under average conditions this may be taken as follows:

Velocity through Fan in Feet per minute.	Horse-power Required per 1000 Cubic Feet of Air Moved
800	0.20
1,000	0.30
1,200	0.40

A disk fan operates most economically when the speed is such that the velocity of the air-flow through it is from 800 to 1,200 feet per minute, and Table III is computed upon that basls.

TABLE IV. DEPTH, FINAL TEMPERATURE AND EFFICIENCY OF PIPE HEATERS.

Temperature of entering air, zero.
Velocity of air between the pipes, 800 feet per minute.

Rows of Pipe Deep.	Temperature to which the Air will be raised from Zero.			Efficiency of Heating Surface in B. T. U. per square foot per hour.		
	Steam Pressure in Heater.

20	140	150	170	1300	1400	1600

Heaters for Hot-blast and Ventilation.

The efficiency of a heater is the number of heat units given off per square foot of surface per hour to the air passing over it. This increases with the difference in temperature between the steam and air, and also with the velocity of air flow. The final temperature depends upon the depth of the heater, and increases with the number of rows of pipe, and with the difference in temperature between the steam and air. Increasing the velocity of air flow, reduces the final temperature. Table IV gives the depth, final temperature, and efficiency for pipe heaters under different conditions. In this table it is assumed that the air enters the heater at a temperature of zero, and passes between the pipes at a velocity of 800 feet per minute. The free area through a pipe heater is approximately 0.4 of the gross or over all area.

Efficiency of Cast-iron Heaters.

The efficiency of a pin radiator 8 to 10 inches in depth may be taken as 1,500 heat units per square foot of surface per hour. Deep cast-iron heaters, made up of several rows of sections, may be treated the same as a pipe heater of the same depth.

The heating surface required may be found by the formula

$$S = \frac{T \times C}{55 \times E}, \text{ in which}$$

S = square feet of surface in heater;

T = temperature to which the air is raised from zero, or the number of degrees through which it is raised from any other temperature;

C = cubic feet or air to be heated per hour;

E = efficiency of heater.

Factory Heating.

The heating surface for factory heating is commonly expressed in lineal feet of 1-inch pipe. With all of the air used taken from out-of-doors, allow approximately 100 cubic feet of space for each foot of pipe for exhaust steam, and 150 cubic feet for steam at 80 pounds pressure. If air from the building is rotated through the heater, substitute 140 and 200 for the above figures.

Air Velocities.

The average air velocities given in Table V may be used in the different parts of a heating and ventilating system.

VABLE V. AIR VELOCITIES FOR DIFFERENT PARTS OF HEATING AND VENTILATING SYSTEMS.

Section of System.	Velocity in Feet per minute.
Through inlet windows	800 to 1,000
Between inlet and heater	800 to 1,000
Through heater	800 to 1,000
Schools and churches—	
Main ducts	1,000 to 1,200
Branches, large	800 to 1,000
Branches, small	700 to 800
Uptakes	600 to 700
Shops and factories—	
Main ducts	1,800 to 2,000
Branches	1,500 to 1,800
Uptakes	1,200 to 1,500

Volume of Air Required.

The volume of air supplied to a building is usually based on the number of occupants. Table VI represents good modern practice and may be used with satisfactory results.

TABLE VI.

Air Supply per Occupant.	Cubic Feet per Hour.
Hospitals	4,000 to 6,000
High schools	3,000
Grammar schools	2,400
Theatres and halls	1,500
Churches	1,200

* * *

In the engineering review of the May issue of MACHINERY it was mentioned that the White Star line planned the building of steamships a thousand feet in length. This statement, however, has been corrected, and it is now reported that the new steamships are to be 840 feet long, which is about 50 feet more than the length of the *Mauretania*, hitherto the longest vessel built.

MAKING CROSS-HEAD PINS FROM BAR STOCK IN THE GISHOLT TURRET LATHE.

The requirements of the railroad shop are so different from those of factories engaged in repetition work, that it is not always possible to use in them the highly developed machines that have been devised to meet modern manufacturing requirements. It is seldom that parts have to be made in large quantities, and the work is, in general, heavier than is usually adapted to elaborate methods of machining.

Despite these general conditions, however, the Gisholt Machine Co., Madison, Wis., some time ago decided that there was a field in the railroad repair shop for the particular turret lathe of which they are the builders. Without requiring any further development in the design of the machine or the tools used with it, it was already well adapted to the machining of such work as bushings, brasses, pistons, cylinder heads, bull-rings, eccentrics and other small and medium-sized cast parts used in the locomotive. But there is not always, in the repair shop of ordinary size, enough of even this wide range of work to keep a machine busy all the time; so it became necessary, in developing the lathe to its maximum of usefulness, to design tools and methods of working for producing miscellaneous turned steel parts, such as the cross-head, valve motion and brake hanger pins, etc., which were previously made from forgings. The accompanying illustrations and description show the successful way in which this machine, primarily designed for chucking, has been adapted to the finishing of such parts from the bar.

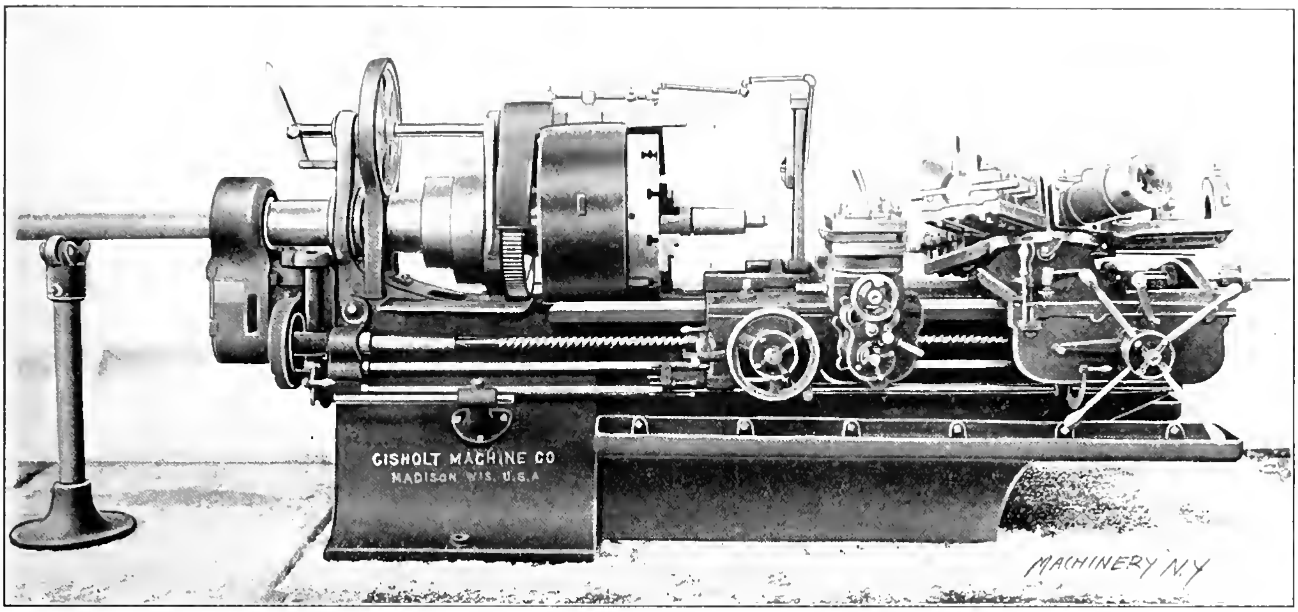

Fig. 1. Gisholt Turret Lathe arranged for Railway Shop Work; shown set up for Finishing Cross-head Pins.

The machine used is of the type called by its builders the "Big Bore" lathe, which is simply the standard machine with an extra large spindle for bar stock, the principal features of special interest in connection with this work being in the tools used rather than in the machine.

In Fig. 1 the machine is shown rigged up for turning a cross-head pin, shown completed in the chuck and ready to be severed from the bar. As is more plainly indicated in the diagram, Fig. 2, which gives the lay-out of operations, this cross-head pin is of the usual type, having a central cylindrical body F which is the journal for the connecting-rod brasses, and two tapered diameters E and G by means of which it is fitted into the sides of the cross-head, being held in place by a nut threaded onto the stem H. It will be noted that all the various portions of the work are lettered, and in following the different operations, the cutting blades in each tool will be lettered to correspond with the parts of the work which they machine, thus making it easy to follow the course of the work.

The stock A is held in a scroll chuck by three hardened jaws B and is further steadied and clamped by the supplementary chucking screws C, threaded into blocks clamped to the face of the chuck alternately with the jaws. The stock being fed to length, as will be described later, the end of the bar is faced with tool N in the cross-slide turret. The first turning operation is performed by box tool No. 1 in the main turret. This tool rough turns all the various diameters and shoulders of the work, the various blades E_1, F_1, G_1, etc., turning the corresponding portions E, F, G, etc., of the work. Two sets of back rests L are provided, the forward one of which bears on shoulder E and the rear one on diameter H. The last tool K_1 finish faces the end K of the work.

The pieces being thus brought approximately to size, the main turret is revolved to bring box tool No. 2 into operation. In this, blades F_2, H_2, and K_2 turn to size shoulders F and J, and face K, the holder being steadied meanwhile by two sets of back rests L_2 bearing on shoulders F and H, as in the first cutting operation. Box tool No. 3, which is next presented to the work, carries taper shaving blades E_3 and G_3 for forming the two taper bearings on the work. These taper bearings fit into corresponding taper seats in the cross-head. The tool is back rested on the work as before while this operation is in progress. The positive stop R determines the length of this taper turning, by stopping against the face K. This arrangement insures duplicate work when cutters E_3 and G_3 are once properly set.

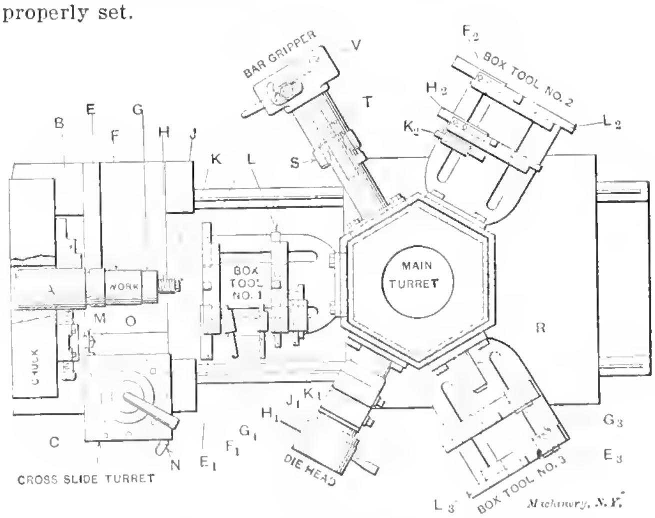

Fig. 2. Tool Equipment used for Making Cross-head Pins.

All the surfaces on the pin having been brought to size, the next operation consists in cutting the thread, which is done by the die-head shown. The part being thus completed, cutting-off tool M in the cross-slide tool-holder is used for severing the work from the bar. Owing to the large diameter of the stock, this slender cutting-off tool is supported by an adjustable threaded post O, more plainly seen in the foreground in Fig. 3.

After the piece has been cut off, jaws *B* and set-screws *C* are loosened to allow the work to be fed out. The feeding is done by the "bar gripper" shown mounted in the turret in Fig. 2. The bar is fed by being pulled through the chuck instead of being pushed from the rear, as commonly done. The procedure is as follows: By the operation of the rapid traversing device for the carriage, the bar gripper is brought rapidly to the piece. The self-acting jaws *V* then grip the stock firmly. The carriage is then returned by power until the bar is drawn out to approximately the proper length after which the gripper is released. The body of the gripper is then swung upward out of the way about pivot *S*, and the turret slide is brought forward to a positive stop, arbor *T*, meanwhile, pushing the work along until it projects just the right amount, *T* being accurately adjusted for this purpose. The operations then proceed as before.

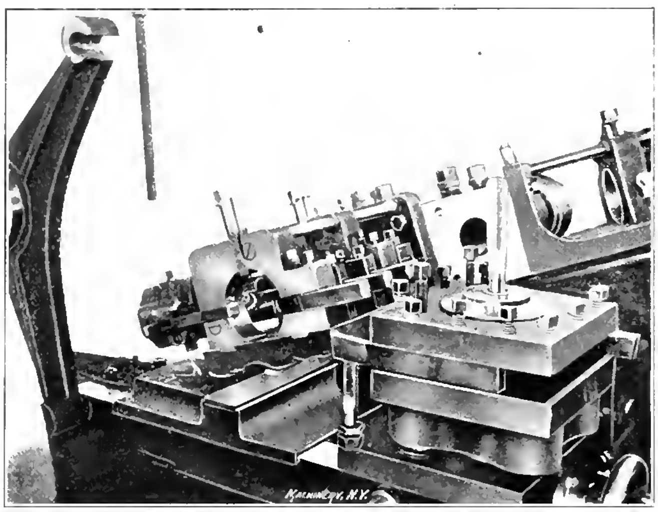

Fig. 3. Box Tool and Cutting-off Blade; note Support for Blade.

Figs. 3 and 4 give a good idea of the tool equipment used. Fig. 3 shows the cross-slide turret or tool-post and one of the box tools in position for operation. In Fig. 4 a front view of the box tool is shown. It will be seen that this outfit of tools is suited for work of a large range of diameters and lengths, although this adjustability is not obtained at the expense of quickness and simplicity in changing from one size to another. The holders for carrying blades and back rest jaws combined, are tied together and with the body of the cutter by threaded tie-rods, which stiffen the whole structure, allowing heavy cuts to be taken.

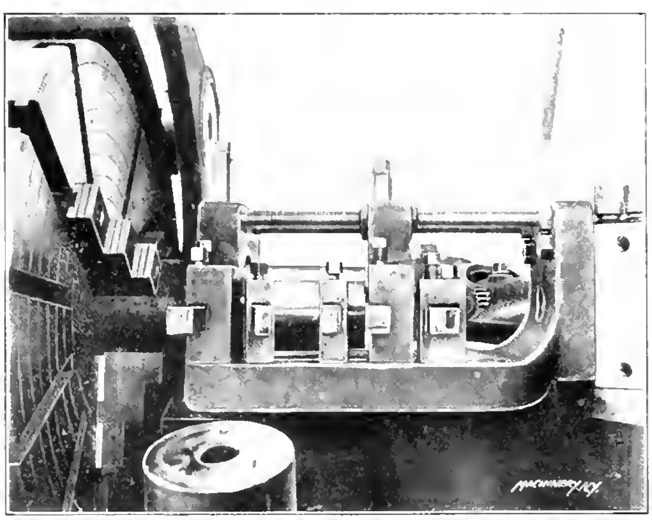

Fig. 4. Front View of Box Tool showing Adjustability of Blades and Back Rests.

The makers state that the convenience of a tool outfit of this kind makes it possible with bar work, as with castings, to finish parts in lots of as few as six or eight of a kind, and still save a large amount of time in the operation. Owing to the fact that the work of this kind may be made from bar stock, the expense of forging the blanks from which these pins were formerly made is done away with. Besides this, owing to the manner in which the work is chucked, there is no time lost in centering as with the older methods. In some shops such parts as knuckle and cross-head pins are made for stock, finished complete except the taper surfaces, which are left large and finished to size and fitted in place as required.

A MASTERPIECE AMONG PERPETUAL MOTION ADVERTISEMENTS.

The following notice, here reprinted verbatim, appeared in a recent issue of a Hartford paper, sent us by one of our readers:

FOR SALE—A Wonderful Machine. A machine that will overcome Newton's third law and transfer a horseshoe magnet force into a revolution, and will produce more power than what is put into the machine. Because not having the funds to build a machine in a perfect way so I can demonstrate it in practical mechanical working order. It is a perfect success from the mechanical laws of nature which I have tested in their natural working order, and from the small machine which I have in perfect working order to demonstrate from that when the electro or the horseshoe magnet system is connected with the machine it will do the work. Just as I have stated, every professor on the face of the earth will have to give the same statement as I have in regard to this machine in the form it does its work, even in case it should not produce more power than what is put into the machine, it would be one of the most mysterious mechanical laws that the professor ever came across which they pronounce correct to-day, therefore it would be a valuable machine to put on exhibition to demonstrate to the world in a mechanical form that it is impossible to make a machine that will produce more power than what is put into the machine it would show then that it was imperative to get the perpetual motion system in a mechanical form. Therefore by putting this machine on exhibition if it should not work it would bring in a small fortune more than the machine would cost to build, and by publishing a book of the six mechanical laws which I have worked out, what is the foundation of this machine to work from that would bring in a small fortune for itself; therefore it is impossible to lose one cent by investing in this machine. I have studied these laws out to their limits and according to the laws the machine can be made to drive small or big machinery. Now I would like to know if there is a lady or gentleman on the face of this earth who has funds enough that will be so generous and borrow me Five Thousand Dollars so I can build a machine and exhibit it before the public.

This man hopes to "catch 'em coming and going," evidently, for he promises that the investment will be a profitable one, even if his machine proves a failure. This is, we believe, a new wrinkle in perpetual motion promotion.

* * *

A clever wrinkle is used by the Stromberg Electric Mfg. Co., Chicago, Ill., in the construction of the Perry time stamp for securing rubber type bands to hexagonal brass printing wheels. The brass wheels are made from hexagonal stock in a screw machine, and are prepared for the rubber type bands by gripping them closely together on a mandrel and covering the edges with a thick coating of brown shellac. When thoroughly dried, the wheels are separated and the rubber type (which is vulcanized in bands), is slipped onto the periphery of the wheel, and then dipped into alcohol. The alcohol penetrates between the rubber and the wheel, softening the shellac and causing it to adhere to the rubber. Upon removal from the alcohol the shellac quickly dries, leaving the rubber firmly attached to the wheel. The reason for applying the shellac in this manner is to avoid getting it upon the face of the rubber and making the mussy job that would unavoidably result from direct application.

* * *

An engineering firm in Hamburg, Germany, contemplates, according to *Frankfurter Zeitung*, the erection of a power plant at the mouth of the river Elbe, the driving power of which it is proposed to derive from the tidal movement of the sea. It is expected that two neighboring cities of comparatively large size will be supplied with electric light, and that electricity may also be supplied for electric railways. The cost of the electric current is calculated to be extremely low. The statements made by the firm itself, however, are to be accepted with considerable reservation. In new departures of this kind the engineer requires to see results before his enthusiasm can be aroused in any remarkable degree.

LETTERS UPON PRACTICAL SUBJECTS.

ON SENDING ELECTROTYPES ABROAD.

Machinery agents and technical editors over here get a good many electrotypes which are in the condition of the dog that was sent by express and ate his tag. The "stickers" of the post-office, custom house and forwarding agents usually cover the sender's name. Blocks should be marked with the sender's name on the edge, not on the bottom. As "samples without value," they come more cheaply and quickly, and make less bother at both ends of the line, than as postal packages. A card of advise should be mailed the same time as the blocks.

Dresden, Germany. ROBERT GRIMSHAW.

QUICK RUSTING OUT OF SMOKESTACK.

We had a steel smokestack 80 feet high, 42 inches diameter, made of No. 8 steel. This stack, after being in continuous use for only three years, was completely eaten up by rust, and had to be taken down. Some of the sheets were so wasted away as to be thin as paper. We would like to know if any of your readers have had a similar experience. What is the cause of it and how can it be prevented? The fuel used was run-of-mine, Kanawha gas coal such as is used in the Cincinnati district, and the analysis is as follows: Moisture, 0.39 per cent; volatile matter, 38.47 per cent; fixed carbon, 58.01 per cent; ash, 3.13 per cent; sulphur, 0.666 per cent. We are at a loss to understand why the stack should have gone to pieces so quickly. Is the kind of steel used in smoke stacks more readily attacked by rust than ordinary grades of steel used in other constructions? THE J. & H. CLASGENS CO.

New Richmond, Ohio.

AN EXAMPLE OF HIGH-SPEED DRILLING.

The accompanying table gives the results of some trials made with our heavy upright drilling machine, illustrated in the March issue of MACHINERY, using a special brand of twist drills. The trials were made to obtain the maximum capacity

HIGH SPEED DRILLING TESTS ON DROOP & REIN DRILLING MACHINE.

$2\frac{3}{8}$	$\frac{18}{1000}$	130	$3\frac{1}{16}$	1	40	$2\frac{3}{16}$	$2\frac{3}{8}$
$2\frac{3}{8}$	$\frac{18}{1000}$	130	$3\frac{9}{16}$	1	48	$2\frac{5}{16}$	$2\frac{3}{8}$
$2\frac{3}{8}$	$\frac{25}{1000}$	120	3	1	15	$2\frac{7}{8}$	$2\frac{59}{64}$

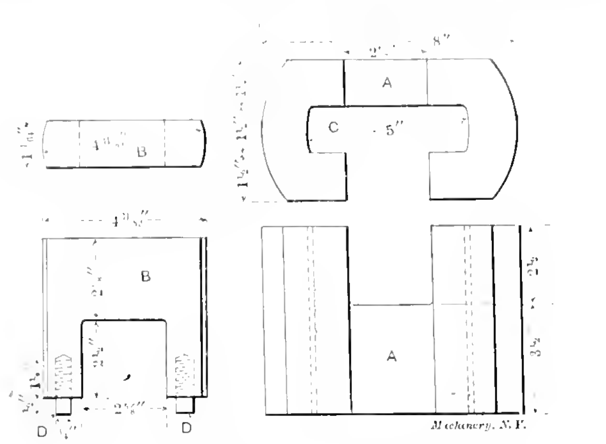
of the drills. The holes were drilled from solid steel of about 55 kilos resistance per square millimeter. Perhaps the table will be of interest to some of your readers. DROOP & REIN.

Bielefeld, Germany.

[The designation "55 kilos resistance per square millimeter" refers to the tensile strength, and gives a comparison for the hardness of the steel. In this case the material had a tensile strength, in English units, of 78,000 pounds per square inch. Inasmuch as the hardness curve of untempered carbon steel is approximately parallel to the curve of tensile strength, it follows that a statement of the tensile strength gives a fair idea of the hardness of the material.—EDITOR.]

CUT-OFF TOOL FOR THE STEAM HAMMER.

A cut-off tool to be used under a steam hammer is shown in the illustration. It is made of tool steel, and can be either forged and used with very little finish, or be made accurately by finishing all over. The one in use at the shops was made rough, and gave very good results, cutting off bar iron as fast as it could be placed in position under the hammer, and only requiring two men to operate, as against three with the old way. The tool shown is intended for cutting either flat or square stock. The rest upon which the steel is placed is shown at *A*. After the bar has been placed upon the rest, the cutter *B* is placed in the slot *C* in the rest *A*, and the hammer brought down. Better results can be obtained by using different cutters for the various sizes of stock. The studs *D* are used to center a pair of springs, which bring the cutter back into position, after a piece has been cut off, ready for another blow. The upper part of the cutter is made 2 5/8



A Tool for Cutting off Stock under the Steam Hammer.

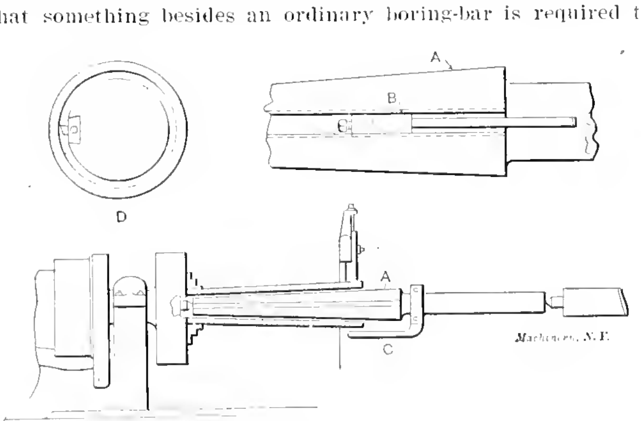
inches, or 1/8 inch longer than the depth of the slot in the rest, so that the piece is cut off before the top of the cutter is flush with the top of the rest.

When it is desired to cut off round bar steel, the same style rest can be used with the exception that instead of the slot a round hole is drilled which is 1/16 inch larger than the bar, and the cutter *B* must have a half circle cutting edge, instead of a flat edge as shown. Very stout springs should be used under the cutter. It is not necessary to have the cutter very hard, as it is liable to crack. For angle irons the same principle can be applied, only the tool must be made stronger in proportion to the size of the stock.

Jackson, Tenn. JOHN BRANDLE.

TOOL FOR TURNING HARD BRONZE CASTINGS.

The specifications for the sleeve bushings which form bearings for the axles of a certain make of gun carriage, call for phosphor bronze as hard as steel can cut. It will be seen that something besides an ordinary boring-bar is required to



A Boring Tool Designed to give Great Rigidity to the Cutter

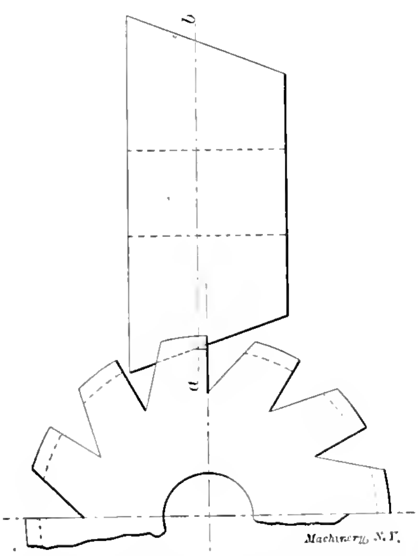
bore these castings, and the bar shown in the engraving is used for this purpose. It consists of a heavy steel bar *A*, turned taper about half its length, the tapered portion being small enough to enter the rough casting without touching any part. The shank portion is smaller than the head of the taper, and a dove-tailed slot is planed parallel with the taper, so that a closely-fitting block carrying a tool, as shown at *B* in the detail, gives a very short and rigid hold for the tool. The block is attached to a rod *C* which is in turn fastened to the tool post on the carriage, by which means the tool is fed to its work. The bar *A* is held on the centers, and is kept

from revolving by a suitable clamp or dog, one form of which is shown at *C*, this being wedged in the lower part of the steady-rest. At *D* is shown a section of the bar and sleeve. The sleeve is turned outside before being bored, and after boring with the tool described, it is reamed.

Ottawa, Ont., Canada. W. L. McLaren.

SELECTING CUTTER FOR CONCAVE MILL.

"M. E. M." offers in the How and Why section of the March issue of Machinery a rather complicated problem in mathematics. As stated by the editor, an exact solution is impossible. Maybe, however, a formula could be worked out that would give the same width of land at three points, *viz.*, the bottom of the segment and the two points on the largest diameter of the cutter blank. It is doubtful, however, if anybody would want to use it, if he had it, as no less than six variables would have to be taken care of, namely, the arc of the circle wanted, its radius, the radius of the cutter blank, the angle included between two teeth, the width of land, and the edge angle of the milling cutter. This rather looks like "more than the job is worth." I can offer no approximation that will fit the case as presented. But if "M. E. M." will go about it a little differently, there is a very simple solution, giving results well within the limit called for on that class of work.



Method of Milling a Concave Mill so that the Width of the Land at the Center and Outside Edges will be Approximately Equal.

First, gash the cutter blank, and then set it with a cutting edge vertical. Then select an angular cutter for the relieving operation of such size that at some plane, as *a b* in the sketch, it will be of the same diameter as the circle on the edge of the blank, and sink it into the blank to this line. In this way a semi-circle can be relieved to a sharp edge with theoretical accuracy. If the land is very wide, there would be an error, most of which could be compensated by a slight rotation of the blank, but this would seldom be necessary, as the land would not generally be over 1/16 inch to 3/32 inch wide, and for all such cases the method is near enough.

Washington, D. C. H. K. Harring.

THE EFFECT OF DISTILLED WATER ON LIFE OF MILLING CUTTERS.

One of the English technical papers incorrectly reported my remark on lubrication on the discussion of Dr. Ashton's paper. [See note on page 454, engineering edition, March issue.] What I really said was that a manager of a motor car works mentioned to a friend of mine that he had increased the life of his milling cutters from two to ten times their original life by using distilled water in making his suds instead of ordinary untreated water. As I had no data to substantiate the statement, I gave it for what it was worth.

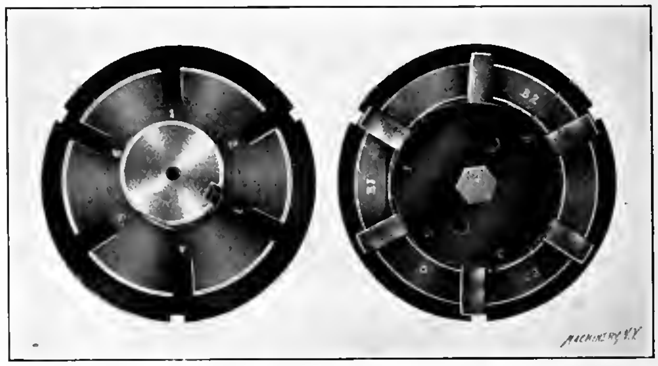
Personally, I am a little incredulous that an improvement to the extent mentioned is possible, yet I am convinced that better results can be gotten by using distilled instead of ordinary water in a lubricant.

The theory upon which I base this statement is that with distilled water the objectionable earthy carbonates and sulphates are removed, and do not, therefore, have a deleterious effect upon the cutting edge of the milling cutter. Also, the magnesium chloride in "hard" water has a slightly corroding action on the tool. The above elements in combination with a lubricant would certainly dull the edge of a tool and consequently reduce its life. The water at the works referred to was particularly "hard." F. Carnegie.

Enfield Lock, England.

LARGE ADJUSTABLE TAP.

The accompanying half-tones illustrate a rather unusual way of constructing an adjustable tap. The tap shown is used for tapping out a large cap, and the diameter of the thread in this cap must be full size all the way to the bottom of the hole. The principle of adjustment in this tap permits it to retain its full diameter on the front end of the inserted chasers. Figs. 2 and 3 show the general construction of the tap. The threaded chasers are held in place by shoes, shown



Figs. 1 and 2. End Views of the Adjustable Tap.

in detail in Fig. 3. These shoes are tightened by the small slotted head screws shown. It will be noticed that there is a shoe between every other pair of blades only, and that the metal of the tap body is left solid between alternate pairs, so that when the blades are tightened in place by means of the shoes, they are held firmly up against the body part of the tap. The means by which the adjustment is accomplished is best shown by the end view in Fig. 2. It will there be seen that the bottom surface of the ends of the chasers rest against the outside edges of a disk or cam, milled with steps so that on being turned, all the blades will move outward an equal amount in a radial direction. This cam is shown in detail in Fig. 3. It is provided with two holes, as shown in

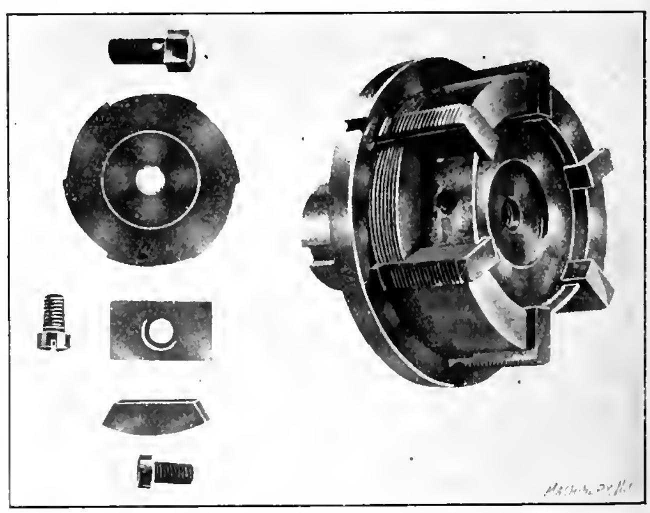


Fig. 3. View showing the Construction of the Tap.

Fig. 2, for a spanner wrench. The chasers can be moved forward in a longitudinal direction, by adjusting the collar shown in Fig. 3, at the upper end of the tap body.

Fig. 1 shows a view of the tap from the shank end. Marks (not shown) on the back of the shank indicate, first, the size of the tap, which is 4.520 inches, then the drawing number, and, finally, the number of the bin in the tool-room where this tap is kept when not in use. The upper ends of the chasers or blades simply bear against the face of the threaded collar.

When having adjusted the tap, it is evident that the front end of the chasers will have all the cutting to do, and for this reason it is likely that many will criticise the construction.

However, this tap was made nearly four years ago, and has given satisfactory service for the purposes for which it was intended, and this is, of course, the main consideration.

Decatur, Ill. ETHAN VIALL.

REASONS WHY SO LITTLE IS HEARD FROM FORGE SHOPS.

In the January issue of MACHINERY the editor remarks that it is strange that there is so little literature on drop forging and machine blacksmithing, considering the importance of the art. It would not seem so strange were the conditions under which the men actively employed at such work were better known. Manufacturers are principally responsible for existing conditions. Quite often we find a thoroughly up-to-date manufacturing plant with the forge shop in the most obscure corner, practically the place the farmer would use for a hog-pen; and the blacksmith is looked upon as a disagreeable necessity or an expensive luxury. Very little has been done to make the art of blacksmithing attractive to the young American, with the result that we depend almost entirely upon the imported article to do our iron and steel working.

Usually the inside of the forge shop compares well with its location: a great and fearful combination of scrap, discarded tools, and smoke, slightly mixed with modern machinery such as an occasional steam- or trip-hammer, usually of a design out of proportion with the work for which it is intended. System is conspicuous by its absence, and as a rule men employed in such shops have adapted themselves to their surroundings. The writer has been employed in shops of from four to ten forges, with scarcely enough tools to equip one fire. The result is that the "borrow-and-lend" or "first-come-best-served" principle had to be adopted. Much time was lost in hunting up tools, and quite often when they were located, some one else was using them.

Too much seems to be taken for granted both by the management and by the blacksmith himself. The manufacturer seems to take for granted that the equipment of our grandfathers is good enough for the blacksmith of the present day; and it takes a great deal of argument to convince him that a fixture for a steam hammer, a set of dies, a former, or a modern furnace, would reduce the cost of production. The same man, however, is willing to get any kind of machine or appliance to keep his machine shop or tool-room up to date. On the other hand, a great many blacksmiths take it for granted that because some one who had a reputation made a piece of work in a certain way, there is only that one way of doing it. They do not seem to trouble about thinking for themselves, and will find all kinds of objections to up-to-date appliances: A furnace will heat too many pieces at one time, the noise deafens them, the trip-hammer sounds like a boiler-shop, and so forth; but they never mention the increase of production or reduced cost. And, too often, when they find a thinker who gets ahead of them, they will brand him the fellow who is trying to get a mortgage on his job.

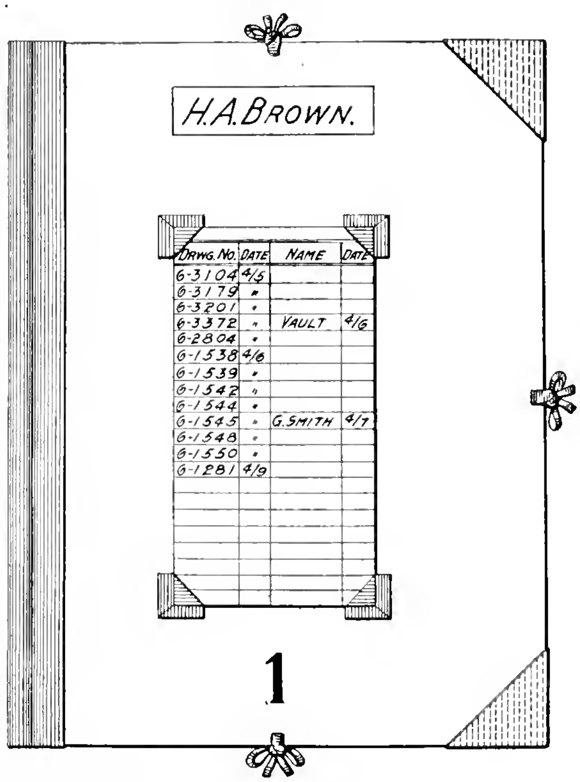
It is very rare that we find a well-educated man in the forge shop. The majority of American blacksmiths are recruited from boys who have had to earn a living at the first thing which would bring in the most money—usually doing odd jobs around the forge shop, or operating a steam hammer, as a start. After a time they may be put to help a blacksmith, and if they are bright and have a foreman who recognizes merit, they may get a forge, doing small work. Once at the forge, they are usually there for life. There are very few who are blacksmiths from choice, and so few of them have a fair education, that it is not surprising that so little has been written on the art of blacksmithing.

If manufacturers would do something to bring the forge shop up to the standard of the average machine shop in the way of equipment, ventilating, heating, provision for wash-rooms, etc., and besides take an interest in the boys who are learning the trade, encourage them to study mechanical drawing, arithmetic and such things as would help them to do work according to mechanical principles, we would in a short time have our forge shops filled with men who would bring the art of blacksmithing to the front. But few people seem to realize the importance of blacksmithing, although there is not a machine-building concern, nor an individual, who does not depend upon it more or less. What would happen to our industries if it was not for the men who earn their living behind the anvil? JAMES CRAN.

Plainfield, N. J.

DRAFTSMAN'S PORTFOLIO.

Difficulty is often experienced, and time is wasted, in "hunting up" tracings. Every large firm has a boy or two to take care of the tracings in the files or the vault, and who are required to see that every drawing is properly charged to the draftsman requesting to borrow it. It is a fact, however, that tracings often disappear among the piles the draftsmen have on their tables. If, for instance, a certain tracing is wanted by the superintendent, the way to get it is usually as follows: After looking up the number, the boy in charge of the vault finds out that the drawing in question was charged to Brown on a certain date. He goes to Brown, looks through the tracings, and after a while, to make sure that the one he wants is not there, upon asking for it, he gets the following answer, "Somebody took it," and the boy is just as wise as before. He will have to look through all the piles of tracings, the number of which may reach to hundreds.



A Draftsman's Portfolio in which the Tracings in Use are kept.

If the boy has good luck, he will find what he is looking for, but he as likely may have to report that the tracing cannot be found, which, of course, will not satisfy the superintendent. This is an every-day occurrence, but the following device or system will do away with this trouble:

Let every draftsman have a portfolio large enough to hold the largest standard size of tracings. This portfolio should be of heavy cardboard, with the back and corners leather-covered. The front should have a number corresponding to the number of the table where it is used. The portfolios being kept in the vault over night, will assure quick distribution when they are taken out of the vault in the morning. A small block of loose leaves divided into four columns should also be attached to the front. The first column is to be used for the drawing number, the second and fourth for dates, and the third for the name of the draftsman to whom the tracing has been given. The portfolio should also have three or more partitions of cardboard to separate the drawings of different sizes or types of machines, thus facilitating the finding of any particular tracing. The drawings should be handled in the following manner: Each person taking a tracing out of the

vault, should register his name and the date on a card for that purpose, to be left in place of the tracing. After returning to his own table, the draftsman should at once put the number and the date in their proper columns. Now, if Smith asks for the same tracing later on, his name and the date should be put down by him in the proper column. When the boy looks for a tracing, all he has to do is to glance at the cover to know at once whether the tracing is in the portfolio or has been given to Smith. In this way he will find the tracing very quickly. If the tracing is returned to the vault or to Brown, the corresponding charge should be cancelled. By this method, the tracings will be kept clean and in good shape. GEO. WILLIAM BOHLER.

Milwaukee, Wis.

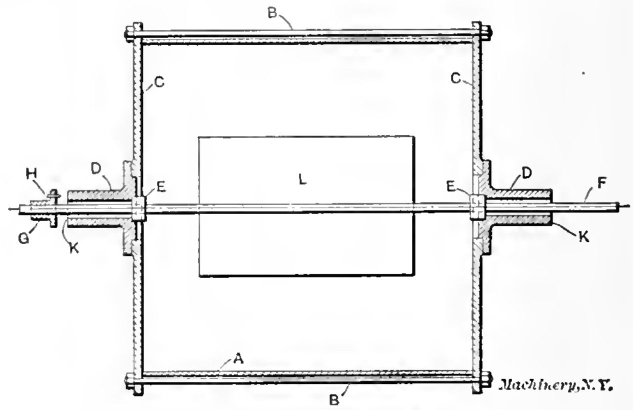
[While the system proposed by our correspondent has many good features, it is likely that the draftsmen would find it troublesome to open up the big portfolio every time they wanted to get or put back a tracing, and after a while it is to be feared that most of the tracings would be found on top of the portfolio, and not inside. That, however, may be a minor matter. A more important point to call attention to in this connection is that *tracings should not be used for reference*. Tracings are made to take blue-prints from, and for no other purpose. The only thing given to the draftsman for reference should be a blue-print; then there is no danger of soiling or spoiling the tracings by constant handling, nor of losing them; and a blue-print is fully as satisfactory as a tracing for reference.—EDITOR.]

FITTING TRUNNIONS TO A LARGE DRUM.

The sectional view shown herewith represents a steel drum held between two cast iron heads by rods with nuts on each end. To each head is bolted a flanged, hollow cast iron trunnion on which the drum is to revolve. In a shop where there is no lathe large enough to swing the drum, the problem is how to get the trunnions turned and bolted on so that they will be in line and true with each other.

Referring to the illustration, *A* is the steel drum, *B*, the rods for holding the drum and heads in place, *C*, the cast iron heads, *D*, the trunnions, *E*, two cast iron collars, *F*, a piece of cold rolled shafting, *G*, a flanged sleeve with a brass thumb-screw to hold it at any desired place along the shaft, *H*, a piece of drill rod sharpened for a scriber and held in the flange of the sleeve *G* by a small set-screw. After removing all rough spots on the bosses against which the trunnions *D* are to be bolted, holes are drilled through the heads *C* for the bolts which are to hold the trunnions. The steel drum is then placed between the heads and fastened by the rods *B* which pass through holes cast in the heads. The drum is now ready for putting the trunnions on. The trunnions are taken to the lathe and caught in the chuck by the flange, and the ends *K* faced. Then catching the end *K* in the chuck, the cored hole which passes through the center of the trunnion is counterbored a short distance at the flange end to fit the outside of the collars *E*, these collars having previously been bored a close running fit for the shaft *F*, and turned true on the outside. After chamfering the corner of the counterbore, the trunnion may be steadied by means of a pipe center while the outside diameter of the flange is turned true with the counterbore. The flange is then faced and fitted to the smallest diameter of the opening in the drum head, assuming that the opening will be somewhat out of round. The trunnions are now put in their places on the drum heads, and fastened by means of a strap across the opening in the head, and a bolt long enough to reach through the center of the trunnion and a washer against end *K*. By reaching in at the opening *L* in the drum, the bolt holes are marked on the trunnion flanges. After marking the trunnion flanges and drum heads so that each trunnion can be put back in the same place and position, the trunnions are removed and the bolt holes drilled after which the trunnions are put back in their places on the drum heads and all the bolts put in and tightened. Ordinarily on a rough job of this kind the flange seats on the drum heads will be true enough so that the trunnion flanges under the pressure of the bolts will come down tight all round, if not, the seat must be chipped or planed to give a fair bearing.

Now, with the trunnions on the drum heads, and bolts all tight, the cold rolled shaft is put in place as shown in the drawing with the two collars *E* in the counterbores of the trunnions. It is evident that the shaft is true with the outside diameter of the flanges at both ends of the drum. After coating the ends *K* with any good marking material, the sleeve *G* is placed on the outer end of the shaft and moved along until the scriber *H* is very close to the end *K* of the trunnion, where it is made fast by means of the brass thumb-screw, not shown. The shaft is now revolved, by taking hold of the sleeve *G*, and at the same time pushed gently until the scriber comes in contact with the end of the trunnion and scribes a circle thereon. It is obvious that the circle so scribed is true with the shaft bearings in the collars *E*, and also true with the outside diameter of the trunnion flanges. The sleeve is now removed, and placed on the other end of the shaft and the other trunnion scribed in the same manner. The trunnions are now removed and taken to the lathe, and



Section showing the Drum and its Trunnions which were turned in a Small Lathe, and then set in Alignment with each other.

caught by the flange end in the chuck and set so that the outside diameter of the flange and the circle on the end *K* both run true at the same time. The cored hole, which passes through the center of the trunnion may now be bored a short distance in at the end *K*, and chamfered to fit a pipe center which may be used to steady the work while roughing, after which the center should be withdrawn to see if the circle is still running true; if not, it must be made to run true with the outside diameter of the flange after which the finishing cut is taken. After finishing to size, the trunnions are put in their places on the drum heads, and bolted up in the exact positions which they were in when the circles were scribed on their ends at *K*, and they will be in line and true with each other as desired. J. T. GRIMSHAW.

Detroit, Mich.

AN ALTERNATIVE PLANER TYPE SUGGESTED.

We have read with much interest your description of the huge Bement (Niles-Bement-Pond Co.) planer, published in your January issue. It seems to us that if we take into account the depreciation, interest on money invested, the large space taken up by the machine and the extra power required, a sum of at least 50,000 to 60,000 francs per annum should be charged against it. The first cost, no doubt, was not far from 300,000 francs. It is a pity that we do not know exactly the kind of work this machine has to plane, but it seems that a planer built on the style shown in the accompanying half-tone illustrations, would have served general purposes much more economically and would have been fully as adaptable, especially so if the bottom table could be raised and lowered by hydraulic pistons so as to place the work at the required height.

M. Morane, of Paris, has a planer of this type in a much smaller size with the hydraulic system to adjust the table, and it is giving excellent satisfaction. In our opinion a planer built according to this plan would not require more than 25 horse-power, and it would take up no more room than the machine illustrated in your January issue. There certainly would be much difference in the capital invested.

SOCIETE ANONYME DES MOTEURS A GAZ A. BOLLINCKX.

Huyssinghen, Belgium.

[The type of planer referred to in the above is that built

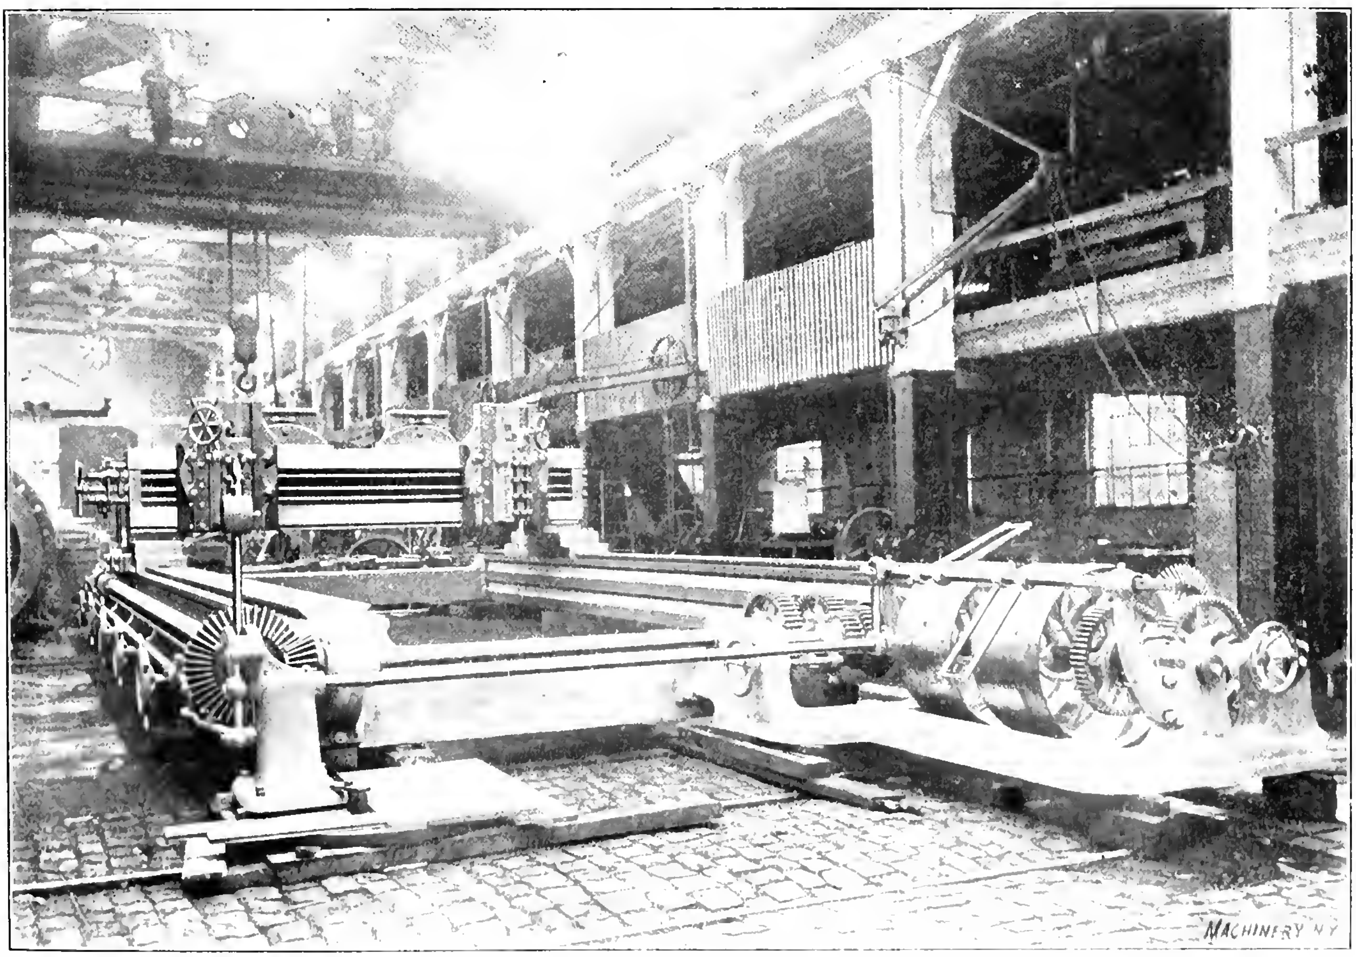

Fig. 2. Another Pattern of Pit Planer built by the Same Concern.

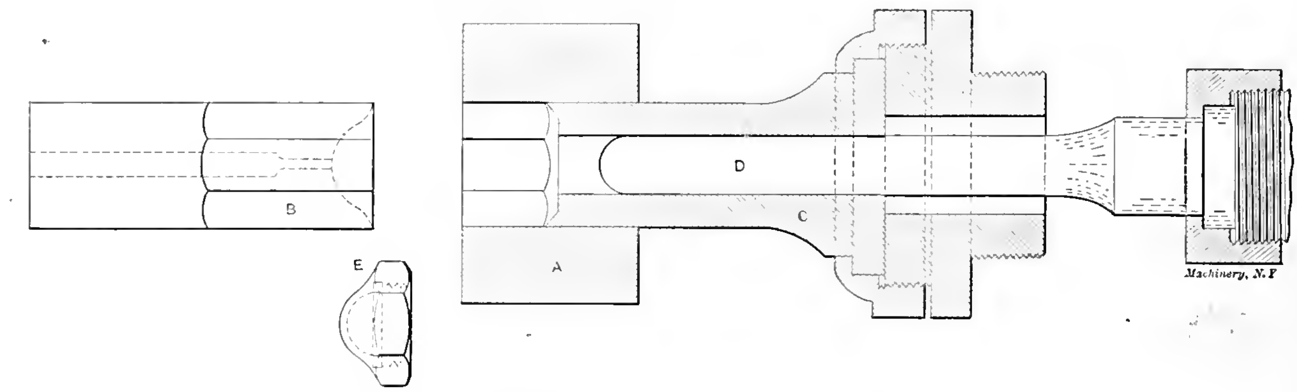
by the Societe Anonyme des Etablissements Fetu-Defize, Liege, Belgium, and is used by such concerns as Fried. Krupp, Essen, Germany; Armstrong Whitworth & Co., London, England; Dillingen Huttenwerke, Dillingen, for planing armor plates, conning towers for forts, and other heavy work having great weight. The same type of planing machine is used in America by the Bethlehem Steel Co.'s and Carnegie Co.'s armor plants.—EDITOR.]

MAKING NUTS FOR FLEXIBLE STAY-BOLTS.

The accompanying engraving shows a method of making nuts for flexible stay-bolts, which may be of interest to some of the readers of MACHINERY. In the shop where this method is employed, a drop forging press is not available. This device was therefore designed to be used on a 1½-inch Ajax nut machine. The nut blank is placed in a holder *A*, and the die *B* holds it in place. The punch *C* then moves forward and crowns the nut, and finally punch *D* is fed forward and makes the recess into the blank for the thread, at the same time that the projection is thrown up on the end of the nut. The finished nut is shown at *E*. This process of making nuts proved a complete success, it being possible to make 1,000 in 10 hours.

W. L.



Device for making Flexible Stay-bolt Nuts on the Ajax Nut Machine.

THE USE AND ABUSE OF THE HACK-SAW.

The most useful tool in the tool-room, and, at the same time, the most abused tool of all, perhaps, is the power hack-saw. Nearly every tool-room has one, and every one, from the new apprentice to the "old man" uses it more or less—but how do they use it? In the average shop this tool is not only neglected in so far as cleaning and proper oiling is concerned, but it is misused in almost every conceivable way, and it has occurred to the writer that a few words in the columns of MACHINERY with reference to the proper use of the hack-saw might be instrumental, to some extent, at least, in calling attention to this matter. The following, therefore, contains a few suggestions which will be helpful for getting the best results out of this machine with a minimum cost for hack-saw blades.

When a piece of steel is nearly sawed off, it is poor practice to try to break it off while the saw is running, by working it up and down, because it is likely to break the saw in every instance. The saw should be stopped, and the saw-frame raised first, before any attempt is made to break off the piece.

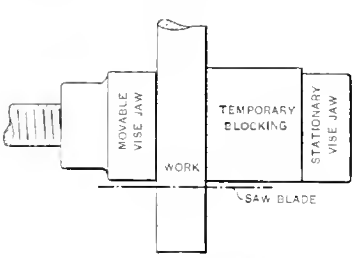


Fig. 1. Temporary Blocking for Using Portion of Saw not yet Dulled

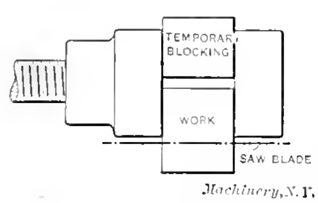

Fig. 2. Blocking for Holding Short Work.

If a piece of steel or iron is sawed through about one-half or three-quarters of its thickness, and the saw blade proves to be too dull to cut through the piece completely, then remove the blade and replace it with a new one, but turn over the piece and start the cut on the opposite side, because a dull saw blade is always worn more or less on the sides, and will always cut a narrower slot than a sharp blade, and if a new blade is forced into the slot already sawed by a dull saw, it will almost always stick, and when started up it is very likely to break.

The duller a saw is, the more pressure or weight should be brought to bear upon it. Whenever the old blade is replaced by a new one, the pressure should be released, to a certain extent, as a sharp blade, with too much pressure back of it, will have a tendency to break. If, by chance, it does not happen to break, it will at least get some of the teeth broken off, which, as far as its usefulness is concerned, to a certain extent, is almost as bad as if the saw itself were broken. This, in fact, is one of the chief causes of the breakage of saws, and it is also a reason why saw blades made by reliable and able makers are pronounced too hard, and discarded, at times, for inferior ones, although the real cause of the breakage ought to be laid to the ignorance and carelessness of the operators.

The writer has often seen saw blades thrown away, that are supposed to be too dull for further use, although they could have been used for a great deal longer time, if the method shown in Fig. 1 had been employed, where that part of the blade is used which has not previously been employed to any great extent. When most of the pieces cut off in the hack-saw are of small diameters, it is often only one small portion of the saw that becomes dull, the remainder being as good as new. The engraving indicates how the piece sawed off is removed from its ordinary position by a temporary blocking between the piece itself and the stationary vise jaw. This, of course, permits the saw to cut with a different portion from that which has previously been employed to do most of the work.

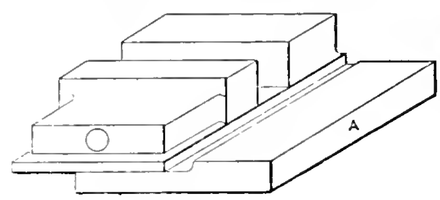

Fig. 3. Shelf for Supporting Portion of Work being Cut Off.

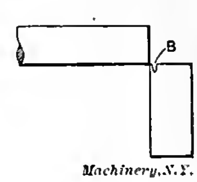

Fig. 4. Effect when End of Work being Cut Off is not Properly Supported.

In starting up a saw, it always pays to slightly lift up the saw frame until the blade has made a few strokes and provided a bearing surface for itself in the piece to be cut off. It is evident that in sawing off a piece of square or flat stock, the blade will first come in contact with the sharp corners of the stock, which, of course, give no bearing surface for the saw at all, and the saw will therefore dig in. If, however, the saw is prevented from coming down upon the work with its full weight until a sufficiently long bearing surface for the teeth has been provided, the life of the saw will be greatly prolonged, and a consequent cutting down of the expense of the operation of the hack-saw will follow.

If a bar is to be cut off, always hold it in the vise in such a manner that the greater portion of the bar is between the vise jaws. This will give a good support to the piece. A piece of work that is insecurely held in the vise will always wobble, and this is a frequent cause of breakage of saws. Should a piece be so short that, when placed in the vise, it will not extend over one-half of the length or width of the vise jaws, then place a piece of blocking of the same diameter at the other end of the vise, as shown in Fig. 2, before tightening it. This will tend to permit the vise to hold the work securely, and also prevent injury to the vise from springing or breakage.

If a hack-saw is of a good design, it usually has a projecting shelf similar to that shown at A, Fig. 3, which provides for support of the piece to be cut off. Otherwise, when nearly sawed off, the piece will bend over, causing the saw to dig into it, as at B, Fig. 4. All hack-saws, however, are not provided with this projecting shelf, and this is rather surprising, as it seems to be a serious defect.

In conclusion, the writer would say that, from personal experience, he believes that the best results are obtained by having all the sawing off, either on the power hack-saw or a cutting machine, done by one man, provided it is seen to that this man knows his business. No one else should be permitted to run the machine. In this way, if anybody is to be blamed for undue carelessness, it is an easy matter to find out who is to blame. Better results are also obtained, from a financial point of view, because a great deal of time is wasted by each man spending a certain time on cutting off his work himself at the hack-saw, when this could as well be done by somebody who is doing this kind of work all the time.

C. F. Emerson.

WHITWORTH OR ENGLISH TAPER PIPE TAPS.

In the article on Screw Thread Systems in the February issue of Machinery, it was mentioned that the manufacturers make the taper on Whitworth or English pipe taps the same as the taper on Briggs standard pipe taps. In the April issue, however, it is also mentioned that in England these taps are made with a 1-inch taper per foot, instead of ¾-inch, and that at least one firm in this country makes these taps with the taper according to this practice. No table, however, is appended, giving any dimensions for English taper pipe taps, when these are made with a 1-inch taper per foot. Mechanical hand-books give nothing on the subject of the taper of Whitworth pipe taps, and for that reason it is highly desirable that the question of correct taper be brought up in the discussion of this subject. The dimensions of these taps should be based upon standard Whitworth pipe tap gages, which are made in England by the Whitworth Company. These gages all taper 1 inch to the foot and are so marked upon the gage.

The accompanying table shows the dimensions of Whitworth pipe taps, as made by the A. J. Smart Mfg. Co. It will be noticed by comparing this table with the one appearing in the March issue of Machinery, for regular Briggs pipe taps, that the diameters at the small end are not the same for the

TABLE OF WHITWORTH PIPE TAPS.
(A. J. Smart Mfg. Co.'s Standard.)
Taper per foot = 1 inch.

Nominal Size.	Diameter at Large End of Thread.	Total Length of Tap.	Length of Thread.	Length of Shank.	Diameter of Shank.	Length of Square.	No. of Threads per inch, Whitworth Form.	Number of Flutes.	Size of Steel.
1/8	0.435	2 1/8	1	1 1/8	0.328	11/32	28	4	15/32
1/4	0.570	2 3/8	1 1/8	1 1/4	0.438	7/16	19	4	19/32
3/8	0.718	2 5/8	1 5/16	1 5/16	0.563	1/2	19	4	3/4
1/2	0.888	3	1 7/16	1 9/16	0.703	9/16	14	4	59/64
5/8	0.964	3 1/4	1 15/32	1 25/32	0.781	5/8	14	4	1
3/4	1.103	3 3/8	1 1/2	1 7/8	0.906	11/16	14	4	1 9/64
1	1.382	3 3/4	1 5/8	2 1/8	1.125	13/16	11	4	1 13/32
1 1/4	1.725	4 1/8	1 3/4	2 3/8	1.453	15/16	11	6	1 3/4
1 1/2	1.958	4 3/8	1 7/8	2 1/2	1.609	1	11	6	1 63/64
1 3/4	2.130	4 1/2	1 15/16	2 9/16	1.766	1 1/16	11	6	2 5/32
2	2.430	4 5/8	2	2 5/8	2.063	1 1/8	11	6	2 15/32

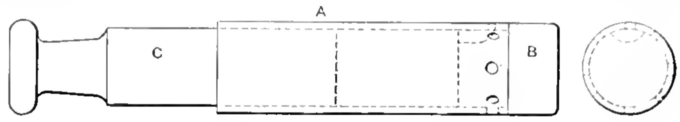
same nominal sizes. This is because English pipe is smaller than American pipe, according to all tables, so that the ends on the Whitworth pipe taps should be made correspondingly smaller. It is believed by the A. J. Smart Mfg. Co. that the proper way to make the taps, therefore, is to make the diameter at the smaller end correspondingly smaller. The lengths of the pipe taps in the table will also be found to be shorter, because it has been found that all users of pipe taps, especially plumbers, prefer the shorter lengths, and many of the tap manufacturers are now making the lengths of the threaded part of pipe taps the same as those given in the table. The A. J. Smart Mfg. Co. also only makes 4 or 6 flutes in its taps. The company has found that customers do not like an odd number of flutes, as the taper with the odd number of flutes can never be measured by micrometers after the flutes have been once milled. This is a great disadvantage (or, to some people, an advantage) in cases of disputes as to the sizes of the taps. In the table given, there will be found a column giving the size of the steel used for the different taps. This information is given for the convenience of the purchasing agent, the superintendent, the foreman, etc., and has often been found exceedingly useful.

Charles E. Smart.

Greenfield, Mass.

DEVICE FOR MAKING WAX FILLETS.

The device for making wax fillets, described by M. R. Kavanagh in the December, 1907, issue of Machinery, is a good thing for a pattern-maker to own, but it may be made as shown by the accompanying illustration with less trouble and expense. The barrel A is a piece of brass tubing. The cap B



A Simple Tool for Making Wax Fillets.

and the plunger C are both made of hard wood. Eight different sized holes are drilled near one end of the tube, all but one being covered by that part of B which extends into the tube, as shown. Any other hole may be uncovered by turning B. To produce a fillet, fill the barrel with wax, warm, and compress in a vise.

W. H. Knowles.

New Britain, Conn.

METHOD OF MAKING SCREW FOR DRILL CHUCK.

Some time ago I had occasion to replace a screw in the Standard Tool Co. drill chuck, and as we did not have any in stock, one had to be made as soon as possible. I gave the job to a tool-maker working under me, and asked him how long it would take to make it, and he said about one hour

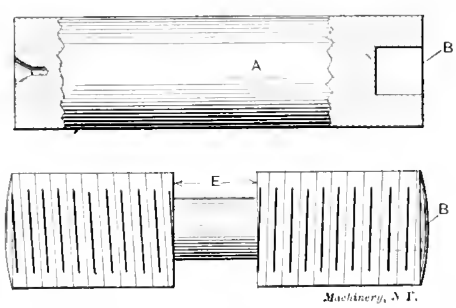


Fig. 1. Two Views of the Partly Finished Chuck Screw.

and a half. I doubted his word, somewhat, on the time, but told him to go ahead, and in less than an hour and a half he handed me the chuck repaired with a good hardened screw, and as true as the day it came from the factory. This is a job that a tool-maker does not have very often, as these screws

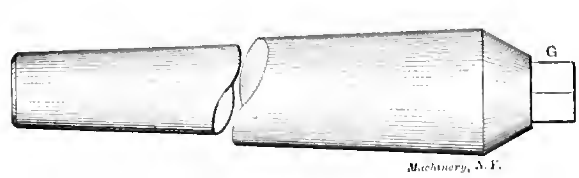

Fig. 2. Lathe Center for Holding and Driving the Work.

are usually replaced by ordering from the factory, but at the same time, when there is one needed and there is none in stock, it is usually a hurry-up job, and it is very important that we should know how to get it out in good time.

Referring to Fig. 1, the first operation is to cut off a piece of stock A long enough to make the screw, allowing a little

stock for finish on both ends; then broach in the square hole *B*, and center the other end. Then it is ready to be turned and threaded as shown. It is also necessary to have a lathe center such as shown in Fig. 2, with a square *G* to fit the hole *B* snugly, the square also acting as driver. Then with a parting tool, cut groove *E* (Fig. 1) about 1/8 inch narrower than it is to be when finished. Then the piece is ready to be threaded. Cut the thread right- and left-hand, using the broken screw for thread dimensions. It is not necessary to take any care in starting threads in the right position, in order to have the jaws come central in the chuck.

After the threads have been finished to size, chuck jaws *D* (Fig. 3) are set in place on the screw and turned around until they come firmly against center pin *H*. The groove *E* can then be made perfectly central with the working faces of the chuck jaws by setting the parting tool with the pin *H*, which is held between the jaws. After the tool has been set in this way, and one side of the groove *E* has been faced, the jaws may be put on the screw again in the same position, and the tool set for facing the opposite side of the groove.

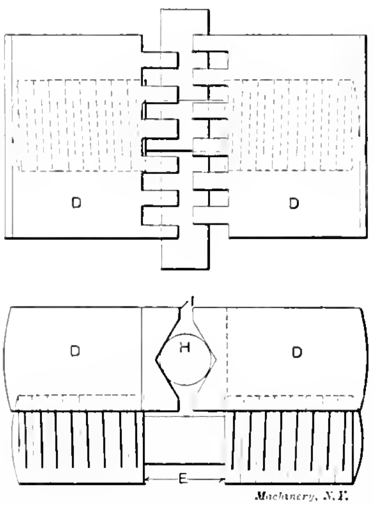

Fig. 3. Method of getting the Groove E and the Working Faces of the Chuck Jaws Central.

It may seem useless to the reader to use the center pin *H*, as it would be just as well to use the chuck jaw at *I* to obtain the center of the groove *E*, but that will not hold good in all cases, as sometimes you will find that the surface *I* is not true with the part of the chuck jaw that holds the drill. In order to be on the safe side, it is wise to take the measurement from the working part of the chuck jaw. It does not matter whether the chuck is old or new, groove *E* is bound to be central with the working face of the jaw. One thing I would like to say in conclusion is that it is wise to have a piece of steel on hand suitable for making screws, as most carbon steel used for reamers, taps, etc., would be too high in carbon to give good results on screws where there is a twisting strain, such as chuck screws. B. M. Weller.

Franklin, Pa.

HARDENING OF HIGH SPEED STEEL VERY IMPORTANT.

Referring to your remarks anent high speed steel for milling cutters (page 453, engineering edition, March issue), users of steel must not confuse "hardness" and "red-hardness." Further, some steel tools last longer than others without re-grinding, on cast iron; while on steel or wrought iron it is the other way about. Too many steel users mix the terms "self-hardening" and "high speed"; also, they consider that all high-speed steel is alike; whereas, there are more sorts thereof (I don't mean brands) than there are of ordinary "binary" or carbon tool steels. The lasting propensity of a tool steel is more dependent on the hardening process than on the manufacturer; and more on the hardener (man) than either. Robert Grimshaw.

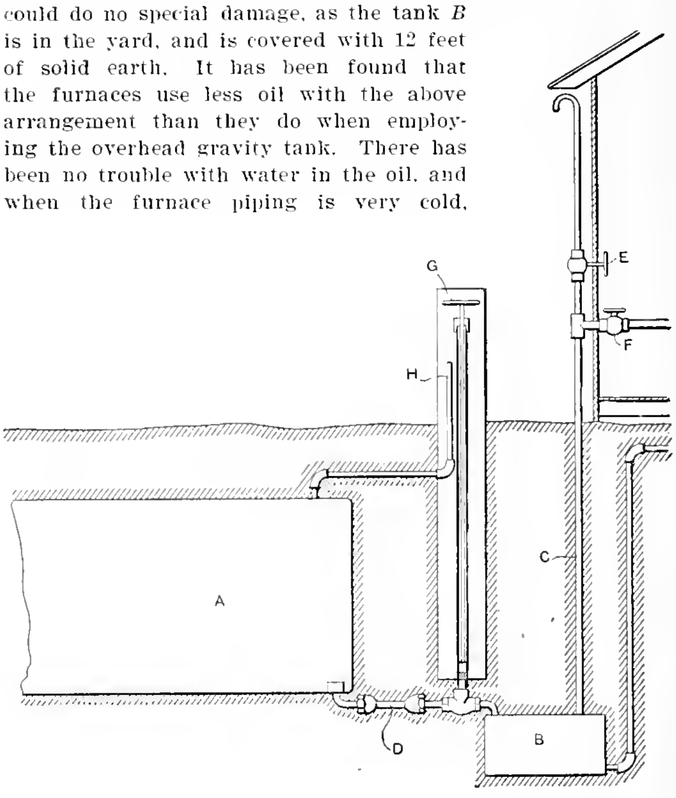
Dresden, Germany.

FUEL OIL STORAGE SYSTEM.

Most oil storage systems are arranged so that the oil will flow by gravity to the places where it is required. This, however, necessitates having the oil tank elevated, and considerable danger is connected with this system. In order to eliminate this danger, the arrangement shown in the accompanying engraving was resorted to by a foundry in the middle West. The object of the arrangement shown is to place all oil below the ground, and to keep it there unless it is forced away from its reservoirs by means of air pressure. As will be seen from the following description, all pumping of oil is eliminated, and at the same time the danger of carrying air pressure on a large storage tank for oil is avoided.

The arrangement consists of a large storage tank *A*, which is 35 feet long and 8 feet in diameter. This storage tank is filled directly from a tank car at that end of the storage tank not shown in the engraving. The small tank *B*, from which the oil is fed to the places where it is used, by means of air pressure, is connected with the storage tank *A* through the piping *D*. This tank is 5 feet long by 2½ feet in diameter. When it is required to fill the tank *B*, the vent valve *E* is opened and the air pressure valve *F* closed. The tank *B* will then be filled, by gravity, in six minutes. The valve *G* and the vent valve *E* are now closed, and the high pressure valve *F* opened, permitting the air pressure to be applied on the oil in tank *B* through pipe *C*. Then, if such furnace valves as required are opened, the oil will flow to the places where wanted, actuated by the air pressure on the oil in tank *B*. It is impossible to get any air pressure on the oil in the large tank on account of this tank having a vent pipe *H* which cannot be closed, and the security is all the greater as the air pressure pipe to tank *B* is smaller in diameter than the vent pipe *H*, so that if valve *G* should be left open, the air will escape directly into the atmosphere through the pipe *H*. When the pressure valve *F* is closed and the vent valve *E* opened, leaving all furnace valves as they are in operation, all oil in the pipes in the shaft will return by gravity at least 36 inches below the floor of the shop.

If, after several years of use, the pressure tank should be weakened through corrosion so that it would rupture, this could do no special damage, as the tank *B* is in the yard, and is covered with 12 feet of solid earth. It has been found that the furnaces use less oil with the above arrangement than they do when employing the overhead gravity tank. There has been no trouble with water in the oil, and when the furnace piping is very cold,



Economical and Safe Storage System for Fuel Oil.

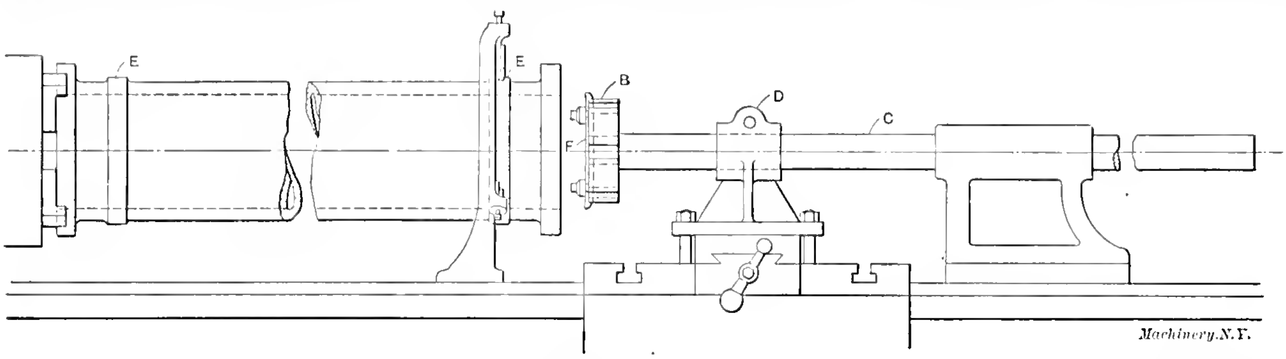
no heating of the same has been required, as was formerly the case, because the oil is comparatively warm in the underground tanks, and, having a pressure of 60 to 80 pounds per square inch, it always finds its way to the furnaces. It should be noted that it is important that a lead pipe be used for connecting the two tanks, permitting each tank to settle independently.

The valve between the two tanks *A* and *B*, which is operated by the hand-wheel *G*, is placed in a box with locked cover. This box enters in the ground so that it comes down close to the valve seat. The vent pipe *H* is also placed inside of this wooden cover, and ten 1½-inch holes bored in the side of the box to permit free circulation of the air.

Racine, Wis. E. Falkenrath.

BORING LONG CAST IRON CYLINDERS.

We had some cast iron cylinders to bore, and as they were ten feet long, and were to be bored twelve inches in diameter, we were obliged to make a special boring tool. The sketch shows this tool, and the way in which it was attached to a lathe. The boring head *B*, which is keyed to the bar *C*, has six dove-tailed slots cut across its periphery. These slots were for holding hard wood blocks which fitted closely into the bore, guiding the bar. A double-ended boring tool was clamped in the groove across the head, as shown at *F*. The split sleeve



The Way in which a Boring-bar was attached to a Lathe when boring Long Cylinders.

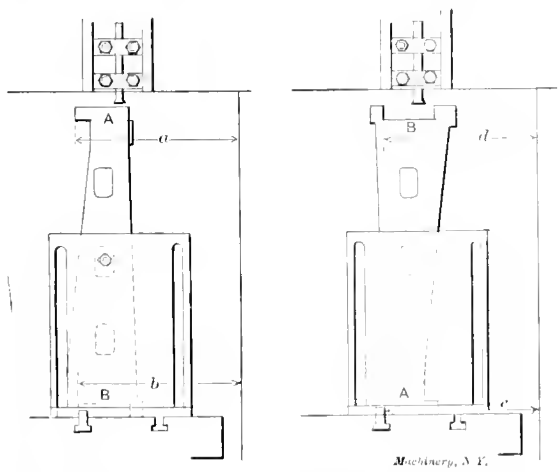
D, which was fastened to the lathe carriage, supported one end of the boring-bar, and the sleeve was clamped to the bar when boring, as the feeding was done by the lathe carriage. The bar was also supported by the tail-stock as shown. Before the boring-bar was placed in position, the enlarged parts *E* of the cylinder were trued up, as the outer end of the cylinder had to be supported by a steady-rest.

In starting the cut, it was necessary to steady the bar by clamping the sleeve nut *D* close to the boring head, but when the head had entered the cylinder, the sleeve was moved out as far as the tail-stock would permit, and again clamped to the bar. In starting this job, the double-ended boring tool and hard wood block referred to, were used. It was found, however, that by using a single tool, and by inserting hardened steel blocks in the two slots opposite the tool, much better work could be done, because in the former case the blocks were rapidly worn away. Of course, it was necessary to adjust these blocks for each cut. The cylinders bored in this way were approximately straight and true, and the work entirely satisfactory. M. B. STAUFFER.

Scottdale, Pa.

METHOD OF PLANING AN ODD-SHAPED CASTING.

Referring to the accompanying engraving, it is necessary that the end *A* and the socket *B* be interchangeable with another end and socket, and that the parts,

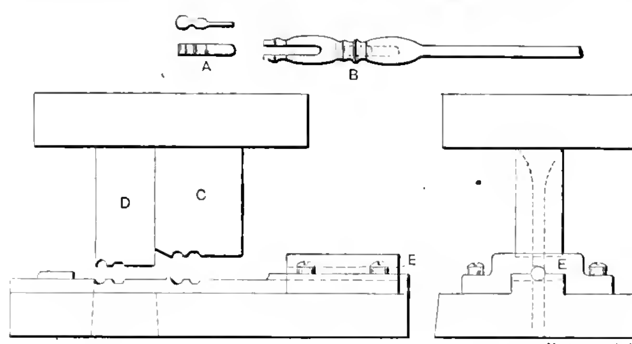


Figs. 1 and 2, showing the Work set up on the Planer.

when in position, line up the same when the extension is in use, as when it is removed and the other end and socket are in position. The length of the extension is such that a very small variation at either end would be sufficient to cause a serious variation at the other end. After several attempts to plane the casting with sufficient accuracy, the following method was decided on as giving the best results: The casting was placed on the planer table with the end *B* down, and with one side of the slot against a tongue inserted in the table slot. The casting was then set with the planer housing by measuring at *a* and *b*, adding enough to *a* and subtracting enough from *b* to allow for finishing. After the end *A* was finished to the required dimensions, the casting was inverted, as shown, and the finished edge placed against the tongue piece in the table. A micrometer measurement *c* was then taken from the tongue to the housing, and one side of the slot in the end *B* of the casting finished to this measurement as at *d*. In this way the finished surfaces at each end of the casting were made parallel, and in the same plane. LEROY K. MOULTON.

A SWAGING AND BLANKING DIE.

A few years ago, I had some small pieces to make as shown at *A* in the engraving. These pieces, I believe, hold the sapphires used on phonographs. The job puzzled me a bit until I hit upon the scheme of running an annealed brass wire through a gang die, and swaging and blanking the pieces from this. At *B* is shown the end of the wire after the swaging and blanking punches have done their work. The swaging punch is shown at *C*, while *D* is the punch that forces the blank



Swaging and Blanking Die for Forming the Pieces shown at A

through the die. The wire is fed through the guide *E*, which keeps it in proper alignment with the working faces of both die and punch. The dotted lines, shown on the swaged end *B* indicate where the next piece *A* will be cut from the stock by the blanking punch *D*. A stripper (not shown) removes the scrap from the blanking punch. The pieces, after coming from the die, are tumbled and then drilled.

New York. JAMES J. KLEIN.

CUTTING OFF STEEL SHAFTS.

The following little kink may be appreciated by many machinists who have had more or less trouble when cutting off steel shafts. By simply turning the cutting-off tool upside down, and running the lathe backwards, it is possible to almost entirely eliminate any digging in of the tool. This method will be found to be far superior to the ordinary method of cutting off stock. Of course, it works to best advantage when using a straight cutting-off tool. It is necessary that the lathe be reversed; or else, if the cross slide permits of the tool being placed on the opposite side of the lathe, in the rear, then the reversing is of course unnecessary.

Birmingham, Ala. JOHN MCLEOD

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

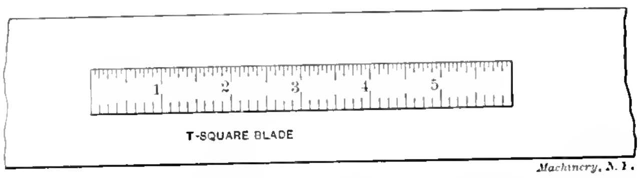
MAKING KNURLS.

A very satisfactory method of making the common knurls, when no other means is at hand, is to turn up the flank in a lathe, then place it in the holder and insert the holder in the tool-post of a shaper. Next clamp a sharp, flat mill file in the shaper vise, flat side up, and run the knurl blank back and forth over it until teeth sufficiently deep are cut. By using a wide file, and shifting the shaper vise, knurls having teeth varying from a considerable angle to those straight across may be obtained. Instead of a file, a specially cut piece of hardened steel is often used. After the knurls are cut, they are hardened and tempered in the usual way and are then ready for use. ETHAN VIALL.

Decatur, Ill.

STEEL RULE RECESSED INTO T-SQUARE BLADE.

The following little kink may be of some value to those readers of MACHINERY who are draftsmen. A 6-inch flexible Brown & Sharpe scale is laid into the T-square blade, which has previously been recessed somewhat to fit the scale, as shown in the accompanying engraving. Shellac is used to



hold the scale in place in its recess. The dividers and compasses may be set directly from this scale, and the annoyance of looking for an ordinary loose draftsman's scale is avoided. Scales graduated to 32ds and 64ths of an inch are convenient for fine work. The writer has found that the Brown & Sharpe scale fitted in this way is very handy. JOHN COAPMAN.

Rochester, N. Y.

A TAPER TURNING KINK.

The usual way of turning a taper in a lathe without using a taper attachment is to set over the tail-stock and use the same centers as are used for straight work. This gives an uneven bearing on the centers, thus wearing the centers away, as can be readily seen from Fig. 1. This method is likely to spoil accurate work. Fig. 2 shows a simple and inexpensive way of overcoming these bad points. All that is necessary

Fig. 1

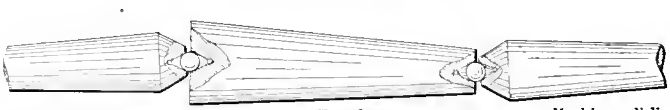


Fig. 2

is to turn up two female centers and put bicycle balls in them. They need not be fastened, as a little oil is sufficient to stick them in place while the work is being put in the lathe. S. A. MCDONALD.

Candiac, Canada.

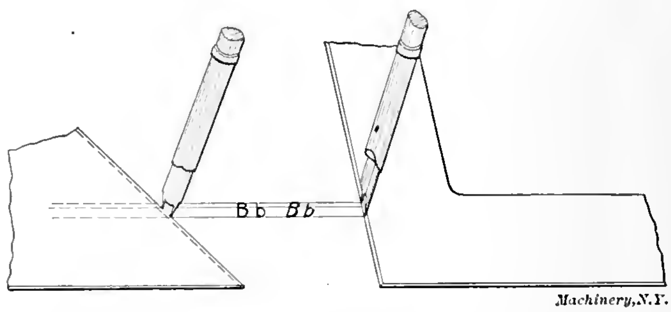
A NEW TRICK IN CAT-HEADS.

Every machinist has had to use some kind or variety of cat-head, and generally when using this same indispensable cat-head, the frame of mind of that same machinist is anything but dee-lighted. The other day I saw a simple method of making a cat-head which made me feel like bumping my head against a brick wall for not thinking of it when I required one for my own use. The man had two levers about four feet long, which had to be turned and machined to a special shape at one end, and the other end was turned round nearly one-half the length of the lever. He procured a bushing which had a hole about ½ or ⅝ inch larger than the diagonal of the lever, and using this as a mold, poured a babbitt cat-head on each of the levers. He used the same bushing on both levers, and then took a light cut over both cat-heads, making them the same outside diameter. Then he adjusted his steady-rest to the cat-head, and finished the job with a smile on his face. J. J. VOELCKER.

Decatur, Ill.

HANDY TOOLS FOR THE DRAFTING BOARD.

If a great deal of lettering has to be done on a drawing, it is convenient to have a gage for a uniform height of the letters. Such gage can conveniently be made of an ordinary pen point, by breaking off the two points and using the two remaining points as a gage. For the height of the capital

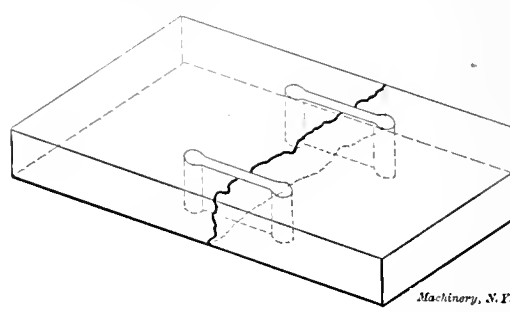


letters point off their space along the vertical side of a 45-degree triangle, and for the height of the small letters use the gage along the inclined side of the same triangle, which will give the right proportion, as shown. I always keep on hand a number of broken-off pen points of various sizes for different gages. MARTIN JOACHIMSON.

New York.

A DUMB-BELL PATCH.

A simple application of a repair "stunt" called a dumb-bell patch, that does not seem to be widely known, is shown in the engraving. The patch, or more properly, the link, gets its name from the resemblance it bears to the dumb-bell, and finds a field of usefulness in joining the parts of a broken casting



that must be held as near as possible to their original position and have no screw heads or indentations in the finished surface. This is accomplished as follows: The broken pieces are put closely together, and the place for the dumb-bell is laid out, after which the casting is drilled and slotted to these lines. A piece of steel is then carefully worked up to fit this opening, but with the distance from center to center of the round ends slightly less than the drilled holes for the dumb-bell. The piece is heated until it is long enough to be driven home, and while cooling, it is riveted slightly to fill perfectly all around, after which the patch can be filed off flush. By this method the broken parts will be held together with considerable force. DONALD A. HAMPSON.

Middletown, N. Y.

* * *

In the May issue we published an article on the "Shop Kinks" page, by Mr. J. J. Voelcker, on the use of the steady-rest. The illustration accompanying this article did not show a driver attached to the work, but, of course, it will be understood that the only function of the leather strip is to hold the work against the head-stock center.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

DEFINITION OF MACHINE TOOLS.

C. L. B.—Please define machine tools.

A.—A strict definition of machine tools is difficult, if not impossible. A machine tool is a metal-working machine, but not all metal-working machines are machine tools, by any means. The standard machine tools are engine lathes, turret lathes, chucking lathes, pulley lathes, screw machines, planers, shapers, slotters, milling machines, gear cutters, gear planers, boring mills, boring machines and drilling machines, these being the chief examples. Then follow key-seaters, broaching machines, nut-tappers, centering machines, bolt threaders, hack-saws, cam cutters, profilers, etc., which are on the borderland. A broad definition of machine tools would include these also, but the narrower sense in which the term is commonly used, does not include them.

CHANGE GEARS FOR MILLING MACHINE WHEN CUTTING SPIRALS.

Machinist.—In the January issue you explained, in a simple manner, to "Apprentice," how to figure change gears for the lathe. I would be pleased if you would explain, in a similar way, how to figure change gears for the milling machine, when cutting spirals.

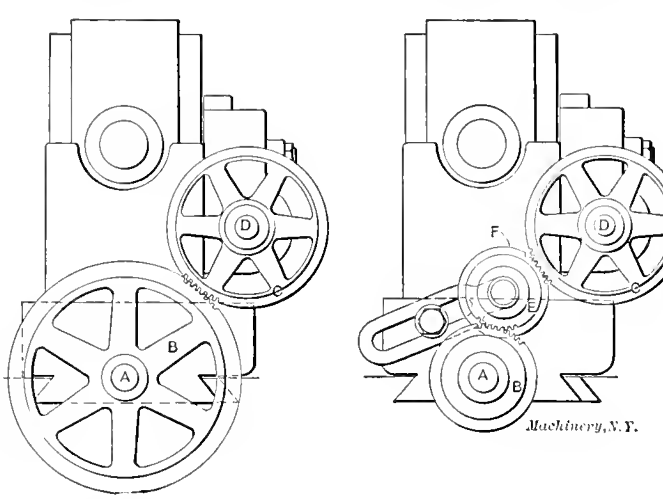
A.—The method for the figuring of change gears for cutting spirals on the milling machine, is, in principle, exactly the same as that used for figuring change gears for the lathe, but it will be necessary to shortly refer to the construction of the mechanism for connecting the index head spindle and the feed-screw to make perfectly clear the fundamental ideas governing the selection of change gears. In Fig. 1, *A* is the feed-screw of the milling machine, and *B* is the gear placed on this feed-screw, commonly called the feed-screw gear. This gear meshes with the gear *C*, placed on the stud *D*, from which, in turn, motion is imparted to the worm in the index head and from the worm to the worm-wheel and the index spindle. The gear *C* on the stud *D* is called the worm gear, because it directly operates the movement of the worm. This expression "worm gear" should not be confused with the worm-wheel, which is placed on the index spindle. The case shown in Fig. 1 is one of simple gearing. In Fig. 2 is shown a case of compound gearing. Here *B* still represents the feed-screw gear, *E* is a gear on the intermediate stud, meshing with gear *B*, and gear *F* is another gear on the same intermediate stud, meshing with gear *C*, thus transmitting motion from the feed-screw to the stud *D* by compounding the gears.

The figuring of change gears for the milling machine consists simply in the selection of the proper gears, *B* and *C*, used in a simple train, as in Fig. 1, or gears *B*, *E*, *F* and *C*, as used in a compound train of gears, as shown in Fig. 2.

In order to figure change gears for the lathe, we remember that it was necessary to first know the number of threads per inch in the lead-screw. Knowing that, we knew how many revolutions the lead-screw had to make to move the carriage and the thread tool one inch along the work. In the case of the milling machine we must know *how far the table travels while the index spindle makes one complete revolution, when gears B and C, Fig. 1, have an equal number of teeth.* This distance is the constant which we used in figuring the change gears, the same as we used the number of threads per inch of the lead-screw in figuring change gears for the lathe. This constant, which may be different for different milling machines, is called the *lead of the milling machine.* We will now see how this constant is found.

Suppose, for instance, that in a milling machine one revolution of the worm gear *C*, Figs. 1 and 2, will produce exactly one revolution of the shaft on which the worm is placed, that is, one revolution of the index crank; and suppose that equal gears are placed on the feed-screw and on the stud *D*, so that one revolution of the feed-screw produces exactly one revolution of the gear *C* and stud *D*. Then, if the feed-screw revolves one revolution, the milling machine table will advance a distance equal to the lead of the feed-screw, because, as we have said before, the lead of the screw is the distance which it will advance in one turn.

Now, when the table of the milling machine moves forward a distance equal to the lead of the feed-screw, or a distance equal to one thread in the feed-screw, the feed-screw turns one revolution, and gear *C* also turns one revolution, the worm-shaft and the index crank turn one revolution, and, there being 40 teeth in the worm-wheel which is mounted on the index head spindle, this worm-wheel, with its spindle, will turn 1/40 of one revolution. To make one complete revolution of the index head spindle, the feed-screw would have to be revolved as many times as there are teeth in the worm-wheel, each revolution, as we have seen, moving it one tooth. The distance which the milling machine table will advance, when the index head spindle revolves one complete revolution, is, as we have said, the lead of the machine. This distance evidently equals the distance that the feed-screw advances the table in one revolution (which is the lead of the screw) times the number of revolutions made. If we assume that the feed-screw has a lead of 1/8 inch, and that there are 40 teeth in the worm-wheel on the index head spindle, the feed-screw, when the gears *B* and *C* are equal, will have to turn 40 times, in order to move the index head spindle around once, and the distance the table will then advance will be



Figs. 1 and 2.

40 times 1/8 inch, or 5 inches. In this particular case, 5 inches is then *the lead of the machine.* If now a piece of work had been affixed to the index spindle, it is clear that this piece of work would have made one complete revolution, while the milling machine table advanced 5 inches, and that the lead of the spiral cut on the work would have been 5 inches.

A general rule for finding the lead of a milling machine may be stated as follows: *To find the lead of a milling machine, place equal gears on stud D, Fig. 1, and on the feed-screw, and multiply the number of revolutions made by the feed-screw in order to produce one revolution of the index head spindle, by the lead of the feed-screw.*

Suppose, for an example, that it is necessary to make 40 revolutions of the feed-screw in order to turn the index head spindle one complete revolution, when gears *B* and *C*, Fig. 1, are equal, and that the lead of the feed-screw of the milling machine is 1/4 inch, then the lead of the machine equals $40 \times 1/4$ inch, or 10 inches.

This rule just given is general, and will apply even if the number of teeth in the indexing worm-wheel were different from that in standard indexing heads, because, in the rule, no consideration is taken of the number of teeth of the worm-wheel directly, but simply the number of turns made by the feed-screw to correspond to one turn of the index spindle itself.

If it is now perfectly clear that the lead of the machine means the distance which the table of the milling machine must move forward in order to turn the work placed on the index head spindle around one complete revolution, it is easy to understand that if we want to get a spiral that is twice as long as the lead of the machine, then we must place gears on the feed-screw and on the stud *D* of such size that

the indexing spindle will only turn half a revolution while the table moves forward a distance equal to the lead of the machine. Suppose, for instance, that we want to cut a spiral, having a lead of 20 inches, that is, making one complete turn in a distance of 20 inches, and that the lead of the milling machine is 10 inches. Then, while the table moves forward 20 inches, we want the indexing spindle to turn once. In order to make the table move forward 20 inches, when the indexing spindle turns around once, the feed-screw evidently must turn twice as many times as it did in the case when the table only moved 10 inches for one turn of the index spindle, in which case we had equal gears on the feed-screw and on stud D; consequently the two studs or shafts, A and D, must be so connected that one will turn twice as fast as the other. The ratio between the speeds then is 2 to 1, which means that the feed-screw, which is required to turn twice while the stud D turns once, must have a gear that has only half the number of teeth of the gear placed on stud D.

If the lead of the machine be 10 inches, and the lead required to be cut on the piece of work is 30 inches, then it would be necessary to have the ratio between the gears 3 to 1, which, of course, is the same as the ratio between the lead of the machine and the lead of the spiral to be cut (30 to 10 equals 3 to 1). We can therefore express the rule for finding the change gears by a simple formula:

$$\frac{\text{lead of spiral to be cut}}{\text{lead of machine}} = \frac{\text{number of teeth in gear on worm stud } (D, \text{ Fig. 1})}{\text{number of teeth in gear on feed-screw}}$$

Expressed as a rule, this formula would read: *To find the change gears to be used in a simple train of gearing, when cutting spirals on a milling machine, place the lead of the spiral in the numerator and the lead of the milling machine in the denominator of a fraction, and multiply the numerator and denominator with the same number, until a new fraction is obtained in which the numerator and denominator give suitable numbers of teeth.*

As an example of the above rules, we will take the case of a milling machine in which we have found that there are 4 threads per inch on the feed-screw, and that 20 revolutions of the feed-screw are necessary to make the index spindle turn one complete revolution when having equal gears on A and B, Fig. 1. On a machine of this kind, assume it is required to cut a spiral the lead of which is 12 inches. The first thing for us to do is to find the lead of the machine. This, as we have already said, is equal to the revolutions of the feed-screw necessary to turn the index spindle one revolution, multiplied by the lead of the feed-screw. As the feed-screw has 4 threads per inch, the lead of the feed-screw is $\frac{1}{4}$ inch, and this, multiplied by 20, gives us $\frac{1}{4} \times 20 = \frac{20}{4} = 5$.

To find our gears we now place the lead of the spiral in the numerator of a fraction and the lead of the machine in the denominator, and multiply both numerator and denominator with the same number until we get a new fraction, in which the numerator and denominator express a suitable number of teeth. Following this rule, we have then:

$$\frac{12}{5} = \frac{12 \times 6}{5 \times 6} = \frac{72}{30}.$$

The gear with 72 teeth is placed on stud D, which, of course, is required to revolve slower than the feed-screw, in order to cut a spiral which is 12 inches, when the spiral cut with equal gears is only 5 inches, or equal to the lead of the machine. The gear, having 30 teeth, is placed on the feed-screw. If it should be necessary to put an intermediate gear between the gear on the feed-screw and the gear on stud D, the number of teeth in this intermediate gear has no influence whatever on the ratio of the speed of feed-screw A and stud D, but serves simply the purpose of transmitting motion from the one gear to the other.

Compound Gearing.

If it is not possible to find a set of two gears that will transmit the motion required, it will be necessary to use compound gearing. In this case the manner of getting the compound gears is exactly the same as that of getting compound gearing for the lathe. We have already explained that the lead of the spiral to be cut is placed in the numerator of the fraction, and the lead of the milling machine in the denominator. We then divide this numerator and denominator into two factors, the same as we did in the case of figuring lathe change gears, and, having divided them into two factors, we multiply each two of these factors by the same number, exactly as before, thus getting the gears we require. As an example, let us suppose that the lead of a certain machine is 10 inches, and that we wish to cut a spiral the lead of which is 60 inches. We then have:

$$\frac{60}{10} = \frac{6 \times 10}{2 \times 5} = \frac{(6 \times 15) \times (10 \times 8)}{(2 \times 15) \times (5 \times 8)} = \frac{90 \times 80}{30 \times 40}$$

The gear having 90 teeth is placed on the stud D, and meshes with the 30-tooth gear F (see Fig 2) on the intermediate stud; on the same intermediate stud is then also placed the gear having 80 teeth, which is driven by the gear having 40 teeth placed on the feed-screw. This makes the gears having 90 and 80 teeth the driven gears, and the gears having 30 and 40 teeth the driving gears, the whole train of gears being driven from the feed-screws of the table.

In general, for compound gearing it may be well to remember the rule given by the formula:

$$\frac{\text{lead of spiral to be cut}}{\text{lead of machine}} = \frac{\text{product of driven gears}}{\text{product of driving gears}}$$

MACHINE SHOP PRACTICE.*

MACHINING A FIXTURE CASTING—2.

This article on machining a milling machine fixture casting is a continuation of the one published in the May issue of MACHINERY. As there stated, this operation was selected as an example of planing, boring, and milling work. The planing operation was discussed, and we shall now deal with boring the bearing and milling the T-slot in the arm. This casting, which is shown on the Shop Operation Sheet Supplement, is the main part of a fixture used for holding lathe chucks while milling the jaw slots. These chucks are mounted on a spindle which is inserted in the bearing of this fixture, and, as this bearing must be in perfect alignment with the table, the boring is done on the milling machine. The casting is shown set up for boring, on operation sheet No. 64 of the Supplement. Before setting the planed surface of the base against the table, care should be taken to see that both table and base are thoroughly clean, as otherwise inaccurate work will be the result. The recognition of the importance of such small matters is very essential in connection with shop work, and, in many instances, such recognition constitutes the real difference between a good and poor workman.

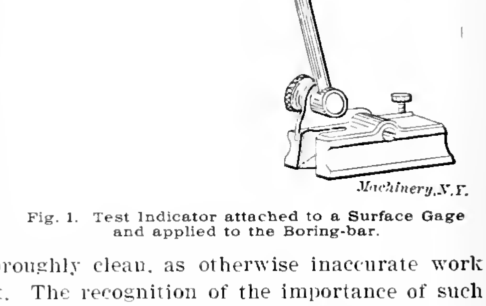

Fig. 1. Test Indicator attached to a Surface Gage and applied to the Boring-bar.

After the boring-bar is inserted in the spindle, a test indicator should be applied to the outer end of the bar as shown in Fig. 1. The indicator A is attached to a surface gage which rests on the table, and the contact point B of the gage is placed against the revolving bar C which, if not in perfect alignment with the spindle, will cause the hand on the gage dial to vibrate, the amount of vibration, of course, depending upon the amount that the arbor is out of true. When adjusting the center of the outboard bearing to the end of the arbor,

* With Shop Operation Sheet Supplement.

care should be taken not to spring the arbor out of alignment with the spindle. The arbor is now set to height by adjusting the knee of the machine vertically, and central with the bosses on the casting by adjusting the table longitudinally. The tool should be set for the first cut so that every part of the hole will be trued up, provided this would not mean too heavy a cut; this is done to prevent the tool from being dulled by the abrasive action of the scale.

After the hole has been bored to size, we come to the final operation of milling the T-slot. The casting should remain in the same position as for boring while the neck of the T-slot is milled with a plain axial cutter, which should remove as much metal as possible in order that the more delicate T-slot cutter shall have a minimum amount of work to perform.

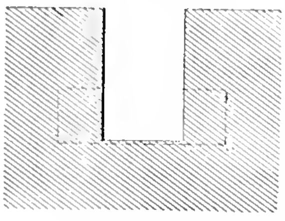

Fig. 2. The First Cut in Forming a T-slot.

A plan view of the work set up on the milling machine table is shown on Shop Operation Sheet No. 65. A right-hand cutter should be used, the direction of rotation being indicated by the arrow. The work will then be fed against the rotation of the cutter, which is preferable, because when the feeding is with the rotation, the cutter is liable to dig into the work, especially if there is any play between the nut and feed-screw. In order to tell whether a cutter is right- or left-handed, notice, when looking at it from that side which is next to the spindle, whether it must revolve to the right or to the left when working; if to the right, it is right-handed, and if to the left, left-handed. After the neck of the T-slot is finished, as shown in Fig. 2, the casting is set up for the final cut as shown on Shop Operation Sheet No. 66. A standard T-slot cutter such as shown in Fig. 3 is used. These cutters have alternate teeth cut on the inner and outer sides, though on some cutters used for this purpose these are omitted, the faces being ground slightly concave. The shank of the cutter should be perfectly clean before it is inserted in the spindle of the machine, and the cutter should be driven tightly in the spindle by tapping it with a soft hammer. All milling cutters which are held by their shanks, and are not supported by the center of the outboard bearing, should be fixed tightly on the spindle as there is a tendency for cutters of this kind to work loose, owing to the vibration due to the cut, which might result in both work and cutter being spoiled. Both cuts for the T-slot might have been taken at this setting of the work by using an end mill for machining the neck of the slot, but in that case a cutter somewhat smaller in diameter than the width of the neck should be used first, as a cutter of this kind, being light, will spring, which would cause the work to be untrue if the neck were finished at one cut. In milling slots of this kind it is preferable, when possible, to

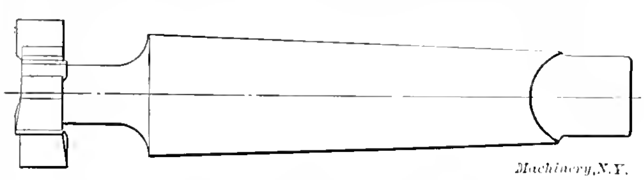

Fig. 3. A Standard T-slot Cutter.

first use an axial cutter because, owing to its greater rigidity, a coarser feed can be used and the work can be finished in less time.

[An axial cutter is one that has teeth on surfaces parallel to the axis, that is, on the cylindrical part. A radial cutter is one that has teeth on the end of a cylindrical body with the cutting edges radial or nearly so. There is confusion as to the meaning of the term "face" cutter. One leading milling cutter manufacturer calls a radial cutter a face cutter, while another manufacturer applies the name face cutter to cylindrical cutters. Our preference is to use the term "face" to designate radial cutters, as it seems to be the generally accepted meaning, and, moreover, is in harmony with the meaning of the word when applied to lathe work. A "faced" surface on a turned piece is always on the end of the cylinder. —EDITOR.]

PACK-HARDENING GAGES.

E. R. MARKHAM *

Pack-hardening, as the term is generally applied, consists in treating steel, generally tool steel, with some carbonaceous material until it will harden in oil. It is well known that steel hardened in oil is less liable to spring than when hardened in water. The tendency to crack is almost entirely done away with, unless the steel is improperly treated in the fire, and it has the maximum of toughness. Now, if we are able to treat the steel so it will be as hard as though dipped in water, and yet have the toughness due to oil hardening, and at the same time reduce the tendency to spring to the minimum, it would seem that we have the ideal method of hardening.

The experience gained during twelve years in charge of large hardening plants, where we not only did our own work, incident to a shop employing several hundred men, but also a large amount of job work from all parts of the country, together with several years spent in introducing the pack-hardening method, leads me to believe that, where it will answer the purpose, it is the ideal method of treating steel. For a number of years I have been giving advice along mechanical engineering lines, and have advised a number of manufacturers to adopt this method of hardening for certain work, and in no instance have I known of its giving anything but satisfaction. It is especially satisfactory when employed in hardening gages of various forms.

The process consists essentially in supplying the surface of the steel with an additional amount of carbon by some material that will not in any way injure the steel. In order to provide the additional carbon, the steel must be packed in

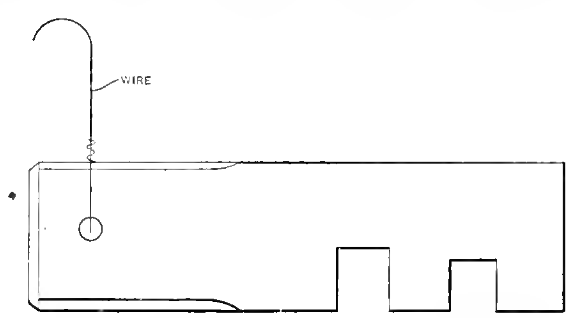

Fig. 1. Piece to be Hardened, and Wire for Handling

iron hardening boxes with the carbonizing material. Some have used charcoal for this purpose. Now, while charcoal is a carbonizing agent, and is used many times in case-hardening machinery steel, and also in the cementation process of converting wrought iron into steel, yet its effect on high-grade steel in the process of carbonizing is not satisfactory, as it renders the steel coarse, and the result similar to blister steel.

No form of bone should be used when pack-hardening tool steel, as bone contains a high percentage of phosphorus, and the effect of this is to make it weak and brittle.

For steel that does not contain more than $1\frac{1}{4}$ per cent carbon (125 points), charred leather gives the best results. Above this percentage I have for years used charred hoofs, or horns, or a mixture of the two. I formerly advocated the use of equal parts of wood charcoal and charred leather, or hoofs, or horns, as the case might be; but now I use no charcoal. The leather, hoofs, or horns, may be used over and over by adding a quantity of new material each time.

The work should be packed in the hardening boxes so no part of any piece of work comes in contact with the iron boxes; in fact, there should be at least $\frac{1}{2}$ inch space between the work and the box. A layer of the carbonizing material should be placed in the bottom of the box, and a layer of work placed on this, taking care that no two pieces touch each other. If we are treating gages, or pieces of steel that are apt to spring unless care is used, we should make sure that they are so placed in the box that there will be as little liability of springing as possible when they are drawn up through the packing material. They must not be packed and

* Address: 66 Dana St., Cambridge, Mass.

dumped into the hardening bath, as is the case when ordinary case-hardening is done.

In order to be able to properly handle the work, each piece should be wired with a piece of *iron* binding wire, as shown in Fig. 1, and the pieces so placed in the box that there will be the least resistance possible when drawing them out. At times they may stand on edge, as shown in Fig. 1. For certain shapes, however, it is advisable to stand them on end.

When several layers of work are packed in a box, the wires should be so arranged around the edge of the box that the various layers may be taken out in order, commencing

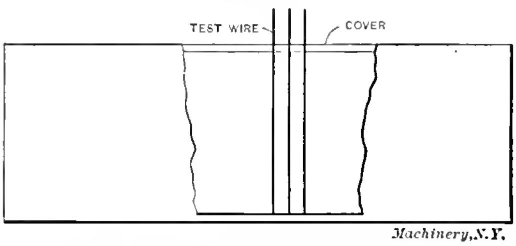

Fig. 2. Hardening Box with Test Wires which enable the Operator to determine when to begin Timing the Heat.

with the top row. This is easily accomplished by marking the sides of the box with chalk, designating the side where the top row of wires is as 1, the one where the second row is, 2, and so on. Unless we adopt some such method, the pieces get all mixed up, and some will be drawn to the surface of the packing material, and will cool before the operator has a chance to dip them.

As in all heat treatment of tool steel, the heats should be as low as is consistent with desired results, and the heats must be uniform throughout the box. It is also necessary that we gage the length of time the steel is exposed to the action of the carbonaceous material. Unsatisfactory results follow any attempt to gage the length of time by the time the boxes are in the furnace. In order that the operator may know when the contents of the box are heated, holes are drilled through the cover of the box at the center, and test wires are run down to the bottom of the box, as shown in Fig. 2. These wires should project about an inch above the top of the cover. The holes in the cover may be of any size to accommodate the wire to be used; however, I generally drill 1/4-inch holes and use 3/16-inch wire. When the box has been in the fire, according to the judgment of the operator, until the contents are heated to a low red, a wire may be drawn, by means of long tongs, and its condition noted; if it is red hot, begin timing the heat; if it is not red, wait a little

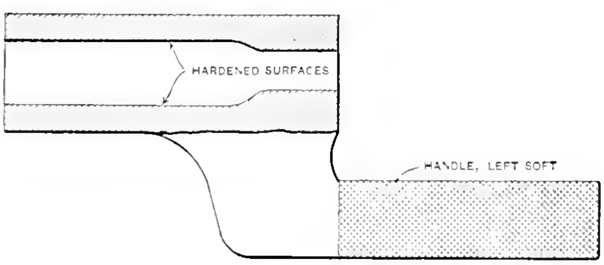

Fig 3. A Gage to be Hardened as indicated.

while, and draw another. Continue so doing until one is drawn that is of the desired temperature. The wires passing down at the center of the box, and between the pieces, will not be red until the pieces are of the same temperature.

The length of time necessary to expose the pieces to the action of the heat depends on how deep we wish to harden the steel. For ordinary snap gages, I have found 1½ hour to 2 hours after the steel is red-hot to work well, but the time must be varied according to the percentage of carbon that the steel contains and its intended use.

Sometimes locating gages are made with the gaging holes made to finish size in the gage. This method is not to be advocated where it is possible to use hardened bushings. In the latter case, the holes in the gage may be made of the proper size for the bushings, and the gage left soft, while the bushings are hardened, ground and lapped, and pressed to place without any tendency to distort the gage. But, when it is necessary to make the gage of one piece, and have the gaging holes to size in the gage without bushings, then the pack-hardening method will be found to work satisfactorily, as the heats may be very low, and the tendency to distortion will be eliminated, provided the processes of annealing and machining have been properly done.

I recall a job of hardening gages that gave a manufacturing concern considerable trouble. The gage was of the form shown in Fig. 3, and it was necessary that the walls of the opening through the gage be hard, yet the opening must retain its shape.

The hole was filled with finely pulverized charred leather; the handle and the portion connecting it with the body were covered with fire clay which was wound with fine iron binding wire to prevent it falling away when baked. The gages were packed in scale collected in the forge shop. This scale came from the outside of pieces of iron and steel as they were being forged. Being free from carbon they absorbed, or took the carbon from the surface of the steel. I should have mentioned that the ends of the opening through the gages were covered with fire clay mixed with water to the consistency of dough, which was allowed to harden before the gages were packed. The fire clay prevented the carbon gas escaping from the leather, as the scale would have taken it up very quickly.

When the gages had been exposed to the carbonizing influence of the leather for one and one-half hour, they were removed from the box in which they were heated, placed in a bath of raw linseed oil, one at a time, and a jet of oil was pumped through the opening after the leather had been removed. The fire clay around the handle and the portion connecting it with the body was left on until the gage was hardened, when it was removed. The walls of the hole were found to be hard, and as the surface of the gage was practically decarbonized, there was little danger of its pulling the piece of steel out of shape. The handle and adjoining portion, being protected by the fire clay, did not harden, or even cool quickly enough to distort, in any way, the gaging portion.

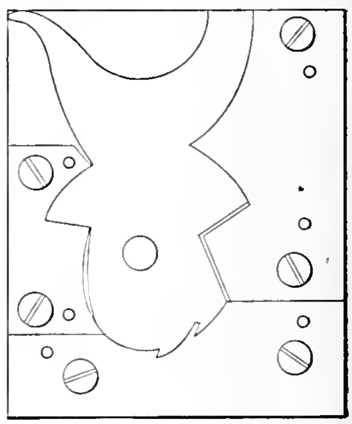

Fig. 4. Receiving Gage which is a Type Advantageously Hardened by the Pack-hardening Process.

I have known a number of instances where pieces which, while not resembling the gage shown in Fig. 3 so far as form is concerned, yet responded nicely to the method of treatment given that gage. Of course, it was necessary to modify the treatment to suit the character of the work. The gage shown in Fig. 3 was made from crucible tool steel. But, considering the small amount of wear to which it was subjected, it could have been made from a low-carbon open-hearth steel, which would have been cheaper, and could have been hardened, in the manner described, as effectively as the tool steel.

Many times receiving gages are made of several pieces which are fastened to a plate as shown in Fig. 4, which is a receiving gage for a gun hammer, and it is necessary that the various portions be gaged accurately, and each portion must bear a certain relation to every other portion.

As shown, the various portions of the gage are made in sections, fitted to place and hardened. Unless these pieces are hardened by some method that eliminates the tendency to spring, they will be of little use after they are hardened. Right here pack-hardening comes in. Pack the pieces in leather in a small iron box, run for one hour after they reach a low red heat, and harden in raw linseed or sperm oil. It will not be found necessary to heat the steel treated in this way as hot as if heated in an open fire and dipped in water. It is not necessary to heat steel in the form of gages quite as hot as if it was made into cutting tools. But, even in the latter case, be sure to keep the heats down, and do not dip in extremely cold oil; in fact, I prefer warm—not hot—oil.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

INGERSOLL COLUMN TYPE COMBINED HORIZONTAL AND VERTICAL SPINDLE MILLING MACHINE.

The column-and-knee type of machine was the first commercial form of miller. It combined the advantages of a reasonable degree of rigidity with great convenience of operation, both as related to holding the work and presenting it to the cutter, and the various adjustments, as well, could be made with the greatest ease. To give greater rigidity to the machine, (though at the cost of quickness in manipulation) there was developed later the Lincoln type of horizontal spindle milling machine—a type which is at the present time extensively used for interchangeable manufacturing and other work in which its advantages are most in demand, and its deficiencies of least moment. Of recent years, the column-and-knee type of machine has been given a rigidity very closely approximating that of the less convenient Lincoln miller, by the use of suitable knee supports, braces, etc.

With the continued use of these machines, it was found that there were many operations which it was inconvenient to perform with the horizontal spindle. For instance, it was soon discovered that the largest quantity of metal could be removed in a given time with the least power, if a cutter of the face mill variety were used in place of the original cylindrical cutter. With comparatively thin work having large areas to be finished with face cutters, a horizontal table and horizontal spindle required that the work be held on a clumsy knee support of some kind. This arrangement was obviously a makeshift, so the vertical attachment to the horizontal miller was designed, and applied to the work of face milling. Though particularly adapted to the use of face and end mills, it soon proved a useful attachment in various ways, being applied to the form and circular milling, and accurate drilling and boring. It was thus possible to finish many parts complete at one setting, that would otherwise have to be reset several times. Owing to the usefulness of the vertical attachment, machine tool builders soon began to build millers in which the frame and driving mechanism were especially designed for the vertical spindle, instead of having it used as an attachment. The vertical spindle milling machine now ranks among the most important of machine tools, and has been extensively applied to the wide range of work to which it is adapted.

There has still been found a field, however, for the horizontal machine with vertical attachment; for one thing, there is the advantage of obtaining a machine capable of performing in a very satisfactory way a wide range of milling at a considerably less capital expenditure than would be required for the two machines otherwise necessary. Besides this it offers the advantage, oftentimes an important one, of being able to finish work complete without removing the part from the machine, since the machine may be changed to use either the horizontal or vertical spindle, as well. For this reason, the horizontal machine with vertical attachment is an exceedingly useful and popular combination. This being the case, it would naturally seem that there might be a field for a milling machine combining the vertical and horizontal spindle mechanisms in permanent form, without the sacrifice of rigidity and consequent producing power which comes from having one of these spindles in the form of an attachment. Such a machine might easily be made, as well, so that on some work both horizontal and vertical spindles could be used simultaneously, thus effecting a material saving in time and cost of work produced. If such a machine is provided with the necessary supports and braces so as to give it a large measure of the ruggedness of the Lincoln type of machine (or its larger counterpart, the planer type miller) the resulting tool should find a wide field waiting for it in the machine-building industry. Such a machine has been designed and is being built by the Ingersoll Milling Machine Co., of Rockford, Ill. It is illustrated in Figs. 1 to 4, shown herewith, and is described in the following paragraphs.

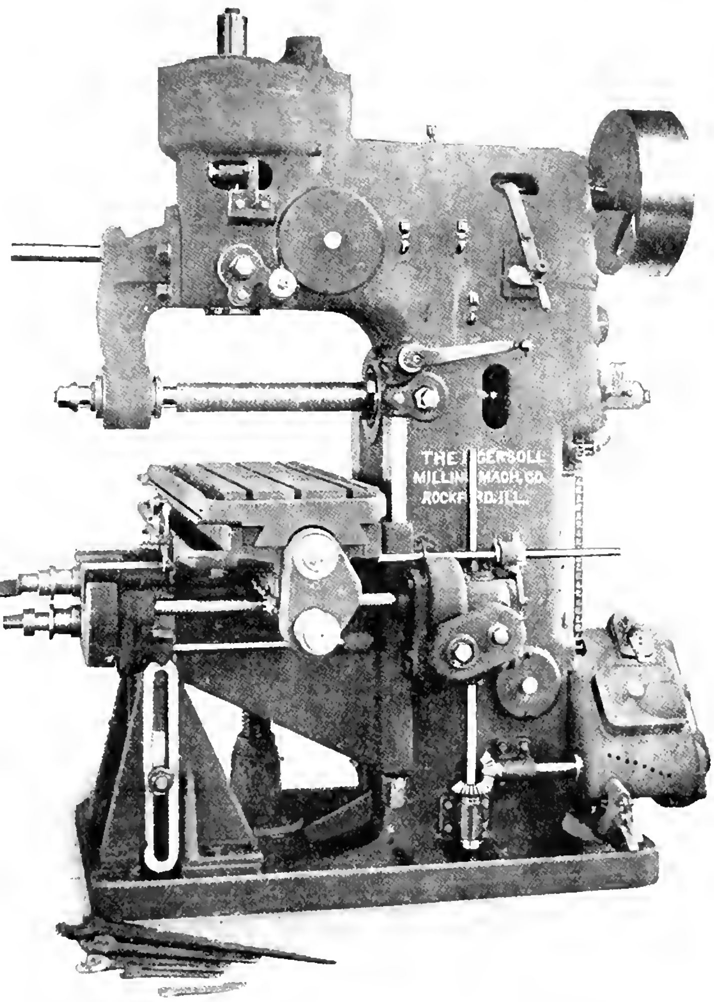

Fig. 1. Ingersoll Combined Vertical and Horizontal Miller.

General Arrangement of the Machine.

As may be seen in Fig. 1, all of the machine below the horizontal spindle is very similar in appearance to the ordinary type of column-and-knee milling machine, though it will be seen that it is unusually rugged for a tool of this kind. Above the spindle, the column of the machine is brought forward to furnish a housing for the vertical spindle, which, owing to the stiff support thus given it, can be carried well out from the face of the column, allowing a considerable range of cross feed. For the same reason, the knee is unusually long, and is therefore well supported at the outer end to give the required stiffness for heavy work and heavy cuts.

In accordance with approved milling machine practice of the present day, the whole machine is driven from a single diameter pulley, and the speed changes are obtained by the operation of positive acting, quick-change mechanisms involving the use of clutches and gearing. As is also required by the best practice, the feeding movement is taken directly from the driving shaft, and the feed changes are made by a positive quick-change gear mechanism. Longitudinal, cross, and vertical power feeds are provided, all of them reversible, and all provided with automatic stops. The out-board support

necessary for the arbor in heavy horizontal milling has not been forgotten, and the usual brace for connecting the knee with this support is furnished, though it is not shown in place in any of the illustrations. The machine will thus be seen to be designed along the lines of the best practice for both the horizontal and vertical types, which it combines within itself.

The Spindle Driving Mechanism.

The mechanism of this milling machine will best be understood by reference to Fig. 2. The power is applied to driving pulley *A*, which is keyed to shaft *B*. This shaft carries sprocket *C* which drives the feed, as will be explained later, and the double pinions shown, which may be shifted to engage either one of the corresponding gears on shaft *D* below them. The shifting of these gears is effected by the handle shown entering the slot in the upper left-hand corner of the column in Fig. 1. Two changes of speed are obtained with this level. Shaft *D* is connected by bevel gearing with the vertical shaft

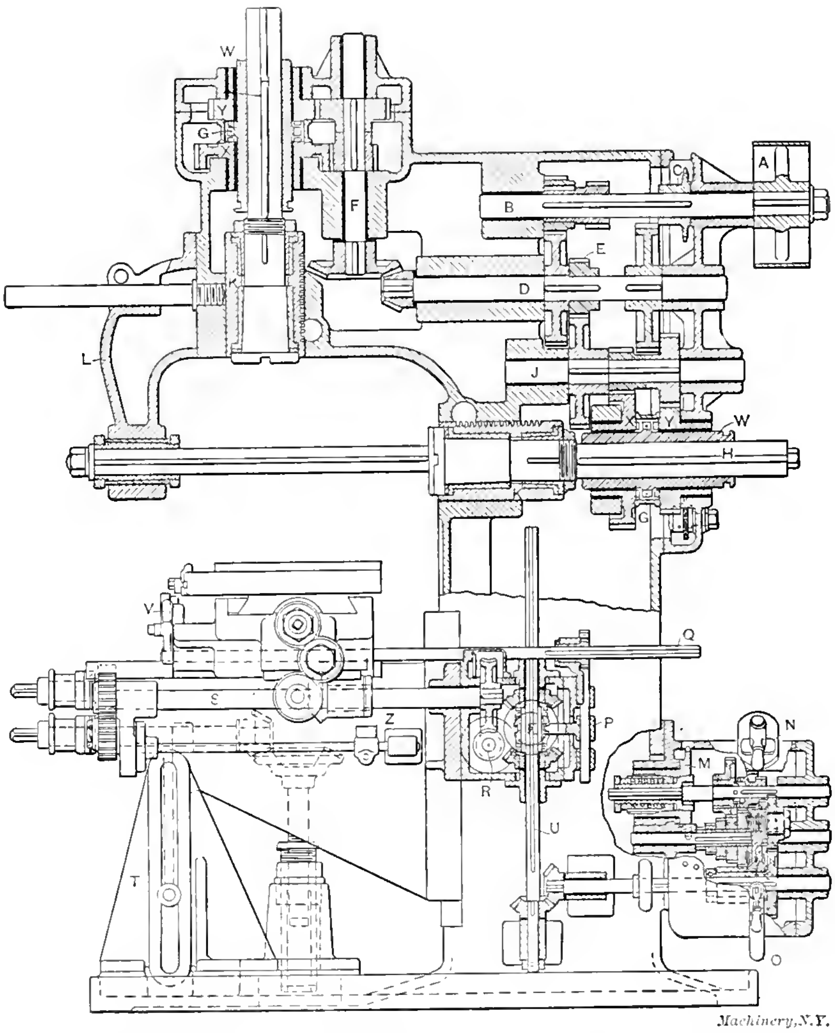

Fig. 2. Vertical Section through the Machine showing Driving and Feed Mechanism.

F, from which motion is transmitted to the vertical spindle. Pinion *E* on shaft *D* meshes with a gear on shaft *J*, from which motion is transmitted to the horizontal spindle. These two spindles are alike in their dimensions and in their driving mechanism, so the same refereuce letters apply to each. Each is supported at the back or upper end in a sleeve *W*, which is keyed to it, and which is provided with clutch teeth *G*. These teeth are adapted to engage corresponding clutch teeth on the hubs of gears *X* and *Y*, which revolve loosely on *W* and in their bearings in the frame. *X* and *Y* are driven by corresponding pinions on shaft *J* for the horizontal spindle, and on shaft *F* for the vertical spindle. It will thus be seen that by the shifting of sleeves *W*, either of two speeds may be given to either of the two spindles or, by putting the teeth *G* in the central position, either spindle may be stopped. Sleeve *W* for each spindle is shifted by the hand levers shown in Fig. 1; one at the back of the column in line with the horizontal spindle, and the other projecting from an opening in the vertical spindle housing. Gear *X* is 13 inches pitch diameter, with four diametral pitch teeth; the smaller one has the same pitch of teeth and is 10¼ inches in diameter. Both have 2½-inch faces, giving a very powerful drive.

Four spindle speeds for each of the vertical and horizontal spindles are thus provided for, with driving pulley *A* running at constant speed. In practice, with belt-driven machines, a two-speed counter-shaft would be used, giving eight speeds in all, ranging from 15 to 100 revolutions per minute. The machine is well adapted for a motor drive, in which case the motor is mounted on top of the column and connected to shaft *B* by means of a silent chain and sprocket wheels. A 10 H. P. motor is used, having a 2 to 1 speed variation, ranging from about 500 to 1,000 revolutions per minute. This would give the same range of spindle speeds as for the belt driven machine, the number of changes being dependent upon the number of steps in the controller.

The front bearing of each spindle is contained in a sleeve *K*, which may be adjusted axially by means of rack teeth cut in it, engaging the teeth of a pinion on a short shaft which projects through the side of the column, and is provided with a squared end for engagement with a hand crank. The axial positions of the two spindles with relation to each other may thus be adjusted to suit the work in hand. This is especially necessary in cases such as shown in Fig. 4, in which both spindles are used simultaneously. The front spindle bearing consists of two tapered journals, one of them being formed on a sleeve adjustable endwise to take up wear. These journals run in phosphor-bronze boxes, supported in the sleeves *K*. The spindles are of hammered crucible steel, 4½ inches diameter in the front bearing. The sleeves or quills *K* are 12 inches long and have 6 inches of adjustment read from graduated scales.

The Feed Mechanism.

As previously mentioned, the feed is driven from sprocket wheel *C* on driving shaft *B*. This is in accordance with approved practice, which makes (so far as possible) the feeds independent of the spindle speed changes. They are nearly independent in this case, being affected only by the 2 to 1 variation of driving pulley *A*, given by the two-speed counter-shaft or by the variable speed motor. The chain from sprocket *C* drives sprocket *M* in the gear box shown at the rear of the base of the machine in Figs. 1 and 2. This gear box contains a quick-change-gear mechanism of the well-known type first introduced in the Hendey-Norton lathe. Eight changes are provided for by the shifting of handle *O*, which controls the sliding tumbler gear, and this number is doubled, giving 16 in all, by handle *N*, which operates a shifting pinion and clutch so as to drive the cone of gears at either of two speeds. The 16 feeds thus given range from 0.48 to 8.9 inches per minute, with the slow speed of counter-shaft or motor; at the fastest speed the feed ranges from 0.97 to 17.8 inches per minute. These rates of feed can be doubled, as described later.

To provide a safety mechanism to prevent damage to the machine in case something should prevent the operation of the feed, and also to permit the feed change mechanism to be operated while the machine is in motion without inducing dangerous shock, sprocket wheel *M* is not directly keyed to the shaft which it drives. Instead of this, its bore is finished with a double taper in which are supported two taper cones, pressed together by the spring shown. One of these cones has a long hub, which is keyed to the shaft. The compression of the spring thus forces the cones together, and furnishes an adjustable frictional driving device between the

sprocket and the shaft, which is sufficient for the heaviest feeds required on the machine, but will yet give way in case of undue strain.

The gear box is connected by a horizontal shaft and bevel gears to the splined vertical shaft *U*. The latter passes through a gear casing attached to the knee, and containing a clutch-and-bevel-gear reversing mechanism of conventional type, operated by clutch fork *P*. The central bevel gear of this mechanism is connected by spur gears with worm *R*, which drives the worm-wheel keyed to horizontal splined shaft *S* from which are derived the various feed movements. The spur gears connecting worm *R* with the bevel gear can be taken off and reversed, being contained in the removable guard shown attached to the front of the casing in Fig. 1. By this means the feeds given in the preceding paragraph can be doubled.

The gearing, shown at the end of the table, connects splined shaft *S* with the table feed-screw for the longitudinal movement. The usual slot is provided at the front edge of the table for the adjustable dog which operates the automatic feed stop. This strikes a tappet connected with lever *V*, which is attached to rock shaft *Q*. The latter extending to the casing containing the reversing mechanism, is splined to a pinion which operates the vertical rack to which the reversing clutch fork *P* is attached. By this means, the dog on the front of the table may be set to automatically stop the feed of the table in either direction. Handle *V* is also conveniently used for reversing the feeds. Connections at the front of the table provide for operating both the cross and vertical feeds by power. The cross feed has the same

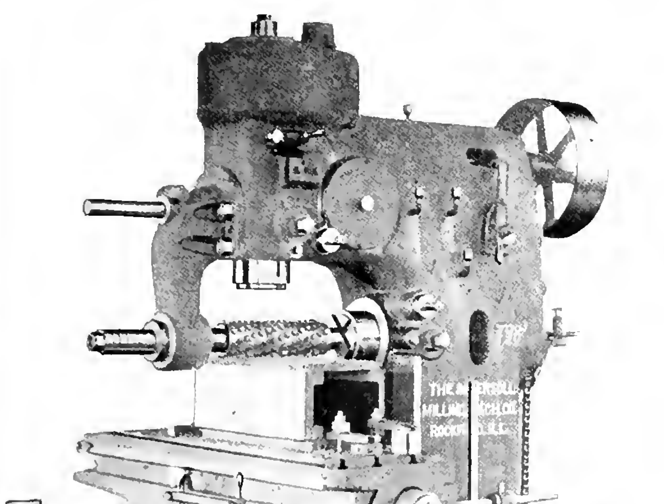

Fig. 3. Using the Machine as a Plain Horizontal Miller.

rate of movement as the longitudinal feed, while the rate of the vertical feed is half that of the other two. Stops are provided for the cross and vertical movements, that for the former being shown at *Z*.

Dimensions and Capacity.

The table is 60 inches long with 48 inches of working length; the full width is 19 inches and the working width 18 inches. It is 5 inches thick, and is provided with three slots cut from the solid, and with drilled holes for stops for the work. The saddle is 60 inches long and 6 inches deep, giving a full support to the table even at the extremes of its travel. The knee is 36 inches long and has a bearing of 28 inches on the column, besides being supported by the heavy outboard support *T*, previously mentioned. The longitudinal feed is 56 inches, the cross feed 16 inches, and the vertical feed 18 inches. As mentioned, the spindles have each a longitudinal adjustment of 6 inches. The maximum distance between the center of the table and the column is 24 inches; the least, 8 inches. The maximum distance from the top of the table to the face of the vertical spindle is 26 inches; the minimum distance with the sleeve extended is 2 inches. The maximum

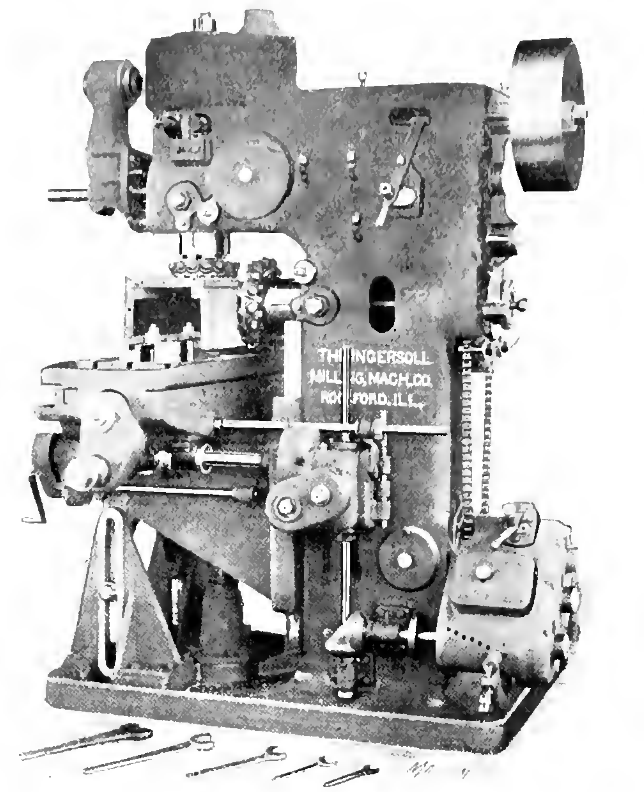

Fig. 4. Using the Horizontal and Verticel Spindles simultaneously in a Face Milling Operation.

distance from the center of the horizontal spindle to the top of the table is 16 inches, and the minimum, zero. A circular table 16 inches in diameter with automatic feed and automatic stop can be furnished if required, at an additional cost. The weight of the machine complete without this table is 9,700 pounds.

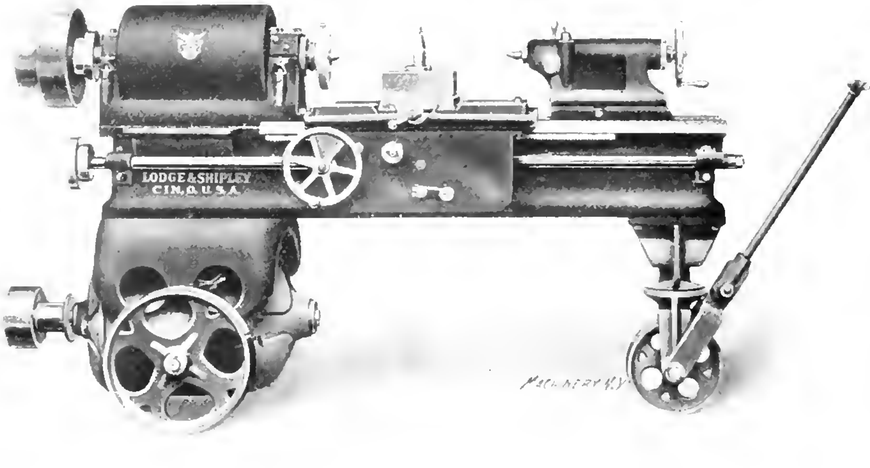
The Operation of the Machine.

In Figs 3 and 4 are two views of the machine in operation. In the first case it is shown with a job of plain slab milling, with the vertical attachment out of commission; as will be seen, the outer end of the cutter arbor is supported by the over-hanging arm (*L* in Fig. 2), so the machine has all the possibilities in the way of accuracy and rate of output found in machines of the strictly horizontal type. In Fig. 4 both spindles are shown in use operating face mills for surfacing the top and side of a hollow rectangular casting. In this case, the outboard support has been loosened and turned up out of the way, being for that purpose swiveled about the stud which carries it. In such cases as this, it will be seen that the output is equal to that of the horizontal and vertical machines combined. As a vertical machine, it should evidently have a greater capacity than the horizontal machine with vertical attachment, and be fully equal to that of the standard vertical machine of the same capacity. The tool has, in fact, been designed by its makers as a general utility machine, able to take the heaviest cuts, either horizontal or vertical, without harmful vibration or other sign of distress.

LODGE & SHIPLEY PORTABLE LATHE.

The lathe shown herewith has been designed by its builder, the Lodge & Shipley Machine Tool Co. of Cincinnati, Ohio, for use in locomotive repair shops for such work as fitting frame bolts, turning up studs, etc., and for doing the various miscel-

laneous fitting work which is met with in assembling heavy machinery. In a word, it will be found convenient for assembling work on any form of machinery so large that it is inconvenient or impossible to move to the lathe the parts into which the work is to be fitted. Bringing the machine to the work, as is made possible by this design, is a much more convenient and economical proceeding.



Portable Lodge & Shipley Lathe for Fitting Work on Heavy Machinery.

As may be seen in the engraving, the lathe is mounted on three wheels so that it is always properly supported, no matter how uneven the floor on which it is placed. The leading truck at the tail-stock end of the bed swivels, and is provided with a handle by which the lathe is drawn from place to place. The "leg" under the head-stock end of the bed is mounted on two wheels, and is arranged to support the motor by which the tool is driven. This motor is of $2\frac{1}{2}$ horse-power and of the constant speed type, fully enclosed. Its armature shaft carries a 2-step cone pulley, belted to a corresponding pulley on the back gear shaft. As the range of work for which the lathe is required is limited, but two speed changes have been provided, resulting in a driving mechanism of great simplicity. The lathe is supplied with a belt feed of two changes, power longitudinal feed, and plain rest. When desired, it can also be supplied with a taper attachment. Nothing which is not required for the simple work it has to perform has been retained in the design of the machine. As constructed, it will do the work for which it is required with great rapidity. If desired by the purchaser, the same tool will be furnished with legs instead of wheels.

THE LE BLOND UNIVERSAL CUTTER AND TOOL GRINDER.

Being convinced, as milling machine manufacturers and users, that sharp cutters are a prime requirement for rapid and economical milling, the R. K. Le Blond Machine Tool Co., 4605 Eastern Ave., Cincinnati, Ohio, has designed and placed on the market a universal cutter and tool grinder. There are a great many machines of this kind made, and perhaps no tool is so far from being standardized in design, each make differing radically in construction from any other with which it may be compared. This new machine likewise differs from others hitherto built, presenting a number of distinctly original ideas in design and construction. These ideas are so strikingly practical and serviceable, however, that the machine is worthy of detailed study. We are permitted to present herewith enough of illustrative and descriptive matter to give a comprehensive idea of the design of the machine.

General Description.

The tool follows in its outlines the general plan of the universal milling machine, with such additional adjustments and movements as are required for the work of a cutter and reamer grinder. As may be seen in Fig. 1, which gives a front view of the machine, the framework consists of a cabinet base, on which is mounted a column surmounted by the grinding spindle head, which is clamped permanently in place. Around this column, marked *A* in Fig. 2, is placed a split sleeve *B*, which may be clamped in any angular position around the vertical axis by handles *C*. The front of this sleeve is provided with ways on which slides the box-shaped knee *D*. A saddle *E*, which may be adjusted towards or away from the column along the top of this knee, is provided with longitudinal ways for the table guide *F*, to which is swiveled, about pivot *G*, the work table *H*. It will be seen that this arrangement differs from that of the universal milling machine only in having the work table swivel on the guide *F*, instead of having the latter swivel on the saddle.

The construction followed is a rigid and durable one, and has been purposely adopted in place of the lighter skeleton design employed in other machines for the same purpose. It will be noted in Figs. 1 and 2 that the sides of the saddle are brought down over its bearing on the knee, and that the ends of table guide *F* project beyond the bearing on the saddle at the extreme limit of the travel in either direction, so that these bearings are well protected from the emery and the grit which always surrounds a machine of this kind. Felt strips are provided for cleaning and oiling the surfaces of the table and saddle bearings as well as the vertical ways on the knee. By this means the continued usefulness of the machine is assured for a long period of years.

The purposes of the various adjustments provided will be better understood when reference is made later on to the different operations for which the tool is adapted.

Details of Construction.

The wheel spindle *J* has taper boxes as shown in Fig. 2, and is driven by a single pulley for a 2-inch belt. The cone on the

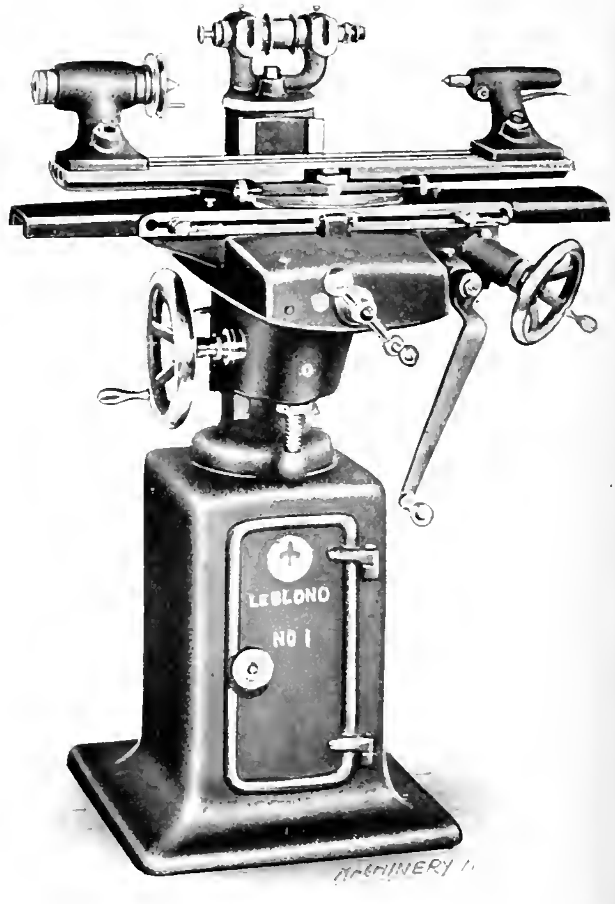


Fig. 1. The Universal Cutter and Tool Grinder built by the R. K. Le Blond Machine Tool Co.

counter-shaft gives three spindle speeds, which should be proportioned to give 3,175, 4,200, and 6,365 R.P.M., respectively. In the engraving, the left-hand end is adapted to the holding of wheels directly on the spindle, between the collars, while a tapered hole for a correspondingly tapered arbor *P*, is pro-

vided at the other end of the spindle. A variety of these arbors may be used with the wheels permanently mounted on them. When this plan is followed the wheels may be removed and replaced without it being necessary to true them up each time. Dust-proof collars are provided, and the oil holes have dust-proof covers, the same protection being afforded all provisions for lubrication throughout the machine.

The head-stock spindle, which is tapering, revolves in a removable sleeve, which can be clamped in the V-block of the universal attachment, described later. The front end is threaded to receive a chuck. The foot-stock has a spring center actuated by a thumb lever. This center can be removed and a special center inserted for grinding reamers. The table is provided with two T-slots, one of them set on an angle, as shown in Fig. 2, for drawing the head- and foot-stock down and forward against the left-hand side of the slot, to insure parallelism; the other at the right provides for the clamping of the various fixtures, vises, etc., that may be used on the machine.

Movements and Adjustments.

The table H, as has been explained, swivels on table guide F about stud G, which is a drive fit in F. The angular movement possible extends through an arc of 90 degrees on either side of the central position, the setting being read from the

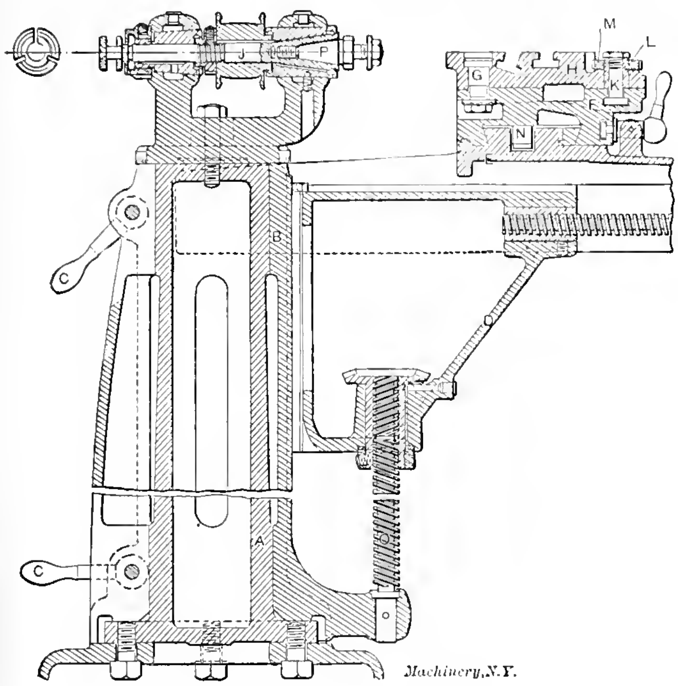

Fig. 2. Vertical Section through the Table, Knee, and Column, showing the General Construction.

graduated surface shown in the engravings. Provision is made for both rapid and fine angular adjustment of the table. The bolt K, by which it is clamped, passes through a threaded sleeve L. If the slotted nut M which is threaded on this sleeve is raised from contact with the boss on the table, the tightening down of the nut on bolt K tightens L down on F, but leaves the table free to be adjusted through the small range permitted by the slot in which L is located. Projecting into this slot are two screws with milled heads, seen in Fig. 1 and other following figures. By adjusting these, the angular position of the table on the table guide may be set very finely to the desired position. When this setting has been obtained, the screwing down of the slotted nut M clamps the table in position.

Table guide F receives its longitudinal movement on the saddle from a shaft carrying a gear meshing with rack N. This shaft passes through the saddle, projecting both at the front and the rear. On either end of it may be mounted a handle for the rapid operation of the table movement. This handle is shown mounted at the front of the machine in Fig. 1 and on the back in Fig. 3. On this same shaft is keyed a spiral gear, meshing with a spiral pinion on the shaft of the hand-wheel seen projecting obliquely downward at the right of the saddle in Fig. 1. By means of this the table may be given a fine angular adjustment. As may be seen at the left of Fig. 5, this hand-wheel and its shaft are mounted in an eccentric sleeve, which may be rotated by the handle shown in back of the hand-wheel, to throw the spiral pinion out of mesh with the gear, leaving the shaft free for the rapid movement by means of the handles described, when this rapid movement is desired. A projecting boss on the top of the saddle is provided with adjusting screws, which act as abutments for adjustable stops in the T-slot in front of the table guide, as shown in Figs. 1 and 2. These stops limit the longitudinal travel of the table.

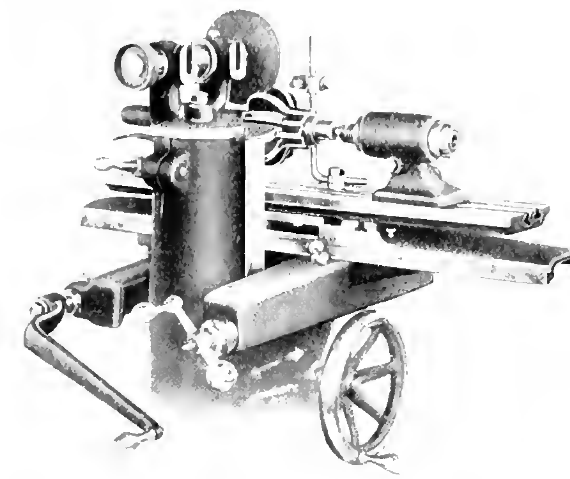

Fig. 3. Grinding a Formed Cutter between Centers

The cross-feed screw is geared with a shaft which passes through to the back of the saddle, so that the movement of the saddle on the knee may be effected through the crank shown at the front of the saddle in Fig. 1, or by that shown at the rear in Figs. 3, 4, 5, etc. This provision for operating either the longitudinal or the cross movements from the rear of the machine is a feature which makes it possible for the operator to work always at the best advantage, so far as the close observation of his work is concerned. It is not necessary for him to take a position which may be convenient for the operation of the hand-wheels, etc., but inconvenient for watching the progress of his work.

The raising and lowering of the knee on the table is effected by screw O, which is connected by bevel gears with the hand-wheel shown at the side of the knee. Graduated dials are provided, reading to thousandths, for the cross and vertical

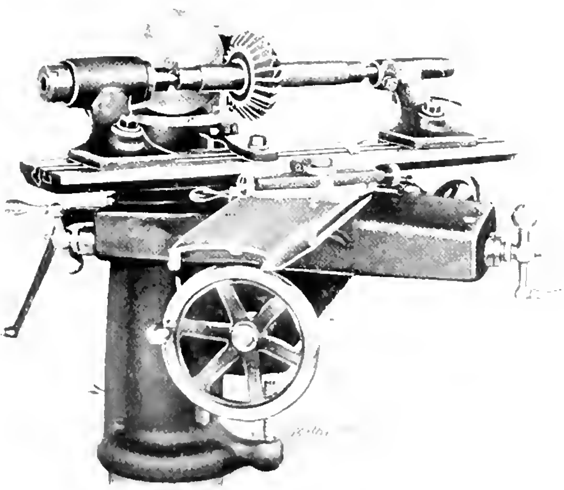

Fig. 4. Table set with Fine Adjustment for Grinding 45-degree Angle Cutters.

movements. All of the various adjustments with the exception of the swiveling and clamping of table H on table guide F, are effected by fixed handles so that the use of a separate wrench is largely avoided. The range of movement provided throughout the machine is such that large saws and face mills can be ground, as well as the smaller work on formed cutters, hobs, reamers, etc.

Grinding Cutters on Centers.

The half-tone reproductions of photographs in Figs. 3 to 8, inclusive, show a sufficient number of the various applica-

tions of the machine to give a good idea of the range of work to which it is adapted. In Fig. 3 it is shown set up for grinding a formed cutter, which is mounted on an arbor between centers, while the radial faces of its teeth are ground. The back of the tooth being ground rests against the stop shown, clamped in the front T-slot of the table. For this work, the operator would stand in the foreground of the picture, with the machine arranged as shown, the operating handle being attached to the back end of the table feed-shaft. The workman can thus easily see the face of the tooth which is being ground—a condition which is not always possible in other machines of this kind.

In Fig. 4 is shown the grinding of an angular mill, also mounted on an arbor between centers, as in the previous case. For this operation, however, the table has to be swiveled on the table guide to the angle of the cutting edge being ground. A disk wheel is used in this case, instead of the dished wheel of Fig. 3, so that the tooth has to be supported from the under side, necessitating the use of a different form of tooth rest. As before, the operator works the table feed from the handle

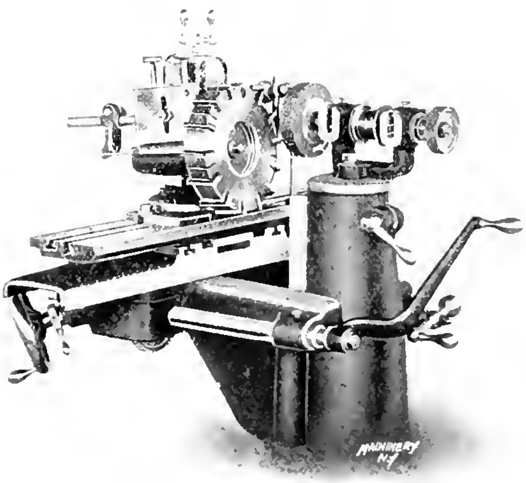

Fig. 5. Grinding Face Mill—Taper Shank held in Universal Attachment.

at the rear of the machine, this being the most convenient position for observing the progress of the work. The table stops are set to limit the movement of the table in one direction, to prevent the wheel from running into the arbor, and in the other direction to allow it to clear the cutter just enough to permit indexing for the next tooth.

The Universal Attachment and its Applications.

In Figs. 5, 6, and 7 is shown the universal head provided with the machine, engaged in holding, for presentation to the grinding wheels, cutting tools of various kinds. Detailed

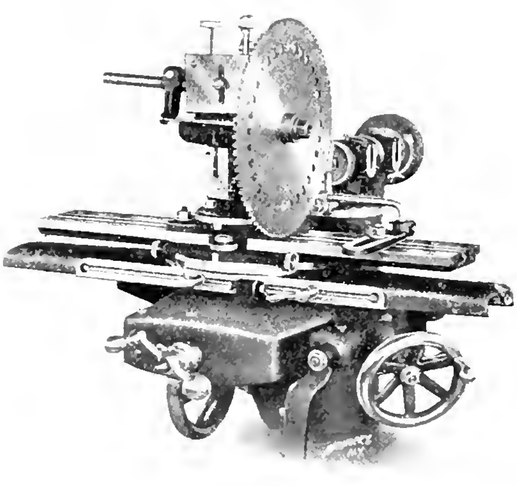

Fig. 6 Grinding a 16-inch Saw held in Universal Attachment

drawings of this head are shown in Fig. 9. It consists of a base Q, to which is clamped the standard R, which may be fastened at any angle about the vertical axis, by means of the bolts shown, the adjustment being read from the graduations on the standard. This column is provided with ways to which is gibbed slide S, which may be adjusted vertically by means of screw T and the attached double crank. Clamped to S, and adjustable on it to any angle about the horizontal axis, is V-block U, the periphery of whose base is also provided

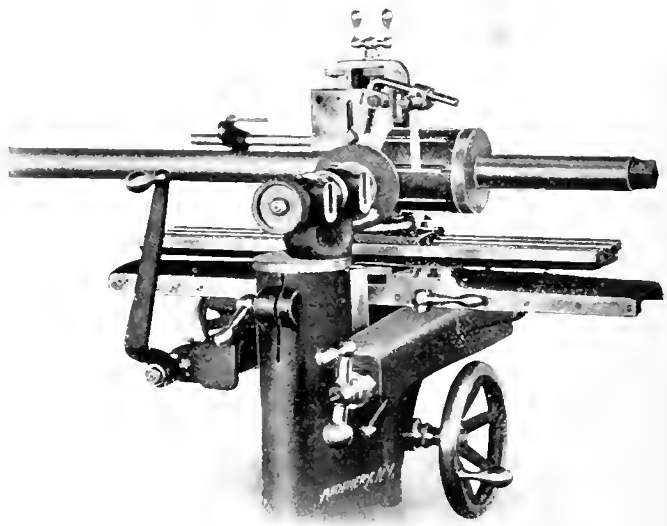

Fig. 7. Sharpening a 5 1-2-inch Shell Reamer without removing it from Arbor.

with graduations by means of which the angular adjustment may be read. Plate X, operated by two adjusting screws W, whose collars enter slots cut in X, is used for holding the work against the V-groove in U. A center stop Y mounted in the holder clamped to adjustable bar Z is used for locating the work as will be described.

The various adjustments provided for this attachment make it of almost universal application. Three of these applications are shown in Figs. 5, 6, and 7. In the first case, we have

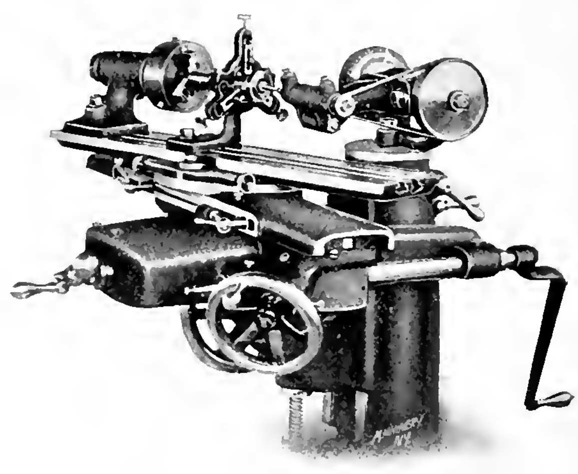

Fig. 8. Grinding a Taper Hole in Spindle, with Internal Attachment.

a face mill being ground on its own taper shank. The shank is inserted in the V-groove of U, and is brought back against the ball point of center Y, which is adjusted for that purpose to the proper position. Then plate X is screwed down to bear lightly on the shank of the cutter by turning handles W, being clamped in this position by the nut and stud provided for that purpose. The tooth rest previously shown is arranged to support the cutter properly for grinding. The whole block U is swiveled on S about a horizontal axis to give the clearance desired. In this case, also, the table is operated with the handle at the back side of the knee.

In Fig. 6 a saw blade of the Higley type is being ground in the taper attachment, which is set in the same way as for the previous case, except that the axis of the taper shank is set in a horizontal position. A cup wheel is being used in this case also. Since it is most convenient to watch this operation from the front of the machine, the table feed handle is placed in front as shown.

In Fig. 7 an inserted tooth reamer is being ground on the long bar on which it is carried, without removing it from the latter. The bar is inserted in the universal head in the

way previously described, and the tooth rest is mounted on the face of the clamping plate of the device as shown. A comparison of Figs. 3, 4, 5, 6, and 7 serves very well to illustrate the adaptability of the form of tooth rest provided.

Cylindrical and Taper Surface Grinding.

Complete provision is made for cylindrical taper and surface grinding in the design of the machine. An example of taper grinding is shown in Fig. 8. The work is secured in a chuck, mounted on the head-stock spindle, while its outer end revolves between the jaws of the back-rest, which is a part

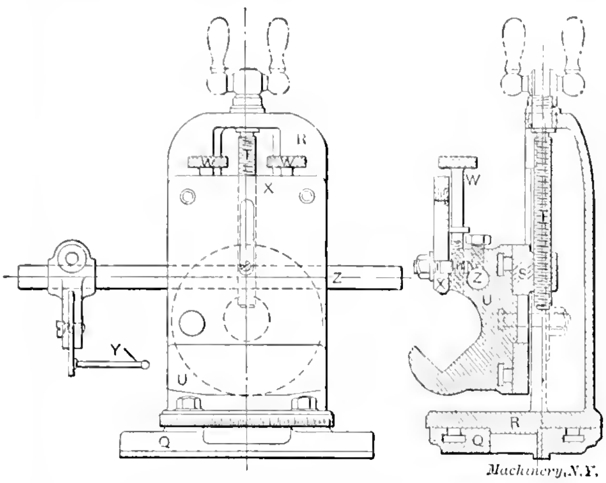

Fig. 9. Details of Construction of Universal Attachment.

of the equipment of the machine. The internal attachment is clamped to the face of the grinding head. It carries a spindle adjustable, as shown, to maintain the tension of the driving belt, which is driven by a pulley mounted on the main spindle in place of the usual grinding wheel. The taper of the table is adjusted on the table guide to the angle required for the taper of the hole being ground. The head-stock spindle is driven by a belt from the drum in the overhead works, which is connected with the main counter-shaft by a 3-cone pulley, giving suitable rates of speed for various diameters of work.

For angular work which may be held in a chuck, the head-stock spindle may be removed from the head-stock and clamped in the universal attachment shown in Figs. 5, 6, 7, and 9. The spindle may then be set to any angle for either external or internal grinding, being driven from the over-head drum as before. For surface grinding, the work may be strapped to the table or a magnetic chuck may be used, or the work, if small, may be held in the adjustable swivel vise which is part of the equipment of the machine.

Gear-cutter Grinding and Other Attachments.

Besides the universal attachment, tooth rests, back rest, internal attachment, and vise, previously described, a number of other conveniences are provided. Among them is a device for grinding, radially, gear-cutters and other narrow formed cutters. This device is shown in Fig. 10. It consists, as may be seen, of a plate bolted to the work table, carrying a swinging gage and two studs, on one of which is mounted the cutter to be ground, while the other carries an adjustable tooth rest. After placing the cutter on the stud (using a reducing bushing if necessary) the swinging gage is brought over until it enters the tooth space, and the tooth rest is brought up until the face of the tooth is forced against this gage. The face of the tooth is then radial, and the slight amount taken off in the sharpening does not perceptibly alter its radial accuracy.

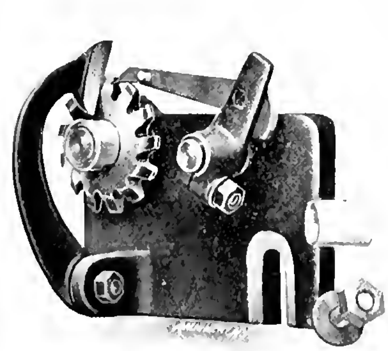

Fig. 10. Device for Grinding Gear-cutters radially.

There are included in the equipment, besides the parts mentioned, dogs for revolving work to be ground on centers, gages for centering the spindle with the work, the requisite wrenches, etc., and a counter-shaft with the necessary tight and loose pulleys, cones, etc., for driving the grinding wheel and work spindles at their proper speeds.

Dimensions and Capacity.

The machine will take 18 inches between the centers, and will swing 8 inches. The working surface of the table is $5\frac{1}{2}$ x 29 inches, and it has a longitudinal movement of 17 inches. The cross movement is $6\frac{1}{4}$ inches, and the vertical adjustment $8\frac{1}{4}$ inches. The machine, as will be appreciated from the previous description, will grind any face of any ordinary shape of cutter, to any angle. It is adapted as well to grinding all kinds of cylindrical and angular work, face mills, end mills, reamers, counterbores, gear-cutters, rose reamers, flat surfaces, punches, dies and other kinds of work. It has been in operation in the shop of the builders for nearly two years, where it has undergone a thorough trying-out on all kinds of operations. During this period, weak points in the design have been eliminated, and many improvements have been made. The builders are now placing it on the market with full confidence in its capacity for doing unusually rapid and accurate work.

FARWELL AUTOMATIC SPUR GEAR HOBBING MACHINE.

The spur gear hobbing process is inherently a very simple operation, as has been brought out in the description of the subject in a previous issue of MACHINERY (see "Gear-Cutting Machinery" in the March, 1908, issue, engineering edition). In most commercial gear-cutting machines of this type, however, the complication required to make them universal in their application has so elaborated the mechanism that the machine is as complex as the orthodox spur gear cutter with its slow feed and quick return, and its automatic indexing mechanism. In Fig. 1 is shown a gear-hobbing machine made by the Adams Co. of Dubuque, Iowa, in which the movements and adjustments have been reduced to a minimum, so that the basic simplicity of the process is fairly shown. The fact that it is not designed for the hobbing of spiral gears, and that it is intended to be fed by hand when hobbing worm wheels, in addition to the particular pains taken to avoid complication, have all resulted in making a strong, simple and inexpensive tool.

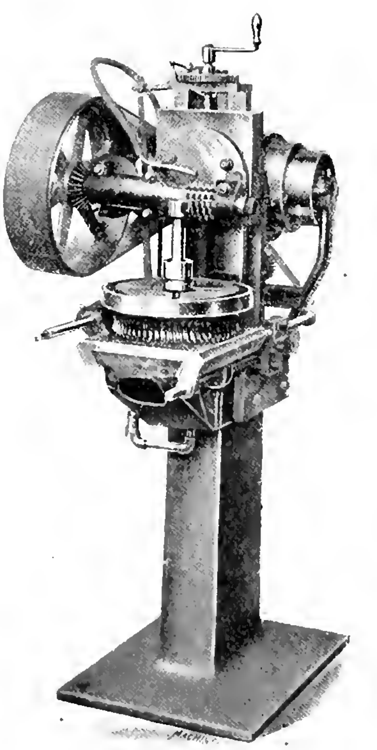

Fig. 1. Simple Spur Gear Hobbing Machine made by the Adams Co., Dubuque, Iowa

A machine of this type must provide means for driving a hob or cutter spindle, which is mounted on a head which may be swiveled to the helix angle of the hob. This hob or cutter must be connected by change gearing with the work spindle or face-plate, so that the two may be rotated together in the ratio of the number of teeth in the gear to the number of threads in the hob. An automatic feed has to be provided for forcing the hob down through the work. These movements are readily followed in Figs. 1, 2 and 3. As will be seen, the frame of the machine is a stout column, provided with a knee along which the work table is adjusted for the diameter of

the blank. The outer face of the column is provided with ways on which the cutter slide is fed. The machine is driven from a cone pulley at the rear, mounted on a counter-shaft supported in a swinging frame; the cutter spindle is driven by a large pulley, belted directly to this counter-shaft. The counter-slide and counter-shaft frame are connected by an adjustable link, so that the proper belt tension is maintained whatever the position of the cutter slide on the column. As before explained, the spindle is mounted on a swiveled head

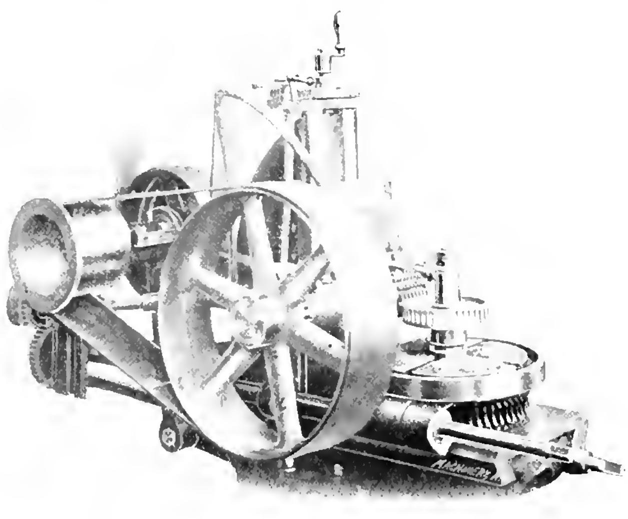

Fig. 2. Side View showing Driving Mechanism and Change Gear Connections.

on the cutter slide, so that it may be adjusted to the helix angle of the hob. The slight angular adjustment required for this is not sufficient to disturb the proper action of the belt which drives the spindle.

The cutter spindle has keyed to it, next to the hub of the driving pulley, a bevel gear meshing with a corresponding gear driving a telescopic shaft which extends toward the rear of the machine. This is best seen in Figs. 2 and 3. At the further end, this telescopic shaft drives one of a pair of change gears, of which the other is connected to the shaft on which is mounted the worm driving the work table worm-wheel. This furnishes the positive connection required between the hob and the work. The change gears are selected to suit the ratio between the number of teeth in the gear and the number of threads (one if single thread, two if double

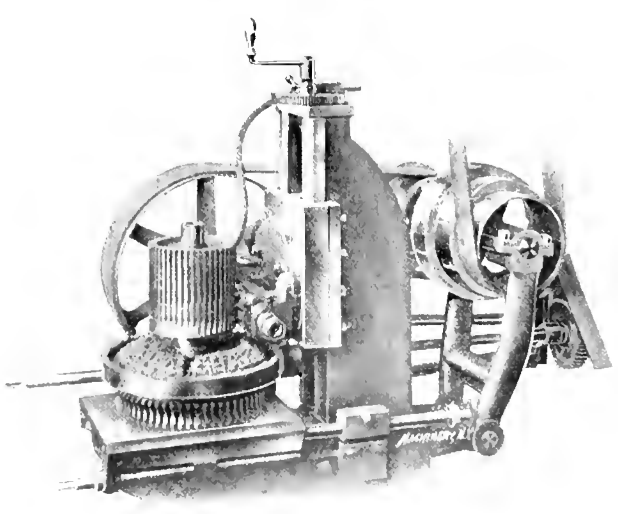

Fig. 3. View from the Right Side showing Stop Screw for Depth of Cut

thread, etc.) in the hob. The table revolves upon a wide angle surface, which gives it great rigidity. This, in connection with the small number of joints, and the large size of the gears and shafts connecting the work table and the spindle, insures a very steady, positive drive for the former. This is essential for accurate work.

The feed of the cutter slide on the head is effected by a ratchet movement, operated from an eccentric on the table worm-shaft. The eccentric rod may be adjusted along the lever operating the pawl, so as to give any rate of feed required. This change can be made without stopping the machine. The ratchet wheel is geared with the screw in such a ratio as to give a very powerful feed. An automatic trip is provided for stopping the feed when the hob has finished its work. Thus no attention is required from the operator other than that of putting in the blanks and taking out the finished gear. One operator may thus run several machines or attend to the gear-cutter while operating other tools.

A rigid stop is provided, as shown in Figs. 1 and 3, against which the table saddle may be run, to give the proper depth of teeth. Instead of setting this stop by micrometer graduations, a hardened steel gage is provided which is of a thickness equal to the depth of tooth required for the desired pitch. To set the stop, the table is advanced until the hob just scratches the outside diameter of the blank. The stop is then screwed up until the gage block is held between it and the saddle, when the gage block is removed and the table advanced to the stop, giving precisely the correct depth, if the blank has been properly sized. A careless operator cannot spoil work, as is often done when the depth is set by micrometer gage.

A small plunger pump is provided which forces a stream of lubricant upon the cutter and work if desired. The knee is hollow, and forms a tank for holding this lubricant, which is conducted thither by holes in the hub of the table. For hobbing worm-wheels the spindle is adjusted to a position central with the blank, the automatic feed being thrown out. The saddle is then fed inward along the knee by hand until the teeth have been cut to the proper depth.

The capacity of the machine is for blanks up to 12 inches in diameter and 6 inches face. The spindle is driven by a pulley 15 inches in diameter, for a 4-inch belt. The cone pulley at the rear provides for three speeds, and is driven by a $2\frac{1}{2}$-inch belt from the overhead counter-shaft. Either a single or two-speed counter-shaft will be provided. The hobs are regularly right-hand, single thread, 3 inches in diameter, and 3 inches long, with $1\frac{1}{4}$-inch arbor hole. Other sizes, of course, may be used. The hob may be moved axially so that the entire length can be used before sharpening is required.

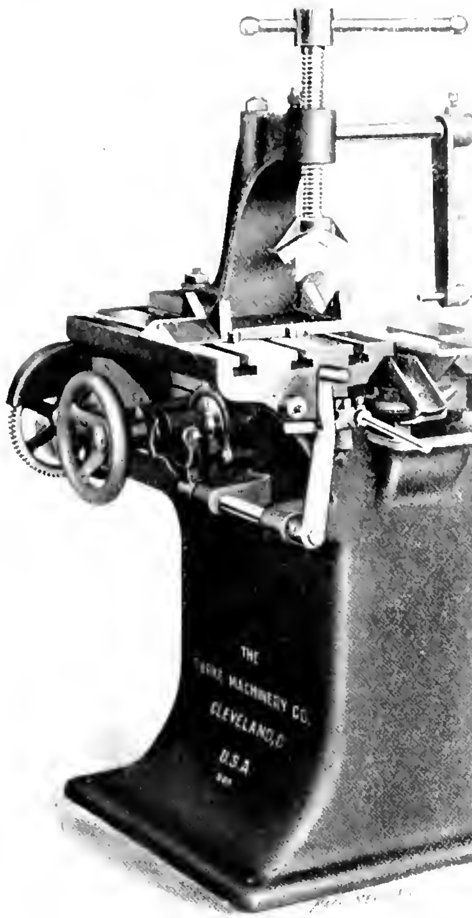
This tool should be an exceedingly useful one for work within its range, which includes automobile gearing and change gearing for machine tools. The manufacturers claim that the output is far ahead of that of any other type of gear-cutter for spur gears, on the sizes to which it is adapted.

BURKE MACHINERY CO.'S CUTTING-OFF SAW.

Few machine tools have been developed so rapidly during the past few years, and in few lines have so many new and radically different designs been brought forth as in the territory of cutting-off machines. In the accompanying half-tone engraving, a new 12-inch cutting-off saw is illustrated, presenting a number of interesting features. The machine consists principally of a main column or frame, provided with ways in which the saw carriage travels. This saw carriage supports the driving worm and worm-wheel and the saw itself, which is bolted directly to the worm-wheel. At the front of the saw carriage is mounted a hardened steel casting which acts, at the same time, as a guide for the saw and as a stripper for carrying away the chips from the saw teeth. The worm shaft is driven by means of a key, mounted in a gear sleeve, placed at the rear end of the frame, this gear sleeve in turn meshing with a pinion on one end of which is mounted the driving pulley. For actuating the feed mechanism, the same pinion engages with a system of gearing driving a worm shaft on the outside of the machine, through which power is transmitted to a worm and worm-wheel, the latter of which has square jaws cast on one side. A sliding clutch engages with these jaws, and a cross-shaft is thereby operated, having at one end a pinion engaging with a rack, which is mounted on the lower side of the saw carriage. This latter travels over an oil-pan, cast in the frame of the machine, which permits one inch of the saw-blade to be at all times immersed in oil.

At the front of the machine is mounted a lever, actuating the outer part of the feed engaging clutch, the clutch being

held out of engagement by a spring. When the saw is running, and this lever is pulled over until the clutch engages, the lever is held by a catch on the front of the machine. Through one end of this catch is passed a short rod, which can be set so that the clutch is automatically tripped at any



Burke Machinery Co.'s New Design of Cutting-off Saw.

desired position, the carriage coming in contact with the end of the rod, thereby throwing out the catch and permitting the lever to return to its original position. Between the driving pinion and the feed worm-wheel shaft is mounted a gear held in position by flanges lined with leather, while a spring mounted on the shaft carrying these flanges gives the necessary compression between the flanges. The compression can be increased or diminished by the tightening or loosening of a nut turned by hand.

The size of machine illustrated will cut circular stock up to 3 inches in diameter, or I-beams up to 5 inches high. The travel being 9 inches, permits flat stock 9 inches wide to be cut off. A guide block is furnished for small round or square stock, as well as suitable clamping device for holding the stock in position. When these devices are not in use, the machine presents a large clamping table with no part of the machine projecting above it, and this permits a great variety of work to be done on the machine. Iron can be cut off at various angles, sprues on castings can be removed, and many other operations performed which cannot be carried out on cutting-off saws of ordinary type. The machine shown in the half-tone is provided with a single pulley drive, but for machines which are to be used for cutting-off tool steel, machine steel, cast iron, and brass, where a large range of cutting speeds would be desirable, a cone pulley may be placed on the driving shaft instead of the standard tight and loose pulley, and a suitable counter-shaft is furnished.

Owing to the construction of the drive, back lash and torsional strain are eliminated, which is so common in arbor-driven saws, constructed with a worm-wheel on one end of the saw arbor and the saw on the other, with the bearings in the center. The makers have found from their own experience that, on account of this fact, the machine can very successfully be used in sawing tubing, by using a fine-tooth saw and clamping the friction clutch tightly. In order to prevent the chips from the saw from getting into the worm-wheel, a gear case covers this entirely.

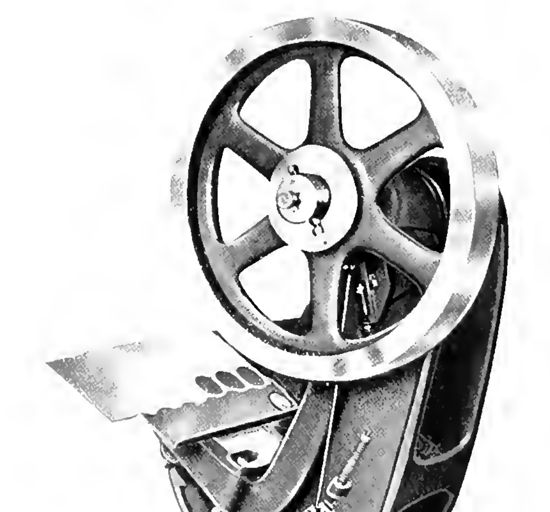
A 20-inch saw is also being prepared for the market by the makers, the Burke Machinery Co., 1837 Thirty-fifth St., Cleveland, O. This saw will have a capacity for cutting off $5\frac{1}{2}$-inch diameter round stock and 12-inch I-beams.

BLISS PRESS FITTED WITH STAGGER FEED.

A considerable saving of stock can be effected in blanking round shapes, by cutting them from a sheet of stock in rows "staggered" with each other, instead of cutting them in series from the strip as is usually done. Various plans have been tried for guiding sheet stock in the blanking press, so that the alternate rows of holes will be staggered with each other, but most of these have been complicated in design and unsatisfactory in operation. The E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., has recently designed and patented an arrangement of great simplicity for effecting this. It is shown in the accompanying engraving, applied to a press of the single pitman, inclinable type.

The sheet from which the blanks are to be cut is placed on the table and fed against a stop finger, which, together with the back gage, locates the work for the first cut. The press being operated continuously, after the first blank is separated, the stock is again shifted against the stop finger and the ram comes down again; pressure is applied to the sheet continuously to bring it against the finger gage, and the operation is continuous. As the sheet progresses, the scrap is sheared off by means of a knife which cuts a true and straight edge for gaging on the second run.

The sheet having been passed through once to punch out the first row of blanks, a treadle is pressed which brings a



Bliss Press fitted with a Special Feed which staggers Alternate Rows of Blanks, and thus saves Stock

second stop finger into play, set at a distance of about half the diameter of the blank from the first stop finger. By this means the cut on the second row is started in a position between the two first cuts in the previous row. In the second stroke of the plunger, this stagger feed finger is automatically released and the operation continues, as before, to be gov-

erned by the back stop and regular stop finger. On every alternate row the operator throws this secondary finger into engagement.

As an illustration of the saving it is possible to effect, the case may be taken of a sheet of tin 20 x 28 inches from which it is desired to cut blanks 2¾ inches in diameter. By the ordinary method of slitting the tin into strips and running them through the press, 70 blanks could be obtained from the sheet. By the method of feeding provided in this machine, 76 blanks may be cut from the same sheet. Another case to which the machine has been applied is in the manufacture of bottle caps, for which a 1½-inch blank is necessary. With the usual arrangement, 234 blanks could be obtained from a sheet of tin; with the method used in the press shown, the same sheet yields 270 blanks. This shows very plainly the advantages to be obtained from the use of the device.

The mechanism is designed for continuous and rapid operation, and the gage system is so accurate that decorated stock can be successfully handled. Another feature of the device is the fact that the knives for separating the scrap remove it entirely from the blanks, and cut it into small pieces, thus greatly facilitating the work of disposing of it.

STEAM TURBINE DRIVEN OIL EXTRACTOR FOR CHIPS.

Figs. 1 and 2 illustrate a simple but ingenious machine made by the Oil & Waste Saving Machine Co., 1307 Real Estate Trust Bldg., Philadelphia, for extracting oil from chips, turnings, etc. The important feature of this construction is the fact that the spindle is driven by a direct connected steam turbine of the impulse type. The exhaust steam from this is led through the chips from which it liberates the oil so thoroughly that the centrifugal force effects a nearly perfect extraction, thus leaving the contents of the basket in a dry condition.

The machine is well arranged for rapid and convenient operation. The machine is shown in Fig. 1 at work extracting the oil, and in Fig. 2, with the basket of chips lifted from the body. The removable basket in which the chips are placed rests on the turbine disk or rotor, and is held in

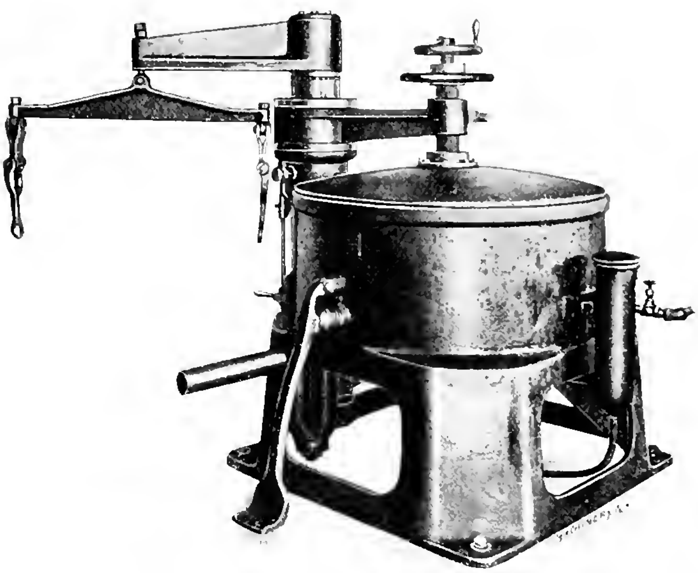


Fig. 1. Centrifugal Oil Extractor for Chips, driven by a Steam Turbine, and using the Exhaust for Freeing the Oil.

place by an inner cover clamped by the smaller of the two hand-wheels shown attached to the radial arm projecting over the machine from the column at the rear of Fig. 1. The lower hand-wheel is used for raising and lowering the outer cover of the casing. These two covers, when raised, may be swung back out of the way on the arm which carries them.

For raising the chip basket from the machine, a steam hoist is used. This consists of a plunger fitted into the cylindrical body of the column at the rear of the machine and provided with a swinging crane arm and sling for grasping the basket as shown in Fig. 2. Steam is admitted beneath the ram by a hand operated valve. The hoist is automatically held at the upper extreme of its travel by a catch, so that it is not necessary to keep the steam pressure on constantly. When so held, the basket may be swung out to one side and the dry chips dumped into any convenient receptacle. To replace the basket after filling it (either from a chute or by shoveling) the hoist arm is swung back into position, and the catch pulled out, allowing the plunger and basket to descend. The latter is so arranged that it seats itself in position on the rotor. The arms carrying the basket and the cover are ar-

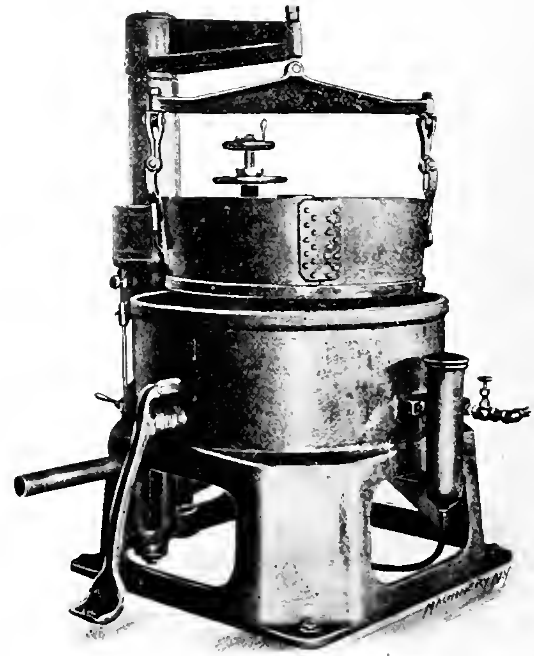

Fig. 2. Using the Steam Hoist to lift the Basket from the Separator.

ranged with ball and roller bearings so that the entire operation of loading and unloading, exclusive of filling the basket, lasts but two or three minutes. The extraction of the oil is thoroughly accomplished in six or eight minutes. The oil is discharged from the pipe seen projecting from the left side of the base. The reservoir at the right side is for supplying lubricant to the step bearing.

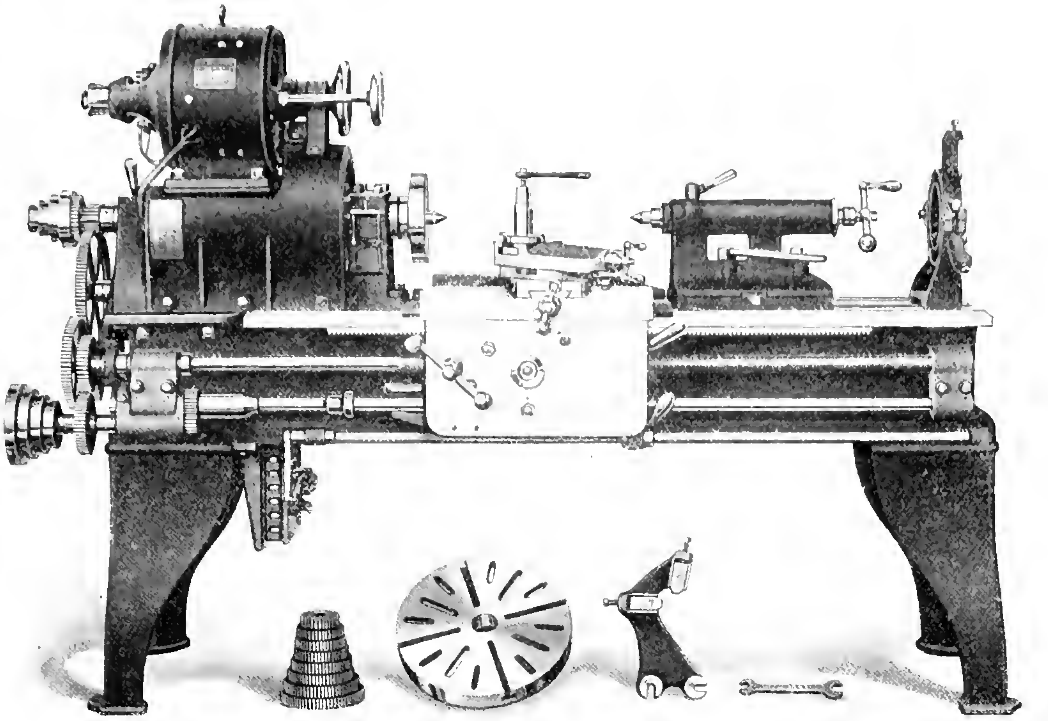
The machine has a basket capacity of 3½ cubic feet, or very nearly three bushels. It is now in operation in a number of plants throughout the country, and has proved to be very satisfactory. It is a development of the makers' waste reclaiming machine, which separates the oil by the combined action of steam and centrifugal force obtained from a steam turbine in the same way as here described. The absence of troublesome quarter-turn belting and high-speed counter-shafts is a very favorable point in the design.

RAHN-CARPENTER 16-INCH MOTOR-DRIVEN LATHE.

The Rahn-Carpenter Co., Cincinnati, Ohio, is applying to its line of engine lathes the style of motor drive shown in the engraving. The use of a variable speed motor and the convenient location of the controlling mechanism make the arrangement a most satisfactory one.

The motor used is the Lincoln variable speed machine which we have previously illustrated. (See "New Machinery and Tools in the March, 1906, issue of MACHINERY.) In this motor no electrical controller is required. The turning of the small hand-wheel projecting from the front of the motor frame moves the cone-shaped armature longitudinally. When it is by this means withdrawn from the taper pole-pieces, the air gap and consequently the magnetic reluctance is increased, decreasing the magnetic flux and increasing the number of revolutions per minute. A speed ratio of 8 to 1 is given by this means, with infinite gradations, the number of changes not being limited by the number of contacts on a controller. This ratio of 8 to 1, combined with the back gear ratio, covers the entire range required on a lathe of this size.

Since no controller is required, a simple starting box only is used, placed beneath the head-stock end of the bed. This is operated by a splined shaft running lengthwise of the bed, connected with a handle at the left of the apron, convenient to the operator at all times. The motor is reversed by the double throw switch shown on the front bearing of the head-



The Rahn-Carpenter 16-inch Lathe as arranged to be driven by a Lincoln Motor.

stock. When set for any given speed the motor maintains that speed almost constantly under varying loads, the drop in speed from full load to no load comparing favorably with the best constant speed motor practice. The special commutator poles provided prevent sparking at all speeds, even with as high as 50 per cent overload.

It will be seen that the motor is mounted low down on the head-stock, close to the spindle, so that the top-heavy construction often found in electrically-driven lathes is avoided. This tends to steadiness of running and consequent accuracy of work. The armature and the spindle are connected positively by gearing. The head-stock is well ribbed and firmly bolted to the bed. The spindle is of high-carbon steel, ground, running in adjustable boxes of the best gun metal.

The lathe, in general, fills the requirements for modern practice with high speed steel. It is rigid and simple in construction, accurate and easy to operate. The carriage is gibbed to the bed both front and back, with a broad bearing for the rest. The apron is of simple design, with all feeds convenient to the hands of the operator. The rack and all the gears are made of steel, and the stud pivots are hardened and ground. The change gearing connects the lathe spindle and the lead-screw directly, and is very simply set for any thread within the range of the machine, it being necessary to change only the gear on the lead-screw.

AUTOMATIC SLOT MILLING ATTACHMENT TO GARVIN MILLING MACHINE.

In the accompanying half-tone and line engravings we show an attachment recently devised by the Garvin Machine Co., Spring and Varick Sts., New York, for automatically operating the milling machine for performing such work as milling drift slots in taper sockets, cutting slots in tool-posts, milling keyways with end mills, and other similar operations in which a groove or slot is cut by feeding successively deeper and deeper with an end milling cutter. The function of the attachment is to feed the carriage back and forth within limits determined by the required length of slot, at the same time feeding the saddle in toward the column by a small amount at each reversal. An automatic stop is also provided for arresting the cross feed movement when the proper depth of slot or keyway has been reached.

The device is operated by the regular telescopic feed shaft of the machine. The mechanism for controlling the automatic movements is attached to the side of the regular feed box as shown in Fig. 1. The mechanism will best be understood from the line drawings, Figs. 2 and 3. Shaft *A* runs constantly in one direction, driven by the telescopic feed shaft. It is connected with worm *B*, driving the feed worm-wheel *C*, by tumbler gears *D* and *E*—a part of the regular mechanism of the machine. Shaft *A* is also geared with and drives sleeve *L*, from which, as will be explained, the controlling movements of the attachment are operated.

Stops *G* and *G'* are adjusted in the T-slots under the front edge of the table to agree with the range of movement required for the length of slot or keyway which is to be cut. These stops act on plungers *H* and *H'*, whose lower ends in turn rest upon and actuate a cross arm attached to lever *K*, pinned to rock shaft *J*. This rock shaft carries at its inner end a fork *Q* whose arms encircle the hub of clutch member *O*, keyed to shaft *F*. Springs *M* force this sleeve forward against clutch body *N*, keyed to sleeve *L*, which latter is driven constantly (as before explained) from shaft *A*.

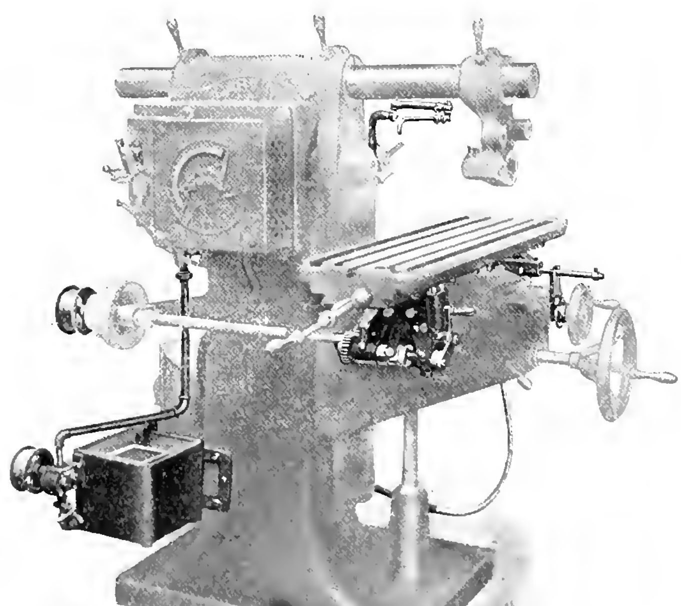


Fig. 1. Automatic Slot Milling Attachment applied to Garvin Plain Milling Machine.

With the table traveling in the direction of the arrow in Fig. 3, stop *G* presses down the top of plunger *H*, rocking shaft *J* so that the right-hand arm of the fork is raised while the left one is brought inward toward the hub of member *O*. By the action of a cam surface on *O*, the latter is by this action released, and allowed to be forced inward by springs *M*, until

the multiple disk friction clutch contained in N engages revolving sleeve L to shaft F. When a half revolution of F has taken place, the cam surface on O engages the pin in that arm of the fork which is now depressed and runs up on it, thus releasing the friction and arresting the rotation. At the outer end of F is a crank disk with a crank-pin P connected by the link, as shown, (see also Fig. 1) with a mechanism for operating the tumbler gears by which the feed is reversed.

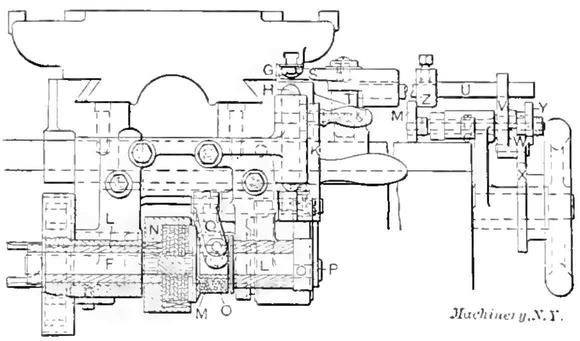

Fig 2. Section through Reversing Mechanism attached to Feed-box of Milling Machine.

From this it will be seen then that when G strikes H, the half revolution thus given to F by the shifting of fork Q throws the tumbler gears over and reverses the direction of rotation of B, and consequently the direction of the feed. The table now moves in the opposite direction from that indicated by the arrow, until stop G' engages stop H', which rocks arm Q in the other direction, allowing another half revolution of F, again throwing the tumbler gears, by means of crank-pin P and the attached link, backward. The reversal of the table feed is thus seen to be automatic and continuous.

The cross movement, feeding the end mill at each reversal of the table movement, is effected by stops R and R' located in the same T-slot which carries G and G'. These dogs alternately strike lever S, which is pivoted in a vertical axis about stud T. Rod U, which is an extension of lever S, is thus vibrated back and forth as the table is reversed. Rod U engages a slot in lever V, to which (above and below its pivot) are attached pawls W and W', engaging ratchet wheel X keyed to the cross feed shaft. Paul W, it will be seen, acts on the right-hand reversal, while pawl W' acts on the other. A cam Y may be thrown to raise both pawls out of engagement with X to stop the feed. The rate of inward feed is adjusted by setting stops R and R' to give greater or less swinging movement to U.

As was stated previously, however, an automatic feed stop is provided which arrests the feeding of the saddle on the knee when the proper depth of cut has been reached. This is accomplished by setting dog Z at the proper position on rod

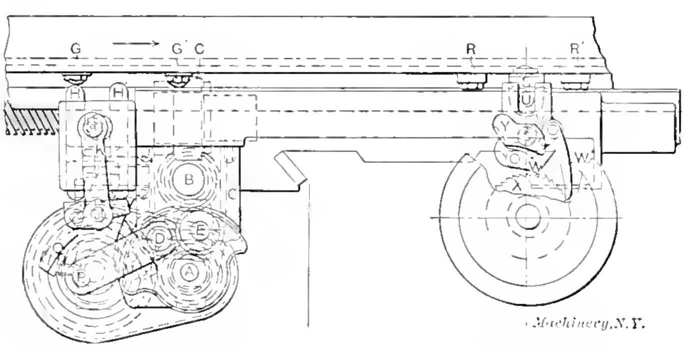

Fig 3 Front View of Reversing and Cross-feeding Mechanisms.

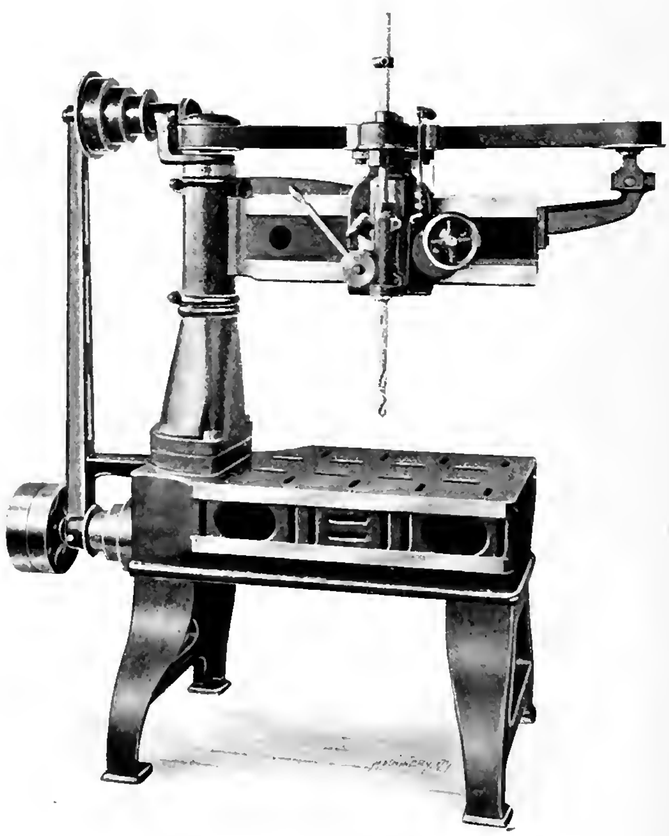
U, so that when the desired inward movement of the saddle has been effected, Z will strike tappet M as the lever U is thrown over at the reversal, thereby drawing inward, strongly, cam Y, which is attached to the same pivot as M. This pressure on Y prevents pawls W and W' from falling back into the ratchet on the backward stroke, thereby stopping the feed.

An especially notable feature of this device is the fact that it effects complicated automatic movements in a plain machine of standard type. The attachment is comparatively simple and need not be removed from the machine when the latter is being used on regular work. It is simply necessary to uncouple the rocker actuated by plungers H and H' from lever K, this being done by a small screw at the front of the machine. The feed is reversed by hand by a small handle seen at the front of the speed box. Pump and piping, as shown, are essential for washing the chips out of the slot being milled. These will be provided when ordered. The attachment can be applied to the Nos. 12, 13, 13½ and 14 milling machines, and the No. 2 universal machine made by the builders.

NEW SENSITIVE RADIAL DRILLING MACHINE.

The machine here illustrated forms the first of a range of sizes designed more especially for dealing with bulky and awkward castings, etc. The box-section table, the working surface of which is 3 feet 6 inches by 2 feet, enables angle plates to be dispensed with, and, of course, permits long work to be operated on at the ends. The arm, which is well ribbed, swings on the column, and can be locked in any position. The spindle, which is of tool steel, is 1 inch in diameter, and is



Radial Drill Press of English Design.

belt-driven as shown, a tightening device being provided for the belt. The spindle revolves in a long sleeve which has an adjustable cap. The thrust is taken on ball bearings. The driving pulley of the spindle revolves in a long bearing, relieving the spindle of strain, irrespective of the tightening of belt. The head is moved along the arm by rack and pinion operated by the hand-wheel shown. The pulleys are turned all over to insure correct balance, and have a long bearing on their studs. The usual adjustable collar is provided on the spindle for repetition work. The machine being self-contained, as regards the counter-shaft, can be driven direct from the line shaft, the steps of the three-speed cone pulley taking a 2-inch belt. The fast and loose pulleys are 10 inches diameter by 2½ inches wide. The vertical movement of the spindle is 5 inches and that of the sliding head 8 inches. The spindle is bored to take No. 2 Morse taper. The distance from the arm to the table is 18 inches; the maximum distance from center of spindle to center of column is 2 feet 6 inches. The counter-shaft is speeded from 280 to 340 revolutions per minute, and the floor space taken up by the base is 4 feet 4 inches by 2 feet 6 inches. The machine weighs about 1,200 pounds, and is built by A. Haworth & Co., Luton, England. J. V.

SELLERS HIGH-POWER DRIVING-WHEEL LATHE.

There is no better example of the great efficiency that can be obtained from machine tools specialized for definite operations, than the modern driving-wheel lathe as developed for the work of the railroad shops. These have been continually increased in rigidity and driving power, taking advantage of the new-found possibilities in high-speed steel, until at the present time the matter of handling the work, clamping it in place, changing and adjusting the tools, etc., has become of greater importance than the time spent in the actual turning operations. This being the case, the recent developments in this line of machinery have been particularly directed toward the matter of securing greater convenience and rapidity of operation, and, at the same time, all the advantages of high cutting power are retained. A recent and most interesting example of this development, the driving wheel lathe built by Wm. Sellers & Co., Inc., of Philadelphia, Pa., is herewith illustrated and described.

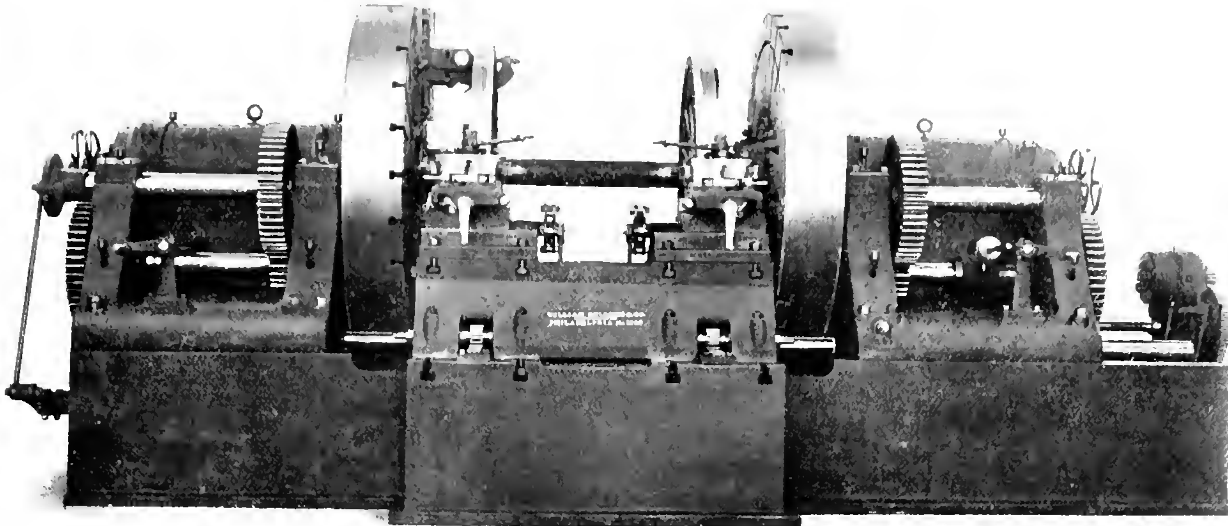


Fig. 1. The Sellers High-power Driving-wheel Lathe.

Head-stock Driving and Adjusting Mechanisms.

As may be seen in Fig. 1, the lathe consists of a bed on which are mounted two head-stocks carrying heavy spindles and face-plates, and a tool bench carrying two tool slides, one for each wheel. The machine is electrically driven, the main motor being partially seen at the rear in the end view of the machine in Fig. 3. Power is transmitted to the right-hand head of Fig. 1 by the heavy splined shaft shown running lengthwise of the bed beneath the face-plate. The end view of the machine in Fig. 3 best shows the driving connection. This splined shaft is provided with a pinion meshing with a gear on an intermediate shaft, which in turn meshes with a gear on the driving pinion shafts. The driving pinion engages internal gear teeth in the rim of the face-plate. The connections for the movable head are similar, except, of course, that the first pinion of the train is splined onto the driving shaft and moves with it as the head-stock is adjusted.

The pinions for driving the face-plates are located in nearly the same horizontal plane as the tools, and on the same side of the center. The cutting strain is thus transmitted directly through the face-plate and drivers without imposing any pressure on the spindle bearings. The spindle caps are made in one continuous piece for each head, producing a nearly solid support for the hardened steel step which is placed at the end of the spindle for taking the thrust. Secured to the face-plates are flanged bearings through which the sliding center spindles pass, which support these spindles and reduce their overhang when extended into the work. These bearings are supplied with split taper bushings for taking up the wear and maintaining an easy fit without allowing lost motion and consequent chatter. When desired, these bushings may be closed tightly on the spindle, thus forming an additional clamp.

The motor provided for driving the lathe is of ample size and has a speed range of 2 to 1, which, together with the mechanical change provided, controlled by the handle seen at the front of the left-hand end of the head stock in Fig. 1, gives spindle speeds of from $\frac{3}{4}$ to $1\frac{1}{2}$ turns per minute, with numerous intermediate steps.

The small motor shown at the extreme right-hand end of the bed in Fig. 1 operates a screw by means of which the left-hand head-stock is shifted outward for removing the work, or inward for placing the work on the centers. It does not drive the screw positively but through the medium of a friction clutch, which will slip if the mechanism meets with undue resistance, such as would be the case, for instance, if it were attempted to throw in the traversing movement before the head-stock clamping bolts had been loosened.

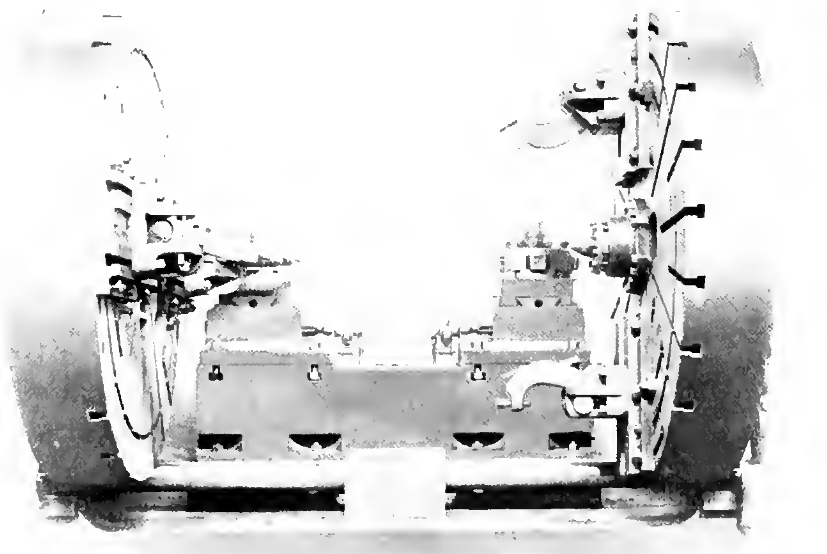

Fig. 2. View of the Double Face-plates showing the Floating Drivers.

The Wheel Clamps or Driver.

A most important feature of the machine is the means provided for driving the work. With the tremendously heavy

cuts taken, the rim of the wheel must be so held that there is no possibility of slippage. The drivers used are best seen in Fig. 2. There are two on each face-plate, located at right angles to each other, as required for the "quartering" of the driving wheels. The drivers consist of slides bolted to the face-plate, carrying holders in which are supported drivers of the C-clamp order. These are so mounted that they float in the holders, being pivoted horizontally (in the position shown

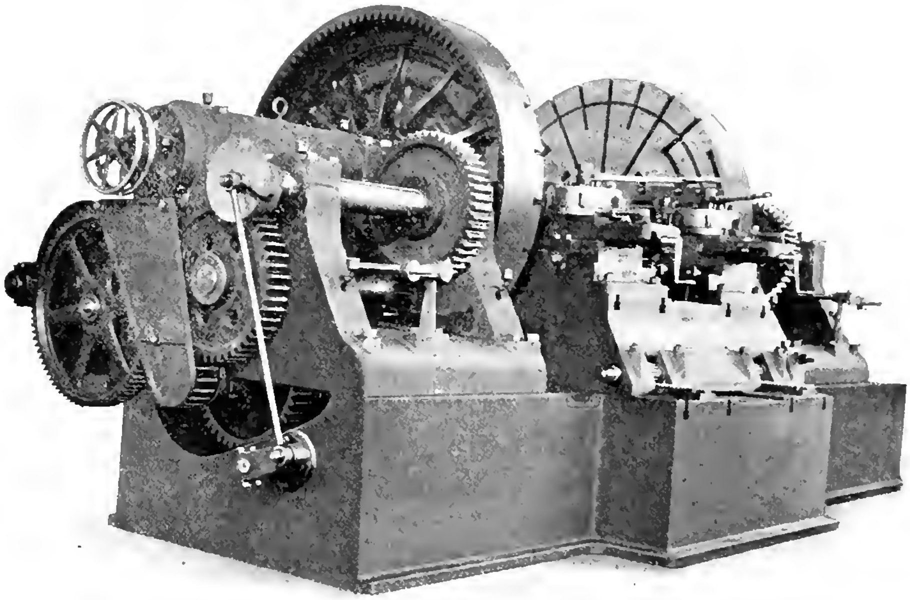

Fig. 3. End View, showing Driving Gearing and Feed Motion.

at the left of Fig. 2) in a block which itself is pivoted about a vertical axis in the holder. The pivot which provides for this latter movement has considerable play in the holder, so that the clamp can adjust itself within limits to the position of the rim of the wheel.

In Fig. 2 the drivers are shown in three positions. The upper one to the right is held by a spring latch in position for inserting and removing the wheel. The one beneath it is unlatched and in position for clamping. When the face-plate is revolved, the drivers will automatically open and latch. The driver on the left shows the gripping jaw in the floating block to which the clamp is pivoted. After the clamps have been swung in under the rim and tightened down, any tendency of the work to slip at once cants the C-clamps about their radial pivots, thus more tightly gripping them on the work. By this means assurance is given that the driving power is always sufficient for the work in hand, and this is done without side strain on the wheel rims. A further ad-

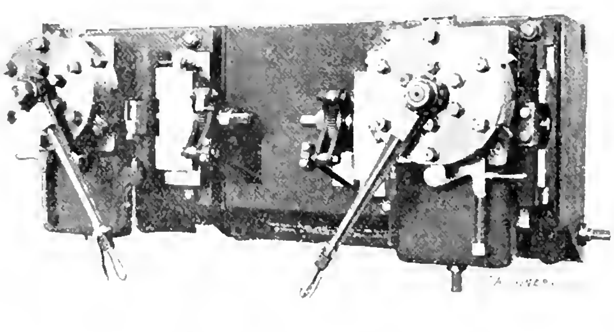

Fig. 4 Top View of Tool Bench, showing the Two Tool Turrets and the Slides on which they are mounted.

vantage is that the drivers are self-contained, without loose parts to be removed or replaced in changing wheels. They are clamped by one set-screw by an ordinary short wrench, the clamping action previously described being depended upon to give the necessary power for driving. It will be seen that these drivers can be manipulated with great rapidity.

As may be seen in Fig. 2, the slides on which the drivers are mounted may be adjusted through a limited distance for angular position about the axis of the spindle. This makes provision for wheels having both odd and even numbers of spokes. Graduations are provided for this angular setting, as well as for the radial position of the drivers on the slides, so that the operator can set the machine for the number of spokes in the wheels and the inside diameter of the rim before the work is placed between the centers. To change from the setting from that for wheels of right-hand lead to that for left-hand lead, the driving pinion for the head at the left of Fig. 1 may be thrown out of engagement with the gear it meshes with, by means of the handle shown at the front, operating the rack and pinion withdrawing movement. This disconnects the face-plate from the driving shaft, so that the other one may be revolved for 180 degrees, after which the connection is again thrown in.

Provisions for Holding and Feeding the Tools.

The bench (see Fig. 4) on which the tool slides are mounted is supported on a forward extension of the bed. It is adjusted in and out on this extension for the diameter of the work by means of a rack and pinion movement, operated by a ratchet wrench, as plainly shown in Fig. 1. The slide rests mounted on the bench are heavy and capable of taking heavy cuts. The bases of these rests are arranged to swivel on the bench to accommodate different angles of wheel tread. The slides are each provided with a ratchet feed motion, connected by a ball jointed rod with a rock shaft in the bed of the lathe. This rock shaft is operated by a slotted crank on the right-hand driving pinion shaft, as is best seen in Fig. 3. The adjustment of the crank-pin toward or away from the center of the crank determines the rate of feed.

Each slide rest carries a cross slide on which is mounted a tool-carrying turret. The mounting of the tools for this machine in a turret is an important improvement, securing great rapidity of operation. These turrets (as is best seen in the top view of the tool bench in Fig. 4) are located in position by manually operated locking bolts held in place by coiled springs. The handle for locking and unlocking the right-hand turret will be seen just at the right of, and below it. The long levers pivoted above the turrets serve the double purpose of clamping and unclamping them, and of indexing them to new position. When the spring plunger is thrown into engagement with the slotted disk at the hub of the lever, the indexing movement can be operated. When the plunger is free from this disk, the movement of the lever clamps or unclamps the turret. The turrets are of steel. A micrometer screw and stop conveniently placed at the side of the cross slide enables the wheel to be rough turned to the desired diameter without calipering. The stop can be swung aside when finishing. The front of the openings in the turrets for the forming tools are made with a slight taper to fit which a corresponding taper is provided in the tool sockets. The latter are thus accurately centered and securely held against side motion. This construction also permits a reduction in

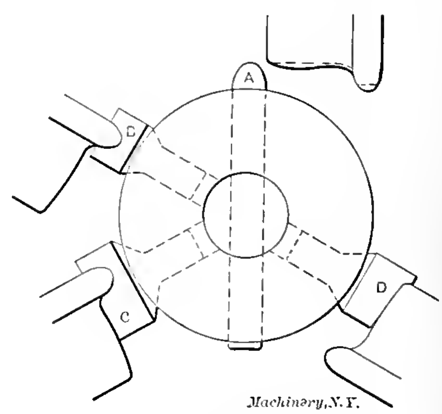

Fig. 5. Usual Arrangement of Tools for Truing up a Worn Driving Wheel.

the size of the tool body without decreasing the broad bearing surface which supports the tool near the cutting edge.

The Order of Operation.

The usual arrangement of tools is somewhat different from that shown in Fig. 4, being indicated in Fig. 5. The first tool *A* is a roughing cutter which may conveniently be made with a long shank extending clear through the turret, a hole being provided for this purpose in the central stem. The forming tools are not subject to so great wear, and may be conveniently made with shorter shanks. After the tread has been rough turned with *A*, the turret is indexed and the tool *B* is used for sizing the flange. Tool *C* is next brought into position for finish forming the flange, and a portion of the tread. Tool *D* forms the other half of the tread and rounds the corner.

The operation of a machine of this kind certainly presents a powerful contrast with that of a wheel lathe of ten or twenty years ago, whose operation was one of the "soft snaps" of the railroad repair shop.

NUTTALL FLEXIBLE INSULATED COUPLING.

The illustrations show an improved flexible insulated coupling manufactured by the R. D. Nuttall Co., Pittsburg, Pa. The coupling consists of two interlocking spiders of cast iron construction which are insulated by means of solid rubber cylinders. The only other parts are two steel rings used to hold the rubber cylinders in position. The rubber members provide ample insulation and at the same time give the desired flexibility. It is furnished in sizes from 5 H.P. up.

Fig. 1. Nuttall Flexible Insulated Coupling.

This flexible coupling is especially desirable where electric motors are direct connected to machinery which is subject to vibration, as, for example, a tube mill or a coal pulverizer in a cement plant, where the coupling relieves the motor from

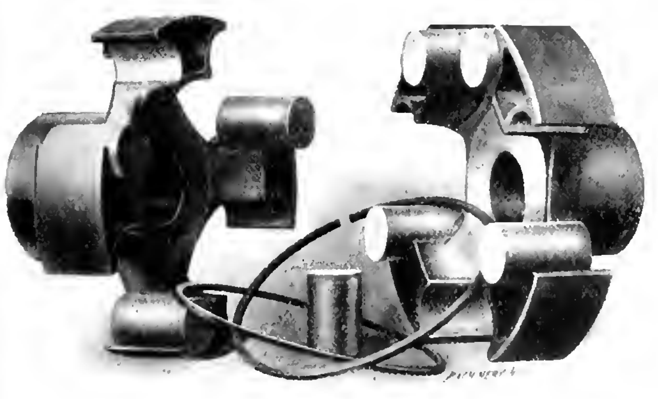

Fig. 2. Parts of Nuttall Flexible Insulated Coupling

the shocks and jars of the machine. In addition, the end thrust of the crusher is overcome and the motor bearings run without heating.

YALE & TOWNE ELECTRIC TRIPLEX HOIST.

As is well-known, the Yale & Towne Mfg. Co., 9 Murray St., New York, has been for many years building a triplex hand-operated hoist, which has found extensive use for all purposes for which a hand hoist can be used. This company also manufactures a well-known electric hoist, which has found much favor for heavier service, particularly for eye-beam trolley systems and for use with traveling cranes. The builders of these hoists have recently placed on the market a new one which occupies a field mid way between the other two, being a hoist of practically the same construction as their hand-operated triplex type, but driven electrically.

The front and end views of this machine are shown in Figs. 1 and 2. The arrangement consists essentially, in the case of the 1-ton electric triplex hoist shown, of one of the builders' regular 2-ton triplex hand-operated blocks, provided with a motor and a controller, the motor being mounted on one side of the block and the controller on the other, as seen best in Fig. 2. The pinion shaft of the hoist is connected by chain and sprockets directly with the armature shaft of the motor. This latter is of the series wound crane type, ruggedly constructed, and designed to take care of the varying loads and varying speeds met with in hoisting work.

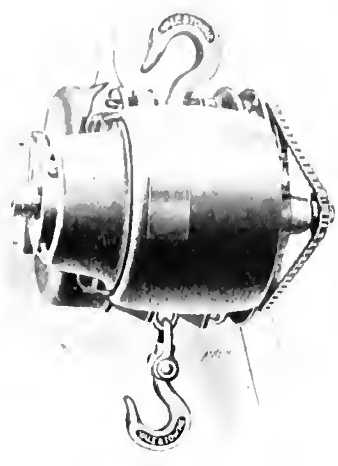

Fig. 1. Side View of the Yale & Towne Electric Triplex Hoist.

The chain drive is very efficient, and in combination with the high workmanship and good material used in the gearing of the hoist proper, insures a very low current consumption. The load is positively sustained at all times by means of a Weston brake. The gearing is shown in Fig. 3 where it is

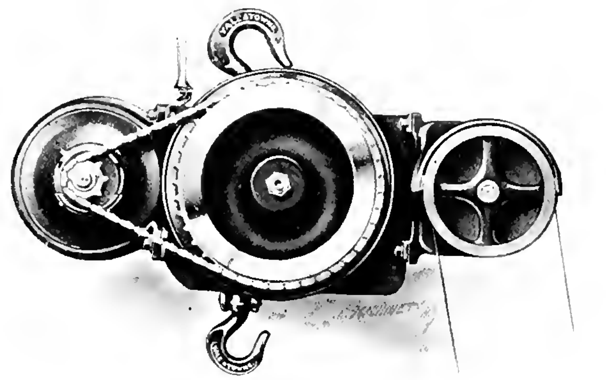

Fig. 2. End View showing Auxiliary Hand Chain Drum.

compared with that used in the hand-operated 1-ton triplex chain block, both of these being intended for the same loads. The parts have been made much heavier for the electrically operated machine, to provide for the wear and tear resulting from the more rapid and severe operation it is subject to.

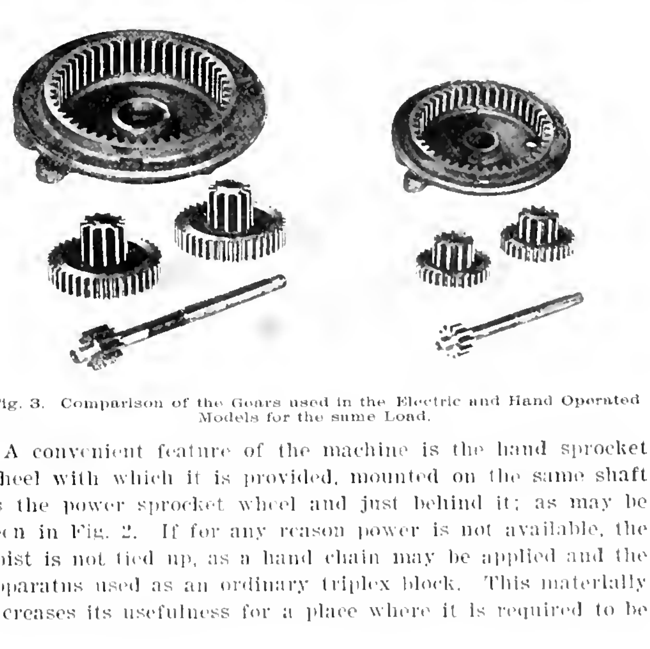

Fig. 3. Comparison of the Gears used in the Electric and Hand Operated Models for the same Load.

A convenient feature of the machine is the hand sprocket wheel with which it is provided, mounted on the same shaft as the power sprocket wheel and just behind it; as may be seen in Fig. 2. If for any reason power is not available, the hoist is not tied up, as a hand chain may be applied and the apparatus used as an ordinary triplex block. This materially increases its usefulness for a place where it is required to be

used occasionally at night, or at any time of the day when power is shut off. It is provided with a safety automatic stop to prevent over-travel of the hoist hook.

This hoist, it will be seen, is adapted to solving the problem of short frequent lifts. For handling 50 pounds or a ton it is five to ten times as fast as a hand chain block, and will do the work of several ordinary laborers. It is especially economical for serving machine tools, running on trolley track, and handling finished parts in the assembling shop. It may be attached to a small traveling crane, swinging jib crane or trolley track, or it may be lashed to shear poles or any other temporary rig. Its installation is very simple, involving simply hooking the hoist in place and attaching two wires for the current. The controller is operated by means of two pendant cords.

While designed primarily for motor service and short lifts, a recent test with this machine was undertaken in which a load of one ton was lifted 10 feet high and lowered the same distance, thirty times in two hours without injury to the machine. This, however, is heavier service than it should be required to undergo. The service for which it would naturally be used consists in lifting loads ranging from 50 pounds to a ton, to a height simply to clear the floor, or at most for a lift of 3 or 4 feet onto some machine. When operated thus, the hoist is suited for reasonably continuous service.

Although, as stated, this hoist has only recently been placed on the market, the design has been developed for some time, and a number of them have been in use in various places under severe conditions, so that it is known that the device is a thoroughly practical one in all respects.

STURTEVANT VERTICAL COMPOUND ENGINE GENERATOR SETS.

The B. F. Sturtevant Co., Hyde Park, Mass., has recently completed the design of a line of vertical compound engines direct connected to generators for small electric lighting and power plants. Success in service of this kind depends quite as much on low cost of up-keep, and freedom from continual attention, as it does upon economy measured in pounds of steam per horse-power per hour, though this latter point is an essential one in all except units of the very smallest size. To fill these conditions this line of engines has been designed, special attention being given to simplicity, reliability, durability and continued economy throughout a long life.

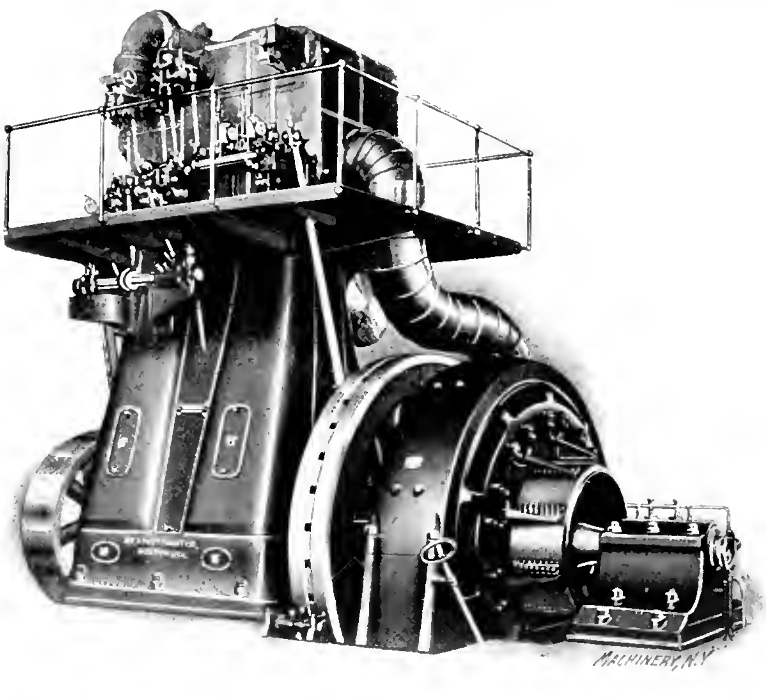

Fig. 1. Sturtevant Engine Generator Set, adapted for the Factory Power Plant.

The item of economy requires that the engine shall be made compound, since steam can be used more economically with a comparatively simple valve gear in two cylinders than can be done in any possible single cylinder design of engine, even though every refinement known to the engine builder is used. The steam distribution is effected by six valves of the gridiron type for each cylinder—two exhaust valves, two steam valves and two cut-off valves riding on the steam valves. Exhaust valves and main slide valves are driven by eccentrics fast to the main shaft, while the cut-off valves are operated by an eccentric controlled by the governor, which is a modification of the well-known Rites inertia type, placed in a

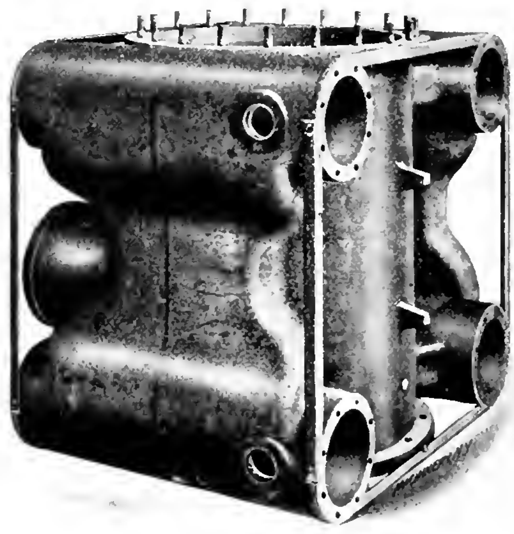

Fig. 2. Method of attaching the Lagging to the Cylinder Casting.

separate fly-wheel. This governor is sensitive enough to regulate the speed so that the variation between no load and full load is less than 2 per cent—sufficiently close for electric lighting. This form of valve gear tends toward high economy, and it permits the cut-off to be adjusted without in any way altering the other functions of the steam distribution, giving the same results as are obtained with the Corliss valve gear. The valves are placed in the cylinders, so that the heads can be removed without disconnecting the valve-gear.

The reciprocating parts are enclosed by a cast iron frame, but are rendered accessible by the removal of oil-tight cover plates or doors. A water shed partition is provided at the top of the frame which prevents the water from the stuffing box from becoming mixed with the lubricating oil in the base. The entire engine is equipped with a system of forced lubrication which positively and automatically supplies oil to all bearings, under a pressure of from 10 to 20 pounds per square inch. A small, independent pump forces oil through the crankshaft web and crank-pin to the connecting-rod, and through the connecting-rod to the cross-head pin. This continuous supply of lubrication reduces friction to a minimum, and makes it unnecessary to make adjustments in the wearing surface except at long intervals.

A neat detail of the design of these engines is the method of supporting the lagging, shown in Fig. 2. As will be seen, the cylinder casting itself is of simple form, both high- and low-pressure cylinders being exactly alike except as to diameter. Angle irons are beveled off to fit the cylindrical surfaces of the valve chambers on each side, as shown, and these furnish the framework to which the lagging is easily attached. The cylinder thus does not have to be complicated to furnish supports for the lagging, though the latter is properly held and applied in a very neat and simple fashion. Provision is made for using indicators without disturbing the lagging or opening the doors of the oil-tight casing.

These engines are made in sizes ranging from 225 indicated horse-power and 150 kilowatt capacity, to 750 horse-power and

500 kilowatt capacity, running from 200 to 160 revolutions per minute. The generators are of the 10-pole type manufactured by the builders, directly connected to the engine shafts by a flanged coupling. They are capable of carrying an over-load of 50 per cent for 2 hours without serious sparking. The insulation will not deteriorate after continuous operation at normal temperature.

The design of these engines is the result of filling the requirements of the builders for their own factory power plant. They proved so satisfactory for the use to which they were applied, that they are now furnished as a regular product of the company, and are recommended as specially adapted to medium-sized factory and power plants.

WILMARTH & MORMAN COMBINATION DRILL, CUTTER, AND REAMER GRINDER.

The well-known "Yankee" drill grinder made by the Wilmarth & Morman Co., 580 Canal St., Grand Rapids, Mich., is shown in Fig. 1 provided with an attachment for grinding cutters and reamers. This adapts the tool to doing nearly everything required for keeping the cutting tools in condition in the average tool-room. The attachment is of substantial construction, and is firmly attached by a bracket to the main column

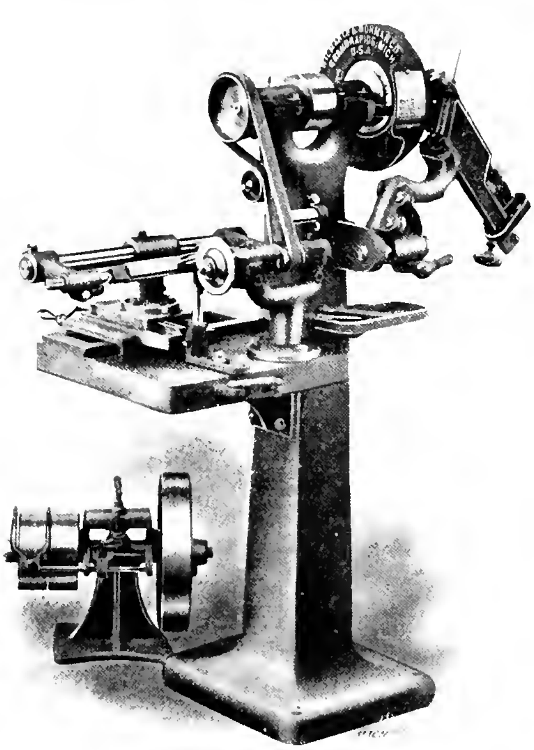

Fig. 1. The Yankee Drill Grinder provided with a Cutter and Reamer Grinding Attachment.

of the machine. It may be supplied with any of the grinders made by the builders, so that the entire equipment will be suited to the range of drills and cutters used by the purchaser.

As may be seen in Fig. 1, the spindle of the attachment is driven from a pulley on the main spindle of the machine by a belt which passes over an idler so that the proper tension may be maintained. The stand which carries the spindle is mounted on a table which forms the base of the attachment. This table is provided with dove-tail ways on which is mounted a slide operated by a hand lever from beneath, as is more plainly seen in Fig. 2. This slide carries dove-tail ways extending at right angles to its line of movement, on which is mounted a second slide, operated by the screw and ball crank shown. This second slide in turn carries a swiveling head which may be adjusted so that the bar it carries may take any position between that parallel with the wheel spindle, and one at right angles to it.

In Figs. 1 and 2 the operation of grinding a reamer is shown. The head which is adjusted in parallelism with the wheel spindle carries a bar provided with centers on which the reamer is supported. A tooth rest is furnished which supports the tooth of the reamer just under the point where it is being ground, so that the hand of the operator may cause the reamer to follow the spiral path of the tooth as the slide is moved back and forth by the hand lever. The adjustment for diameter is, of course, obtained by the ball crank and adjusting screw.

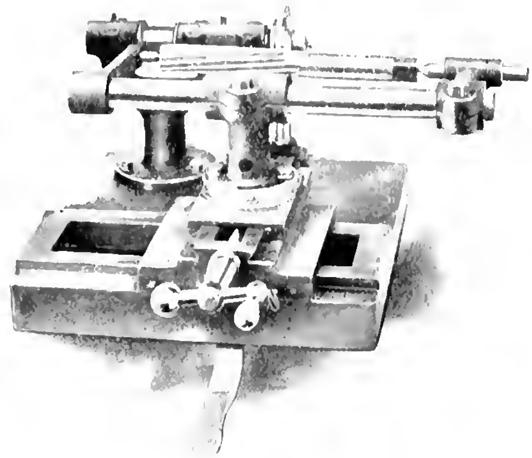

Fig. 2. Grinding a Spirally Fluted Reamer.

The operation of grinding a face mill is shown in Fig. 3. In this case the tooth rest is mounted in the work-carrying head, and moves with the cutter as it is shifted back and forth past the edge of the wheel by the operation of the handle. For grinding the periphery of the cutter, the head is swung around

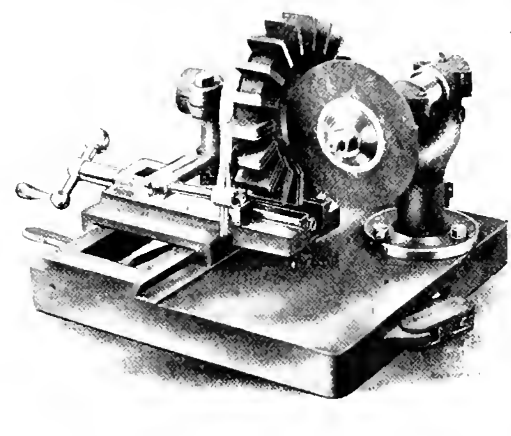

Fig. 3. Sharpening the Face of an Inserted Tooth Cutter.

through 90 degrees to present the other edge of the inserted blades to the wheel. In Fig. 4 a 45-degree angle cutter is being ground in the same manner, though with the head set, of course, to the proper angle. The proper clearance is readily obtained by adjusting the height of the spring tooth rest.

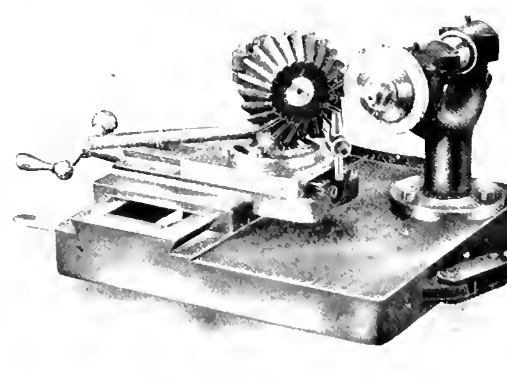

Fig. 4. Grinding a 45-degree Cutter.

The method of formed cutter grinding employed is shown in Fig. 5. A gear-cutter is here being sharpened. A special attachment is used in place of the swiveling head previously shown. This attachment comprises a small table mounted on the cross slide, which table carries a vertically adjustable stud on which the cutter is placed. In setting the device to grind the teeth of the cutter radially, the sliding table is first set

so that the grinding face of the dished wheel is in line with the center of the cutter. In this position the slide is fastened to the base by a thumb-screw provided for the purpose. The micrometer attachment of the stud is then operated to center a cutter vertically with the center of the wheel. The gage provided is then set into position which corresponds with the grinding edge of the wheel. The cutter being thus held, the spring tooth rest or index dog is brought up to bear on the back of the tooth. The grinding is done by moving the slide in and out by the crank, a couple of turns giving sufficient movement. The work is indexed by hand from tooth to tooth, backing up each time against the tooth rest.

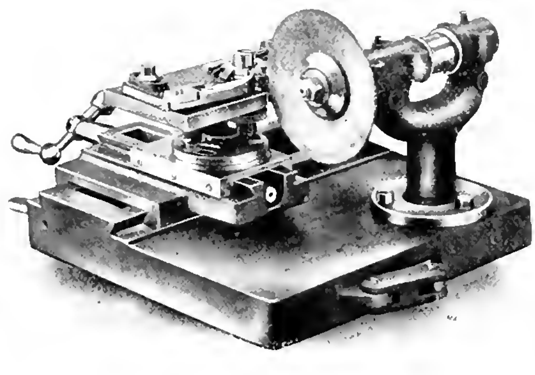

Fig. 5. The Attachment for Sharpening Gear-cutters.

With this convenient attachment, cutters and face and side mills up to 8 inches in diameter may be ground. For angle cutters such as shown in Fig. 4, the diameter limit is 8 inches. The gear-cutter grinding attachment will take work up to 6 inches in diameter, while reamers 8 inches in diameter and with flutes 8 inches long are within the capacity of the machine. The attachment is substantially built and firmly attached to the column of the drill grinder. The bearings, ways, and all other details of construction are carefully designed and fitted, with the idea of giving the machine a long and useful life.

VERTICAL DOUBLE SPINDLE MILLING ATTACHMENT.

The accompanying half-tone and line engravings illustrate the application, construction, and use of a new vertical double spindle attachment, which has been designed by the Kearney & Trecker Co., Milwaukee, Wis., for some special work. The manner of mounting the two heads is plainly shown in Figs. 1 and 2. In Fig. 2 one of the vertical heads is sectioned through the center of the vertical spindle, while a section of the other is shown through the center of the milling machine arbor. On the arbor of the milling machine are placed two spiral gears *A*, which engage with spiral gears *B* on the vertical spindles *C* of the attachment. The gears mounted on the arbor are larger in diameter than the gears on the vertical spindles, which permits the use of angles of helices more favorable for a drive of this kind than if the gears were of the same size. The angles are 54 degrees for the driver, and 36 degrees for the driven member.

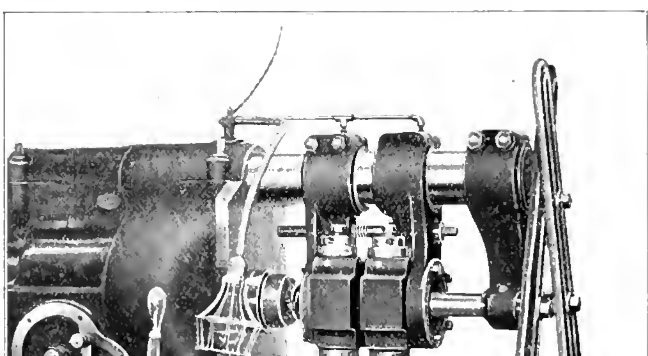

Fig. 1. Kearney & Trecker Vertical Double Spindle Milling Attachment.

An outline of the top surface of the work to be milled in this particular case is shown in Fig. 3, which also indicates the application of the mills. It is evident that in order that both cutters may run against the cut, when cutting the shoulders *E*, one must rotate in a left-hand and the other in a right-hand direction. This is taken care of by the direction of the helix in the spiral gears. The two heads can be adjusted in relation to each other by the adjusting screws shown both in the half-tone, Fig. 1, and in the line engraving, Fig. 2 at *D*, immediately below the overhanging arm. In the special case for which this attachment was built, it was necessary that the distance *F*, Fig. 3, should be maintained in all the pieces milled, regardless of the wear of the cutters. The adjustment between the heads was introduced for this reason, and permits a movement of one-quarter of an inch after the device has once been set up and mounted in place. Of course, a greater adjustment could be obtained by furnishing a spiral gear on the arbor which could take its end thrust against the bearings in the housing, in place of against the arbor itself, leaving the arbor without collars.

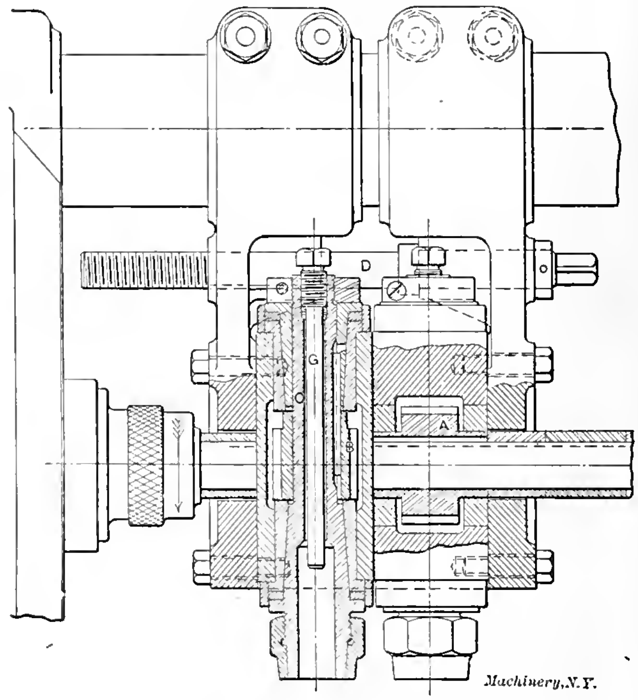

Fig. 2. Design of Vertical Double Spindle Milling Attachment.

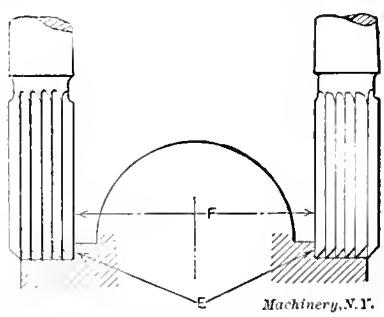

Fig. 3. Example of Uee of Double Spindle Milling Attachment.

In order to make it convenient to set the spindles square with the top of the milling machine table, the casting containing the spindle bearings is made separate from the parts that are clamped to the overhanging arm. The cutters and arbors used in these spindles have straight shanks, and are backed up by screw *G* shown passing through the hollow spindle in the section in Fig. 2. This arrangement permits a slight vertical adjustment of one cutter, in order to bring both cutters to an exact level, when this is required.

MOTOR DRIVE OF THE ACME AUTOMATIC MULTIPLE SPINDLE SCREW MACHINE.

In applying the motor drive to its well-known multiple spindle automatic screw machine, the National Acme Mfg. Co. of Cleveland, Ohio, has introduced a number of improvements which tend toward a considerable increase in the effi-

ciency of the tool. These improvements include positiveness of drive, elimination of belting and counter shaft, simplifying the setting up of the machine, and increasing the output.

As may be seen in Figs. 1 and 2, the driving motor is mounted on a bracket at the rear of the machine. Its armature shaft carries a pinion which meshes with a large gear on the driving shaft of the machine, taking the place of the

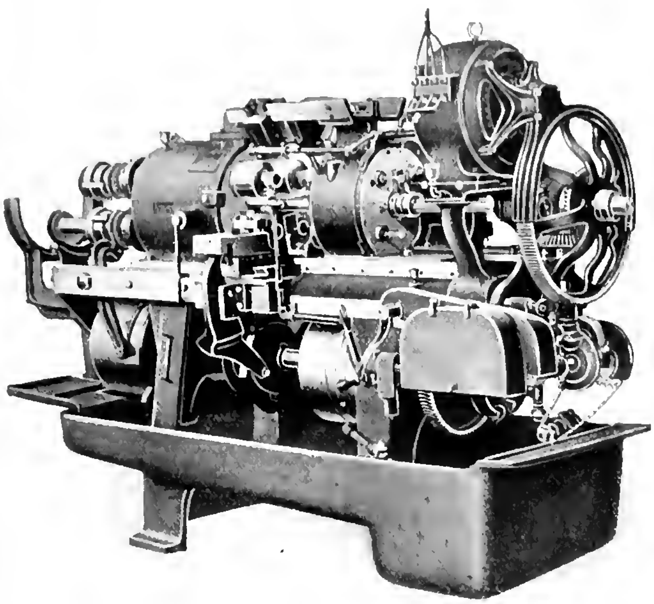

Fig. 1. The Acme Automatic Screw Machine arranged for Motor Drive.

driving pulley furnished with the belt-driven styles. In Fig. 2 will be seen gearing which furnishes a back gear connection between the driving gear and the shaft on which it is mounted, so that either of two rates of speed may be used.

The driving gear is connected with a short horizontal shaft at the base of the machine by the vertical shaft and bevel gears shown. The oil pump is driven from this shaft by a chain and sprocket wheel connection; since the driving gear always runs when the spindles are revolving, a supply of oil

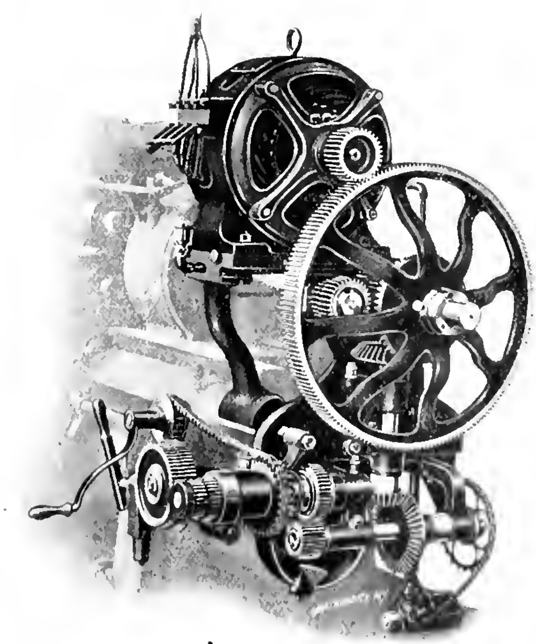

Fig. 2. Arrangement of the Driving Gears

to the work is assured under all conditions when it is possible for cutting operations to take place. In this respect it is far superior to the usual belt-driven pump, in which the breakage or slipping of the belt means disaster to the cutting edges of the tools. A clutch, operated by a convenient handle, is provided for changing the speed of the cam-shaft from fast to slow. The crank shown is attached to the worm-shaft driving the cam mechanism, the power feed being operated by a chain of the silent type, leading to clutch. Change gears are provided for altering the rate of revolution of the cam-shaft and the consequent rate of production of the machine.

It will be seen that when the clutch is in the central position, the sprocket wheel driving the cam mechanism is entirely free on its shaft, so that the hand operation by means of the crank is rendered very easy, the entire transmission mechanism being entirely out of operation. The clutch lever may also be used for operating the tools intermittently in setting up or in testing. The same mechanism is used for the single belt drive, the large driving gear being replaced by a pulley which, if desired, may be directly connected with the clutch pulley on the line shaft, the counter-shaft being then unnecessary. In the motor-driven machine, any standard motor may be used without alteration, the size being properly selected for the size of the machine used, ranging from 3 to 5 horse-power. The machine shown is the builder's No. 56 size, arranged as exhibited at the Atlantic City convention of the Master Mechanics' Association.

CHAMBERSBURG LINE OF STEAM DROP HAMMERS.

The Chambersburg Engineering Co., Chambersburg, Pa., a firm which has had wide experience in building steam hammers, was the pioneer in the development of this machine as specialized for drop forging. The employment of the steam drop hammer for this work was necessitated by the increased use of large drop forgings for parts formerly made of malleable iron, or steel castings. The first of these machines put on the market for this purpose, were capable of doing larger and better work than the previously used board drop hammers, and were less expensive to maintain. Like all new machines, however, a number of weaknesses developed in the severe service to which they were put. The builders have carefully corrected these weaknesses as fast as they have appeared, and have now developed a line of drop hammers that have proved to be thoroughly satisfactory in the service exacted of them.

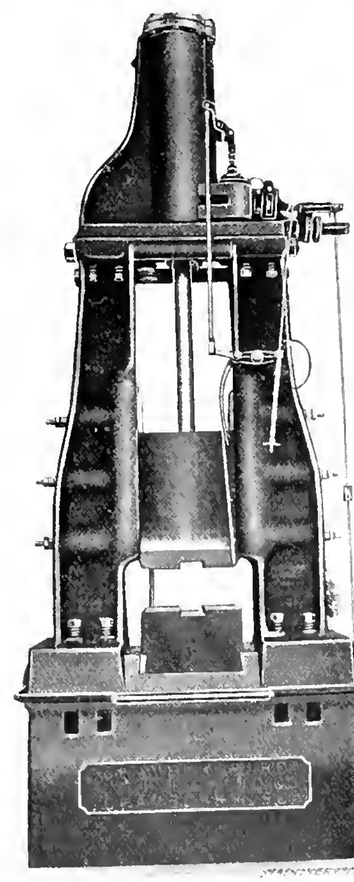

Fig. 1. The Standard Chambersburg Steam Drop Hammer for Drop Forging and Similar Work

The standard form of the Chambersburg steam drop hammer is shown in Fig. 1. A special feature of the construction is the form of tie-plate used, which is provided with ledges or lips fitting around the top of the frames and around the face of the cylinder, thus taking the strain off the bolts and holding the upper members of the hammer in line. The anvil also lips the frame on four sides, relieving the anvil bolts and preventing the shifting of the frames on the anvil. This arrangement makes the hammer very rigid and keeps it in permanent alignment—an important consideration in producing first-class forgings. The hammers are quick acting, re-

quire but little attention, and are always under the control of the operator. The frames and anvils are made of air furnace iron, except where extra hard service is required of the machine, in which case steel castings are used. The hammer shown in Fig. 1 has steel side frames and a cast iron anvil.

In addition to this standard design, the firm has built a slightly modified style, of which an example is shown in the 6,000-pound drop hammer in Fig. 2, built for the Bethlehem

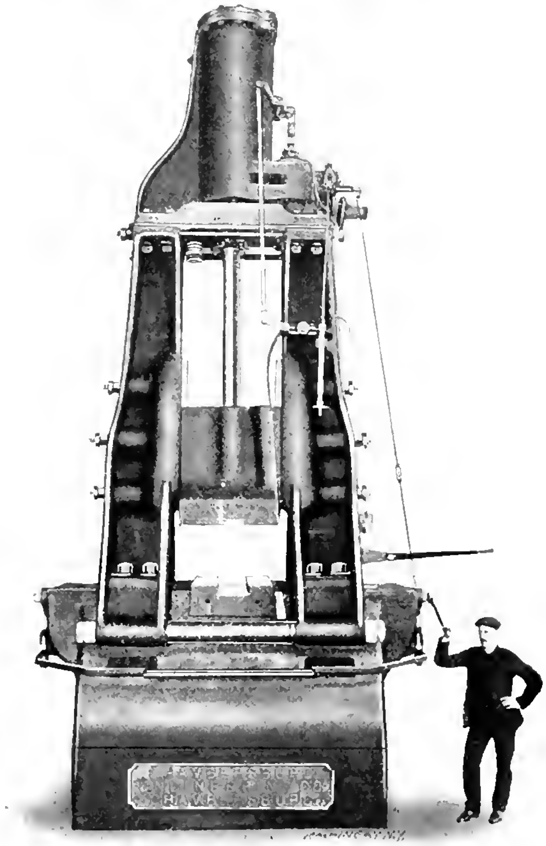

Fig. 2. Special Form of Drop Hammer furnished to the Bethlehem Steel Co.

Steel Co. The special feature of this design is the method of aligning the dies, by adjusting the frames on the anvil, instead of employing the usual taper gibs in the die-block and ram. These hammers have cast steel anvils and frames, and have been successfully used on the heaviest kind of drop forging work.

ARMSTRONG SHORT RATCHET DRILL.

A new ratchet drill of a design which differs from those in common use has been brought out by the Armstrong Bros. Tool Co., 113 N. Francisco Ave., Chicago, Ill. The principal feature of

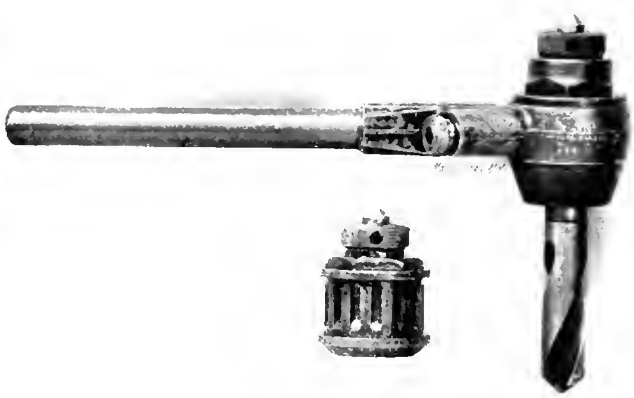

Fig. 1. Armstrong Short Head Ratchet Drill.

this appliance, designated by the makers as the Armstrong short ratchet drill No. 2, is that the mechanism for feeding has been designed in such a manner as to make the head of the tool shorter and more compact than usual. How this has been accomplished can most easily be seen from the line engraving, which shows at the left a section through the head of the type furnished for taking drills with No. 3 Morse taper shanks, and at the right, a type intended for square taper shanks. This latter construction gives a head shorter than that of any ratchet drill made, length of feed considered.

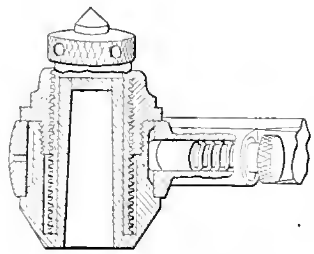

Fig. 2. Head for No. 3 Morse Taper Shanks. Length, 3 3-4 inches; Feed, 2 3-4 inches.

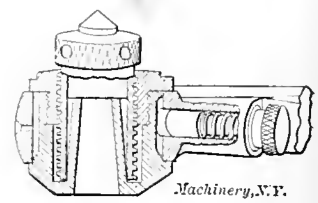

Fig. 3. Head for Square Taper Shanks. Length, 2 3-4 inches; Feed, 1 1-2 inch.

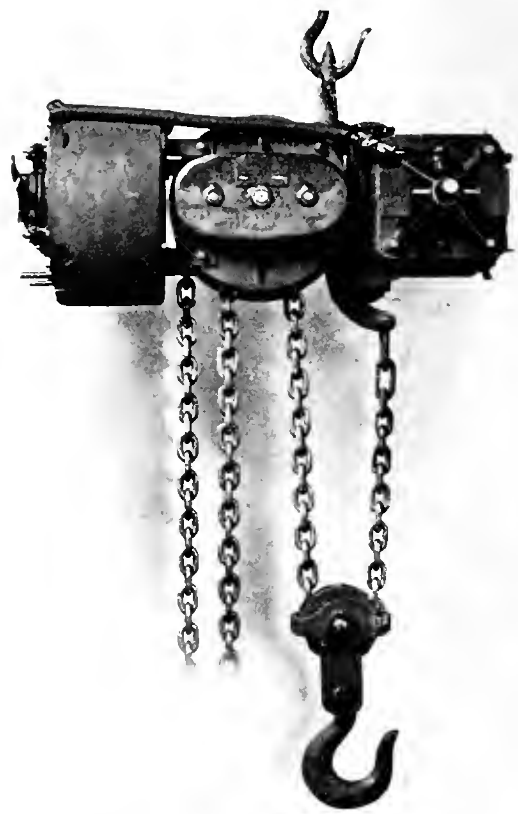
There are no castings used in the construction of these drills, all parts being made either from drop forgings or from bar steel, the pawl and center being of tool steel, hardened.

NORTHERN ELECTRIC CHAIN BLOCK.

A new electric chain block has been brought out by the Northern Engineering Works, 26 Chene St., Detroit, Michigan. This hoist is designed to supplant the ordinary hand chain block, suspended by a single hook. It is known as the Northern C type electric chain block, and is a modification of the original C type placed on the market three years ago. The present design embodies several improvements over the old one, one of the advantages obtained being a shorter space between the hooks, insuring higher lifts under low ceilings.



Northern Engineering Works C Type Electric Chain Hoist.

Referring to the half-tone illustration, it will be seen that the hoist is of the same general design as the hand chain blocks, excepting that it is driven by a crane motor with a standard crane controller having ample resistance. The block can be operated at several different speeds, and it is possible to obtain a speed ten times faster than that obtainable by hand-power. At the same time a hoist of a given capacity is of about double the size and strength that it would be if designed for hand-power. This larger factor of safety is used on account of the more severe service to which the electrically-driven block will be subjected. Worm gearing, bevel gears, and planetary gear combinations have been avoided in the design of the hoist, and spur gears cut from solid steel blanks are used throughout. This increases the life of the block, and

decreases the amount of repairs necessary. All gearing is properly covered, and the principal gears run in oil.

As compared with the ordinary drum hoist, a block of this design has the advantage of suspension by a single hook, and tipping or getting out of line will not force the sprocket chain out of the sprocket groove, as would be the case with a wire rope on a drum. The hoist can also be swung sideways without meeting with this difficulty.

Motors of any standard make can be used, and will be furnished for either direct or alternating current. The sizes range from 1 to 6 tons capacity, and the hoists are intended primarily for moderate service, especially over tools in boiler shops and machine shops, in warehouse service, and in some kinds of foundry service.

MILWAUKEE 16-INCH LATHE.

The lathe shown herewith, built by the Milwaukee Machine Tool Co., Milwaukee, Wis., is designed to meet the requirements of manufacturers in need of a high-grade tool of simple construction, combining durability, power, and high cutting capacity. It is at present built only in the 16-inch size, which can be furnished in any length of bed desired from 6 to 16 feet. The head- and tail-stock are strongly made, fitted to a V bearing at the rear and a flat bearing at the front. The head-stock has two large oil reservoirs located beneath the spindle, supplying oil to the bearings by a wick. The tail-stock is so designed as to leave ample clearance for the compound rest when the latter is used for angular cuts. The carriage is fitted to the V's at both front and rear. The apron has a clutch for engaging the longitudinal feed, and a sliding gear for the cross feed. The feeds are reversed in the apron, and a safety lock is provided for the split nut. Special care has been taken in the design to place all the handles so as to be most convenient to the operator.

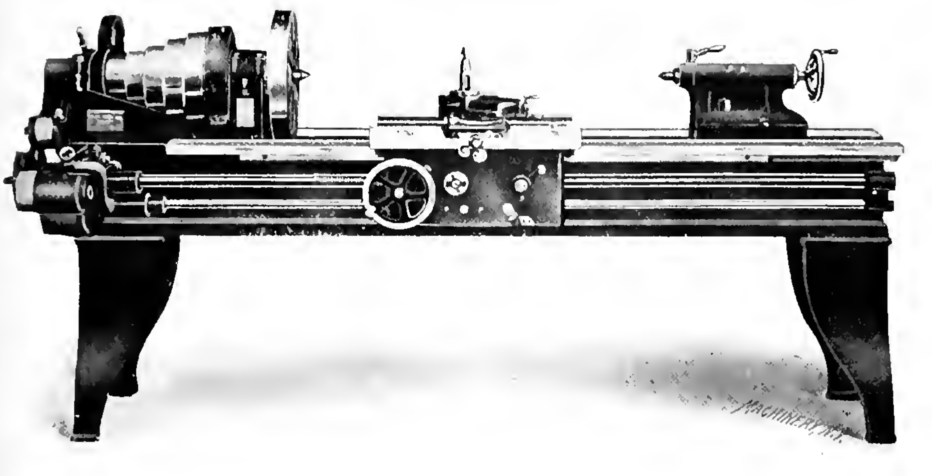


Fig. 1. The Milwaukee 16-inch Lathe.

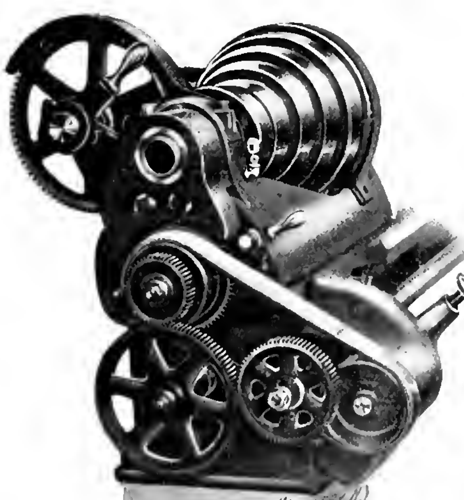

Fig. 2. End View of Head-stock.

A feed box giving four quick changes is provided, driven from the spindle by a wide belt furnished with a belt tightener conveniently located. The change gearing may be used to provide an additional feed when a coarse, positive roughing cut is required. For thread cutting, the different pitches are obtained by change gears in the usual way. The following dimensions will give some idea of the proportions of the design. The main spindle bearings are of phosphor bronze, the one at the head end being 3 3/16 inches in diameter by 5 inches long. The spindle has a 1 9/16-inch hole through it from end to end, and is made of high carbon crucible steel, cut from the solid, and accurately ground. The cone pulley takes a 2¼-inch belt, and is 11 inches in diameter on the largest step. All the important pinions and gears are of steel, cut from the solid. The net weight of the machine with an 8-foot bed is approximately 2,500 pounds, complete. The equipment regularly furnished includes a counter-shaft, compound rest, steady rest, follower rest, large and small face-plates, and all the necessary change gears and wrenches.

SCHELLENBACH 16-INCH GEARED HEAD LATHE.

The John B. Morris Foundry Co., 933 Harriet St., Cincinnati, Ohio, has placed on the market an engine lathe involving so many original and ingenious features that it is difficult to know where to begin in describing it. The main purpose of the design was to build a lathe adapted to the use of high speed steels to their full capacity, on work of all diameters from the smallest to the full swing of the lathe, and still preserve all the quickness and convenience of operation found in the usual engine lathe. In the actual working out of the design, however, not only has the convenience of the standard engine lathe been retained, but this new machine "goes it one better" even, being built on lines so original that little of standard lathe design is in evidence. Among the features of the tool, should be mentioned the Schellenbach taper attachment, the provision for using the rack in roughing threads, to save the lead-screw from wear, a support for the carriage, directly beneath the work, provision for sixteen changes of speed in the head-stock, and the use of a face-plate drive for both chuck and face-plate work of large diameters. It would be impossible to go thoroughly into the details of the machine within any reasonable space, but the description we give herewith, with the illustrations, will serve to give a general idea of the construction of the lathe and the advantages which it is intended to furnish.

The Head-stock and Spindle Gearing.

As has been stated, the head-stock gearing gives sixteen changes of speed from a single speed driving pulley, loosely mounted on the spindle. One of these drives is direct, the pulley being clutched to the spindle for the purpose. Seven of the speeds are obtained by gearing applied to the spindle, while the eight slower ones drive the face-plate through a pinion meshing with the internal teeth cut in its rim. An index combined with the mechanism for changing the head-stock gearing shows the operator the diameters for which the spindle speed he is using is suitable, for various cutting speeds ranging from 20 to 60 feet per minute. The operator need not know the number of revolutions per minute of the spindle, as he can thus deal directly with the diameter of the work in hand and the cutting speed in feet per minute desired. The various movements of the sliding gears in the head are so interlocked as to make it impossible to engage them wrongly, so that making changes can be done quickly without fear of a false move.

Provision is made for motor drive in the original design of the machine. Cored openings are made through the head-stock, so that a motor may be attached beneath the bed and

connected directly by a belt or chain with the driving pulley of the spindle, or with a sprocket similarly placed. Where it is desired to mount the motor above the head-stock and connect it by gearing with the spindle, the hinged cover provided for the change gear mechanism is cast with a motor base, making but a very slight alteration in the design of the machine. Owing to the great number and range of the speed changes in the head-stock, a constant speed motor may be used for driving, no electrical changes of speed being required. The maximum increment of speed in the mechanical changes is only 28 per cent in two successive steps.

The face gear is of steel, and is secured to a flange on the spindle on the outside of the front bearing. It extends out

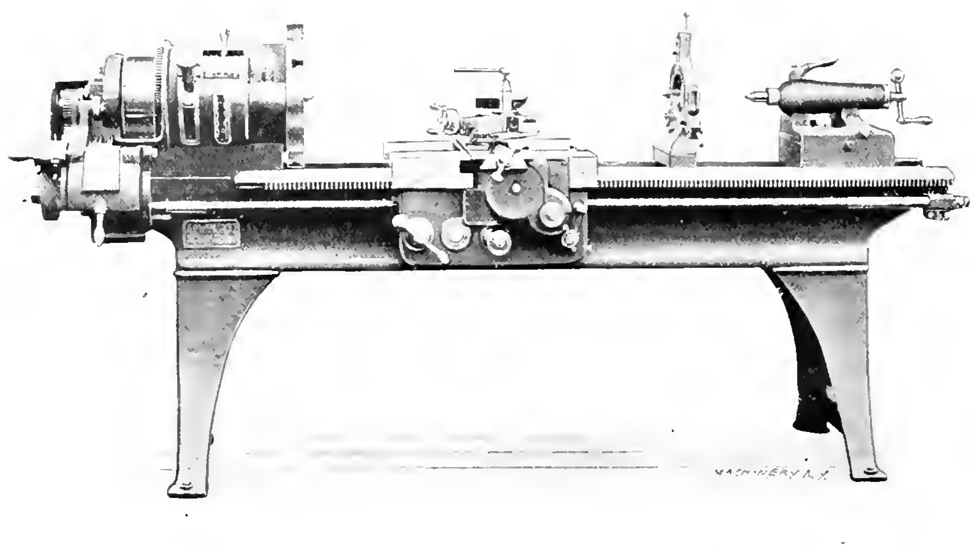

Fig. 1. Schellenbach Geared Head and Feed 16-inch Lathe.

through the head-stock and is threaded to receive the face-plates or chucks. Since the driving pinion is placed on the front side, it is properly located to resist the action of the cut without causing undue strain on the top cap of the front spindle bearing. The spindle itself is of forged crucible steel, bored throughout its length, and ground true. The head-stock casting is of box construction, with the sides extending above the center of the spindle, tying the front and back bearing together to resist end thrust. Excepting for the opening for the driving pulley, it is entirely enclosed, though the interior is rendered accessible by releasing a single screw and throwing back the hinged cover mentioned.

Feed Change Mechanism.

The form of quick change gear device used is one that is entirely novel, so far as we are aware. The handle seen projecting from the change gear casing is not used in shifting the gears, as might be imagined, but is simply employed for raising the lid of a receptacle in which loose change gears are placed. The one of these gears desired is slipped by hand on a stud, which is thrown into engagement with that one of three intermediate gears, which is at the time set to engage it. As there are eight change gears, this gives 24 feeds or pitches of thread. A second change is provided which doubles this number, making 48 changes in all, ranging from 2 to 112 turns per inch. The connections are such that the threading, turning, and facing movements are all at the same rate, so that one dial reading may be used for all three. It is the belief of the designers of this machine that this quick change device combines all the simplicity and directness of drive of the old style of change gearing with the ease of operation of the later forms of quick change mechanism. The steel gears used are slipped on by hand and do not require to be held by a nut, cotter pin or other device. Power is transmitted from the spindle to the screw in as direct a manner as in the regular form of engine lathe, and there is no complicated mechanism to be damaged by accident or wear out in use.

The Carriage, Tail-stock, and Bed.

The design of the bed may be best understood by reference to Figs. 2 and 3, in which the arrangement of the ways and the bearing of the carriage and tail-stock on them is plainly shown. The carriage is very deep and strongly ribbed to resist the torsional and direct stress produced by the cutting action. The legs are set well in to give better support, and are of wide span. The carriage runs on a V at the front side of the bed and a flat bearing at the rear, and is also supported on a central sliding surface to which it is held by gib *A* and strap *B*. It has often been customary to give the carriage an inner bearing on the flat ways which serve also for guiding the tail-stock, but this has the disadvantage that the wear produced by this carriage bearing disturbs the vertical alignment of the tail-stock spindle. This supplementary bearing at *A*, it will be seen, gives the carriage strength where it is most needed, providing, in combination with the regular bearings, a firm support to the tool, whether it is working on large or small diameters.

The tail-stock also slides on a V at the front side of the bed, and on a flat bearing at the rear. Not only is this arrangement of the ways the simplest for obtaining a good fit, but it is the most durable as well. The tail-stock is clamped from the front side by screw *C*, which bears against the point of clamping lever *D*, pivoted at *F* and provided with a short lever arm which engages the under side of the ledge in which strap *B*, in Fig. 2, takes its bearing. The bearing points in this arrangement are made of tool steel. It will be seen that a very slight pressure exerted against screw *C* will cause the clamp to bear very tightly under the shear of the lathe bed. The side adjustment of the tail-stock can be effected independently of the clamping of the base to the bed, an arrangement met with on many larger lathes to insure against slipping back when setting tapers for heavy work. All the adjusting screws of the tail-stock, and every other adjusting screw in the lathe, for that matter, can be operated with the tool-post wrench.

Apron and Cross Slide Mechanism.

As shown at *E* in Fig. 2, the rack is set with the teeth on the vertical face instead of on the under surface as usual.

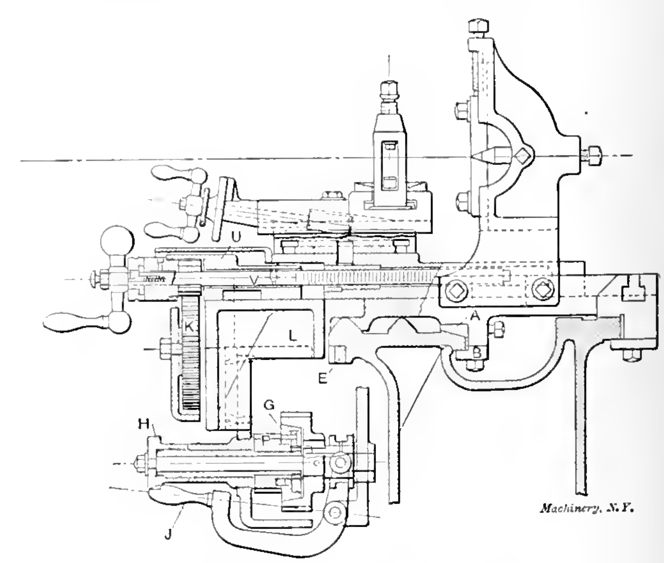

Fig. 2. Section of the Apron, Carriage, and Bed.

This permits setting the pinion shaft in a vertical position, so that it has a bearing in the apron on each side of the pinion, making a very strong and durable mounting. The rack and pinion feed is driven from the spline of the lead-screw through bevel and spur gearing, connected by the friction *G*, operated by knob *H* in the usual manner. The ratio of this connection is such as to give the same travel per revolution for the lead-

screw as is given the carriage when the split nut H in Fig. 3 is thrown into action. The rack is cut with such accuracy that it may be used with confidence by the operator for rough threading, to within a few thousandths of the finished size, using the lead-screw only for the fine finishing chips, thus greatly prolonging its useful life. In this use of the rack and pinion in threading, a positive connection is engaged in place of friction G, shown in Fig. 2. This positive connection is operated by lever J. The split nut does not require a locking device to prevent its engagement at the same time with the friction feed, since both give the same movement and both may be thrown in together without damage of any kind. The upper end of the pinion shaft projects through the top of the carriage and is provided with a dial graduated to read to 64ths of an inch.

The power cross feed is transmitted from the apron gearing to the cross feed screw through an intermediate gear K, shown in Fig. 2. The movement given this screw, as has been explained, is the same as that given the carriage by the lead-screw or the rack-and-pinion feed, so that the table of feeds and threads serves for facing and scroll cutting as well as for the longitudinal movements. The compound rest slide is tipped up slightly, as shown in Fig. 2. This brings the handle sufficiently high to avoid interference with the cross feed screw, at the same time allowing the rest to be made very low and rigid. The top slide is offset to clear the tail-stock when set at or near 90 degrees. Its feed screw, as well as that for the main cross slide, is provided with a graduated collar reading to thousandths of an inch.

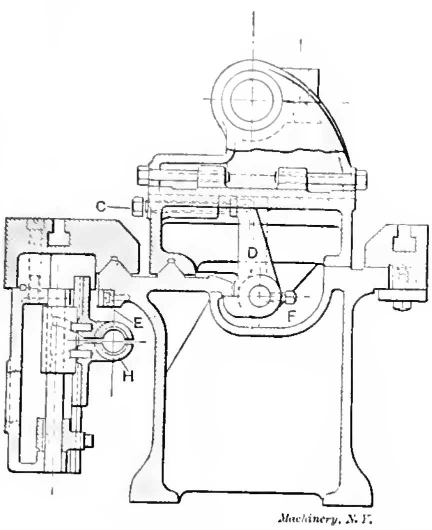

Fig. 3. The Tail-stock and the Method of Clamping it.

The apron is tongued, grooved and bolted to the carriage. All the handles and levers are placed in convenient position and about the same location as found in the conventional apron. Owing to the position of the legs at the end of the bed, and to the fact that the split nut is placed at the left side, it is possible to run the carriage to the extreme end of the bed, where the mechanism is exposed for examination without removing the apron.

The Taper Attachment.

The most radical departure in construction from the conventional lathe design relates to the form of taper attachment

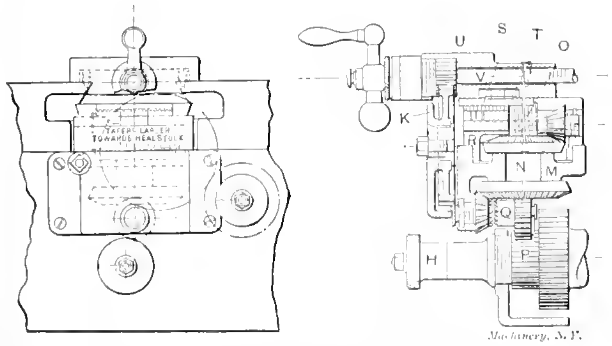

Fig. 4. An Ingenious Taper Attachment operated by the Apron Gearing.

used. A "dummy casting" L, Fig. 2, is removed and in its place may be inserted the casting holding the mechanism comprising the taper attachment, shown in M in Fig. 4. This casting carries the double vertical bevel gear N, meshing at the upper end with a bevel pinion, driving screw O. The lower gear of double gear N is driven from pinion P on the friction, through clutch Q, which may thus be operated to engage or disengage screw O from positive connection with the rack and pinion feed of the carriage. Screw O is carried on a pivot in swivel block R, which may be adjusted about the axis of N. R carries a guide on its upper surface in which slides the bronze half nut S, engaging screw O. To S is pivoted the block

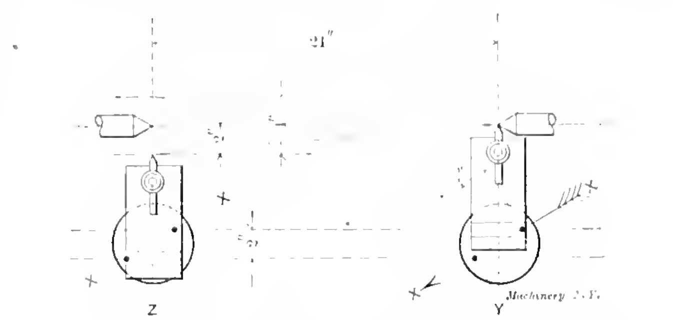

Fig. 5. Diagram illustrating the Principle of the Taper Attachment.

T, which is seated in a cross groove in the base of cross slide screw carrier U, which is in turn dove-tailed into the same ways in which the cross slide is dove-tailed.

With mechanism arranged in this way, it will be seen that when (by the operation of the power feed or the apron hand-wheel) the carriage is traversed by the rack and pinion movement, a corresponding movement through the train of gears just described is imparted to nut S and block T by the rotation of screw O. If the angular adjustment of R is set so that the axis of O is parallel with cross slide, screw O will transmit all of this longitudinal movement to holder U and cross slide screw V, which will thus be moved axially. If, on the other hand, R is adjusted through an angle of 90

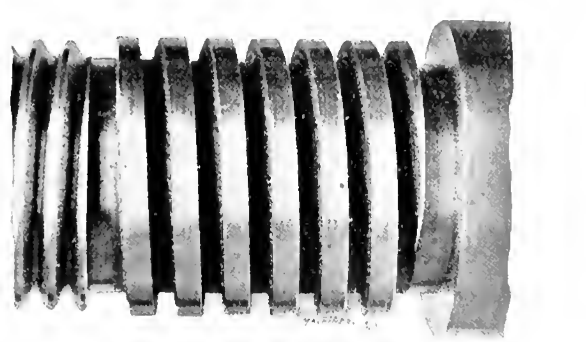

Fig. 6. A Square Thread roughed with the Rack Feed and partly finished with the Lead-screw.

degrees so that the axis of O is parallel with the center line of the lathe, the half nut S and block T will have a movement in the same direction, the latter sliding freely in the groove in U without imparting motion to it. In any intermediate position within these two a greater or less movement will be imparted to U for a given travel of the carriage, depending on the sine of the angle at which R is set. In a travel of 24 inches, with block R set as shown at the right of Fig. 4, the full travel of block U, 4 inches, is obtained. This gives a taper of 8 inches in 24 inches, or 4 inches to the foot, the maximum for which the attachment is adapted.

In Fig. 5 is a diagram showing the action of the device when set at an intermediate position between two extremes. As shown, in traveling from position Y to position Z, a distance of 24 inches, nut S and block T in Fig. 4 have a movement of 4 inches on axis X X. This, with the angular setting given, results in a cross movement of the cross feed screw of 2 inches, giving a taper of 4 inches in 24 inches, or 2 inches per foot. For tapers smaller toward the head-stock, block R is adjusted around the other side of the zero point, graduation being provided for the setting as shown at the left in Fig. 4.

Before the pin which engages clutch Q can be operated, the casing holding gear K has to be removed. This disconnects the power cross feed mechanism, which is, of course, never used at the same time as the taper attachment. When the taper attachment is in use slide U also has to be loosened, it

being located firmly in place in the top of the carriage for ordinary straight turning. The mounting of the taper turning device on the apron instead of at the back of the machine, is a great convenience.

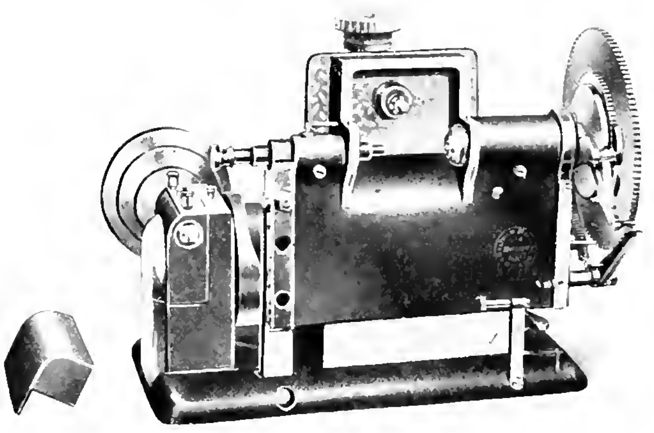
Accessories.

The follow rest provided straddles the tool slide, being clamped to the carriage on each side, furnishing a firm, steady support to the work. It has three jaws. The back rest is separate from the base by which it is attached to the ways, and may be reversed on that base so as to face either way. This provision overcomes the difficulty ordinarily met with in the usual construction where the V and a flat way are used for supporting it, in which case the steady rest is ordinarily irreversible. The counter-shaft provided is operated by two friction pulleys. Where it is not thought necessary to drive in both directions, two forward speeds may be used, thus giving 32 changes to the head-stock spindle instead of the 16 provided by the head-stock gearing with the single speed counter-shaft. This machine is manufactured at the present time in 14-, 16- and 18-inch sizes, and may also be supplied with the 3-step cone type of head as well as in the style here illustrated. It is also made with plain change gears in place of the quick change devices we have described.

A number of samples of work done on this machine have been sent us, all of them interesting, of which we have room for but one. This (see Fig. 6) illustrates the use of the machine in roughing threads with a rack feed and finishing them with a screw feed. As will be seen, a roughing cut has been taken in the square threads shown, followed by a finishing chip which has been carried to but half the depth, showing both cuts plainly. This is an operation that may be followed on threads of fine pitch, great care having been taken in the cutting of the rack to make it match the lead-screw accurately.

WALTHAM AUTOMATIC PRECISION GEAR-CUTTING MACHINE.

We show herewith an illustration of a precision gear-cutting machine recently designed by the Waltham Machine Works, Newton St., Waltham, Mass. Like other machines for



Precision Machine for Cutting Clock and Instrument Gears, etc.

precision work the movements are cam operated, from a shaft driven through worm gearing by the grooved cone pulley shown at the left. This worm gearing is enclosed and runs in oil, but can be removed without disturbing other parts of the machine. The movements effected by the cams on this shaft are the feeding of the work past the cutter: separating the cutter and the work for the return stroke, and indexing. The latter movement takes place while the work is being returned, thus making a considerable saving of time over those machines in which the cutter travels back in the tooth cut, and has to be held clear of the work longitudinally before the indexing can be effected. The index disk is proportionally of large diameter (10 inches), and is arranged to cut from 12 to 240 teeth.

A noticeable feature of the machine is the complete protection afforded to the index plate, cams, and other working parts, from the chips produced by the cutting operation. These are very troublesome, especially if the work is of brass or some similar material. As may be seen, the head- and footstock spindle project through two side plates in the work slide, which are so arranged that a cover with a scraped fit may be brought down over them, entirely enclosing the cutter and work, and forcing the chips to drop directly down in front of the machine instead of flying all over the mechanism.

If desired, the machine may be arranged for going twice around the work, taking two cuts through each space, automatically shifting to a slightly deeper cut the second time around.

The capacity of the machine is for gears up to 3 inches in diameter when the chip protection is used; for cutting iron and steel without the protection, blanks 4 inches in diameter may be handled. The machine may be furnished with a heavier spindle if required, in which case gears as coarse as 24-pitch may be cut. The construction of the machine is in line with that of the automatic watch machinery built by the same firm, being provided with hardened steel pinions and other working parts, and finished with the utmost accuracy.

ROCKFORD MACHINE & SHUTTLE CO.'S SENSITIVE DRILL.

The Rockford Machine & Shuttle Co. of Rockford, Ill., is building the sensitive drill press shown in the accompanying illustrations. The construction is simple and rigid, and a number of new features are provided in the accessories furnished with the tool.

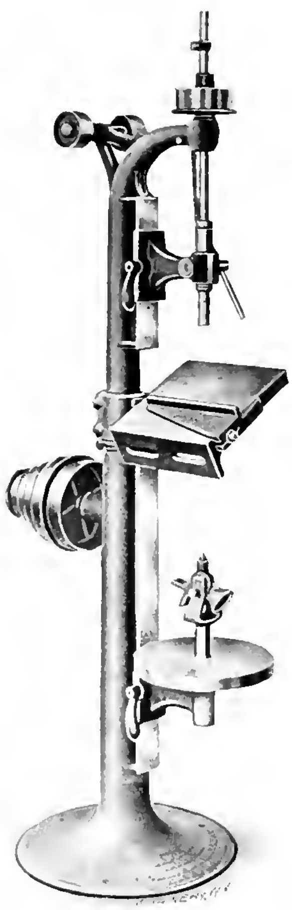


Fig. 1. Drill arranged to use Tilting Square Table.

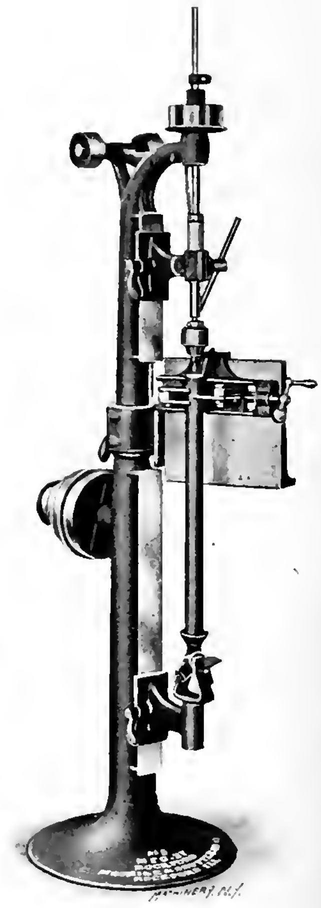

Fig. 2. The Centering Attachment in use.

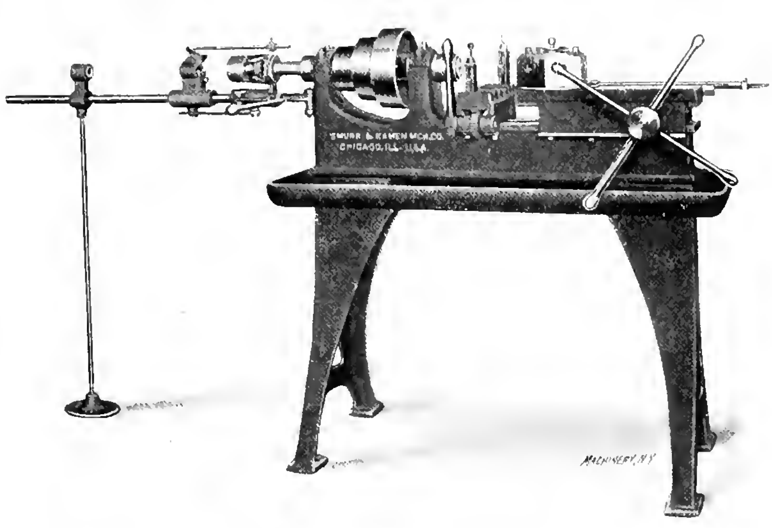
As will be seen in Fig. 1, the regular table provided can be tilted to any angle for work that requires holes to be drilled out of the perpendicular. A squared straight-edge is provided for lining up work. This may be conveniently used as a V-block for round parts. One edge of the table is widened to provide a clamping surface for work which is more conveniently held at the side than on the top of the table. On ways at the bottom of the column is fitted an arm carrying a circular table, as shown in Fig. 1, which may be used for holding work when the upper table is swung around out of the way.

This table revolves on a stem in the arm, and may be removed and replaced with the combination center vise shown in place in Fig. 2. This, it will be seen, contains three forms of centers: a cup center, a pointed center, and a V center. The cup center is shown in use.

In Fig. 2 the upper table has been tipped into a vertical position and has a centering vise clamped to its face. A piece of stock is being centered with a combination center drill. The vise is located in line with the spindle of the machine by a taper pin which fixes the swinging arm of the table in proper relation to the spindle. The lower end of the work is being held on the cup center as shown. This makes an arrangement fully as easy to operate as the usual horizontal centering machine, for stock which is not too long to be outside the range of the machine.

SMURR & KAMEN PLAIN HEAD SCREW MACHINE.

The Smurr & Kamen Machine Co., 97-101 S. Clinton St., Chicago, Ill., has been for some time building a plain screw machine which it has been trying out in actual use in the shops of customers, to determine its durability and efficiency. The results of the use of these machines have been so satisfactory that it has been determined to place them actively on the market, where it is believed that the simplicity and effectiveness of their design and the accuracy of their construction will give them a permanent standing.



The Smurr & Kamen Plain Head Screw Machine.

The feature of prime importance in getting good results from a screw machine is the accurate alignment of the center of the spindle with the center of the turret holes, and the maintenance of this alignment throughout the life of the tool. This prime feature is taken care of in the machine shown herewith by providing such sliding surfaces and gibs that the turret can be adjusted either vertically or sidewise to bring the holes back into alignment with the spindle as soon as they are thrown out of position by wear. The vertical movement is taken care of by a taper gib placed between the turret slide saddle and the bed of the machine. The adjustment of this gib alters the vertical position of the turret to allow for the wearing away of the bearing of the turret on its seat. This wear is much more rapid than that of the spindle in the box, thus necessitating occasional re-alignment. The turret slide is gibbed to the turret slide bed by taper gibs instead of by a more common and less expensive plain strip adjusted by set-screws. The bearing obtained with a taper gib is much more satisfactory, extending the full length of the slide instead of being concentrated around the points of the set-screws.

The turret is hexagonal in shape, so that heavy tools can be fastened to the face, giving better support than when the shank only is used for holding them. Instead of the usual hand lever for clamping the turret after the indexing, an ingenious arrangement is provided by means of which this clamping is effected automatically by the action of the pilot wheel which operates the slide. This is a most satisfactory arrangement, greatly enhancing the accuracy and the usefulness of the tool, since, with the usual construction, the workman is free to clamp the turret or not, as he pleases, and he often neglects to do so. As this arrangement does away with the necessity for the usual stud for clamping, it is possible to feed' stock clear through the turret, or to use drills with shanks of indefinite length. The standard automatic indexing mechanism is used for the turret. A large index ring and a lock bolt of the horizontal type are employed. The latter is supported on either side by steel taper gibs, by the adjustment of which it is possible to maintain the parallel alignment before referred to for lining up the center of the spindle.

The wire feed is of a new design developed by the builders. It is continuous in its action to the full length of the bar used, it being unnecessary for the operator to stop his work to push a sliding head or clamp collar back for a new grip on the stock. The counter-shaft provided has two friction clutches for reverse motion. Special attention has been given to the design of these clutches, which are provided with unusually large area of gripping surface. In the case, for instance, of the machine shown, the friction face is 9½ inches diameter and 1¼ inch wide.

It will be seen that nothing startling or revolutionary has been undertaken in the design or construction of these machines. The plan of the builders was to follow lines which, while original, were not so radical as to be of doubtful usefulness, but every effort was made to provide the user with a tool that would not require rebuilding at the close of every busy season. The best of material is used, all the duplicate parts being made with jigs and fixtures on the interchangeable plan, and full use being made of accurate surface plates, straight-edges and test indicators in measuring and testing the separate parts and the finished machine. These provisions, with the means furnished for preserving the vital alignment of the turret holes and the spindle, should make it a most accurate and durable machine.

This screw machine is made in five different sizes, ranging from 10 inches to 18 inches swing over the bed, and with a maximum automatic chuck capacity of from 2 to 2¾ inches.

EASTMAN KODAK CO., Rochester, N. Y. Copying camera for making copies of drawings, tracings, etc., on bromide paper without the use of a negative.

BOSTON TOOL CO., 207 Bridge St., Cambridge, Mass. A new threading tool which is said to greatly reduce the time required for threading, especially on such difficult material as cold rolled steel. The tool straddles one thread and cuts the adjacent faces of the two threads on either side. Since but one face of the thread is cut at a time, the chips are free to roll away from the work, and very heavy cuts may be taken. The device is made in the shape of a circular forming tool held in a suitable holder, or, as a plain straight face forming tool. A special cutter is required for each pitch.

WHITNEY MFG. CO., Hartford, Conn. Chain belt and adjustable pulley for high speed and light, noiseless service. The chain is composed of center blocks, rivets and special side links. A piece of formed leather is wrapped around each pair of side links and is held in place by a steel link on the top surface. The chain belt thus made runs over grooved pulleys, and nothing but the leather comes in contact with these pulleys, making the belt noiseless at the highest speeds. The chain center gives great flexibility even when running over the small pulleys, and prevents the belt from stretching. The flanges of one of the pair of pulleys are made adjustable to keep the proper tension on the belt.

AN AMERICAN MECHANIC IN EUROPE—3.

THE THIRD OF A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

TURIN, ITALY, May 14, 1908.

Trade Conditions in Austria.

The machine industry in Austria has, generally speaking, not suffered very much from the general depression. The machine export business of Austria is mostly confined to Hungary, Turkey, and to the smaller states on the Balkan Peninsula. The exports to the larger industrial countries in Western Europe are small, and, therefore, a depression in these countries is not felt to any large extent in Austria. Aside from this, many of the machine shops, especially those devoted to railway equipment, are engaged in filling orders for the Austrian State railways, and this does, of course, influence the machine building trade throughout the country.

Present Industrial Conditions in Italy.

A depression in the industries in Italy is plainly in evidence, and in addition to the general business depression experienced everywhere, the dullness in Italian business has also a local cause. A short time ago the automobile industry in this country passed through a severe crisis, and several firms failed. As this industry is one of the largest of the machine industries in Italy, the machine tool business suffered to a great extent because of the loss of one of its best customers, and many of the leading machine tool dealers report a drop in business of from 20 to 80 per cent, mostly in machine tools, and to a smaller extent in small tools. In spite of this, however, the present sentiment seems to be optimistic. The automobile trade, according to reports from various factories, is improving, and one concern, Fabbrica Automobili Itala, Turin, is now working full time with full force. It is also stated that the shops devoted to railway equipment have on hand large orders from the Italian Government. Since the railways passed into the hands of the government in 1905, many long-needed improvements in the rolling stock have been undertaken, or are under way, and this means more work for the machine shops. The railway equipment shops need more tools for executing their orders, but they are postponing the buying, expecting prices to go down.

The Machine Tool Market in Italy.

The Italian machine tool industry does not as yet amount to very much. There are only a few small factories for machine tools, but judging from the extensions being completed for these factories, Italy may soon produce a large part of the machine tools for its own use. At present, however, machine tools from nearly all countries—America, Germany, England, Sweden, etc.—are sold and used. As there is but little chance to talk about favoring a home industry in this case, both dealers and users are able to judge and compare the different makes of machine tools in a fairer manner and with less prejudice. The prevailing opinion is that American machine tools are, in general, better than the makes of any other country, but this does not mean that there are not some German makes considered superior to some American. It is considered here that the superiority of the American machines lies principally in the design, which is to the credit of the American draftsman, but also, although in a smaller degree, in the workmanship.

The claim that American machines are not strong enough, which is so often heard in Germany, both from dealers and users, is not mentioned here so much; in fact, only two persons out of a dozen whom the writer has interviewed on this subject, had anything to say to this effect, and one of these persons, a manufacturer, admitted that it was common practice here to use the machines for much heavier work than they were ever intended and built for. An interesting fact, needing no comments, is that in the automobile shops visited by the writer, he found that the large majority of machines used were of American make, and only a few of German and English manufacture.

It may not be out of place to mention that although the workmanship of American machines is good in general, there are sometimes found deplorable examples of carelessness of inspection in some of the machines of American manufacture. A few days ago the writer, when calling on a machinery dealer, saw a machine of American make which this dealer had sold and delivered, but which afterward had been returned, because of not being satisfactory, there being blowholes in the castings in places where such could not be tolerated, and several other defects. It must be added, however, that the dealer himself was very much surprised, and said that it was the first trouble of the kind that he had met with. The only reason for mentioning this is to suggest that too much attention cannot be paid to thorough inspection of machine tools before being sent abroad, in order to prevent occurrences of this kind, which, while everybody over here acquainted with American machine tools knows to be exceptional, still will prove harmful.

"Talking Points" in Selling Machine Tools.

The ease with which a machine can be sold depends, of course, in the first place upon the real merits of the machine, that is, on the amount and on the kind of work the machine is able to do; but so-called "talking points" have also proved themselves to be of great importance. Of two machines which are, in general, capable of doing the same amount of work, and are sold for the same price, the one possessing the largest number of talking points will prove to be the best seller. These points are, in the first place, of course, features of real merit in the machine, but in the second place, also features which are of no great importance as far as the working of the machine is concerned, but which nevertheless will attract the attention of the prospective buyer. One feature will draw the attention of one person, another, that of another person, the difference depending largely upon the technical standpoint of the man in question, and, therefore, one feature may be presented to good advantage at one time and in one country, while the same feature may be of less importance in another country and to other customers, depending on the conditions.

The general appearance of the machine, the smoothness of the unfinished cast surfaces, etc., is a point which some buyers pay attention to, while others do not. In Italy, the smoothly finished machine is preferred to the one of a coarser appearance. The writer had an opportunity to compare two lathes, capable of doing the same work, and which sold for about the same price, but one of these lathes was said to sell much better than the other. The special talking points for this better seller were simply that there was, in the first place, a less number of gears in the speed change mechanism running at the same time, and therefore there was less wear and less frictional loss; and in the second place that the pinion for engaging the rack for transmitting motion to the carriage could easily be disengaged, thus permitting the carriage to be pushed back and forth by hand, a feature which really is of small importance. In the stock-rooms of the same dealer a drill press could be seen which was said to sell well. The special feature about this was that instead of the spindle sleeve only being fed down, the whole spindle head with the bearing was fed down with the spindle, on account of which the spindle was less apt to get out of alignment on account of looseness and wear in the bearings. Another point which is found more frequently in German machines than in those of American make, is that nuts which often need to be loosened and tightened for the sake of adjustment are made with handles instead of being hexagon for adjustment by a wrench.

The Italian Automobile Industry.

Up to a few months ago the automobile industry, as already mentioned, occupied one of the leading places in the Italian machine industry. The Italian automobiles have succeeded in establishing for themselves a very high reputation, mostly because of having won prizes in a great many important international automobile contests. A great deal of the success of the Italian motor cars has been due to the importance with which the designing department in Italian motor car factories has always been regarded, and the older Italian automobile concerns have developed designs of very high standing. Nearly all the automobiles made here are of a high class and high priced, and the efforts of the designing department, as well as of the construction department, have been more

in the direction of obtaining the best possible motor car, than in the direction of turning out a car at a price within the reach of the average buyer. Although both the magneto high tension, and the low tension ignition systems are used in the motors, the first mentioned seems to be the one used to the largest extent. This system is more adapted to the high speeds used in automobile contests, while the low tension ignition system is better for ordinary speeds.

Italy as compared with America has an advantage because of its cheap labor. America has supplied Italy with its latest and most up-to-date machine tools, and Italy has been keen enough to learn and adopt a part of the American system of manufacturing, and is now, because of the cheap labor, able to put more efforts into getting the very best possible workmanship. An Italian firm can afford for the sake of good appearance, a thing which attracts the buyer with the long purse, to put exceedingly high finish on parts where it is really not needed; but this increases the reputation of the cars.

In automobiles where lightness is of great consequence, the quality of material used must be the very highest. The gears used in motor cars are, of course, one of the most important of the details, and some of the best concerns stated that they were using a special French steel for the gears, this steel having been developed especially for automobile gearing. The cylinder casting is a part on which much skill and thought has been expended by the designer as well as by the foundryman. The cylinders, because of being subjected to very high temperatures, simultaneously with high pressures, will develop severe internal stresses, which have to be taken care of both by the design and by the manner in which the cylinders are cast. A few of the Italian motor car makers, among them Isotta Fraschini, Milan, do not make their own cylinder castings, but buy them from France and Germany. Other concerns, as R. Züst, Milan, and Fabbrica Automobili Itala, Turin, make their own castings. Although the cast iron used in these cylinders is prepared with special care for the purpose, it seems that the largest importance is placed on the making of the molds.

Foundry Practice in Italian Automobile Factories.

At the outset, the Fabbrica Automobili Itala used wooden patterns for the molding of the cylinders, but in the long run, these became worn, and, therefore, produced castings of untrue dimensions, and besides, other troubles were found to present themselves when using wooden patterns. They, therefore, now use patterns of aluminum not only for the cylinders, but at present make all their patterns from this material. The best material to be used for the molds and cores themselves, has required careful study. For the sake of binding and hardening purposes the molding sand is mixed with potash, sugar, and salt, which mixture is carefully worked in a rotary mixer of the ordinary type, having crushing rolls and mixing blades. This material is used for molds of all kinds, as well as for cores.

Vent holes in the small cores are made in a manner similar to that mentioned in one of my former letters as being used in a German foundry. A thread coated with tallow is put in the core, and when the core is heated for drying purposes, the tallow melts, and the thread can easily be pulled out. A new system of molding is being adopted here and has, in fact, already reached a high degree of perfection. The idea is to divide up the mold into a few integral parts, which can be made entirely separate from each other in the same way as the cores are already made separately from the mold proper. These parts are then assembled to make up a complete mold. This simplifies greatly the art of molding, and also saves a large amount of time and labor, because each integral part, being made separately from the other parts, can be produced in a large number at a time, and stored away until needed for the purpose of assembling the complete mold, which can be done at any time, immediately before the metal is ready to be poured. The writer had an opportunity of seeing a mold for a cylinder piston, made according to this system, assembled and again taken apart. This mold was made in three parts, the first part constituting the bottom of the mold and the core, and the second part being the outer walls, which are made heavy in order to stand the strain produced by the hot metal when poured, and the third part was the top piece, having the necessary holes for pouring and for the vent. The three parts were made to fit nicely into each other, being easy to assemble and still permitting strong joints, a thing which is of great importance. This system is as yet used only for pieces of comparatively simple design, but it is expected that within a short time the same system will be used even for more complicated molds, as, for instance, for the cylinders. These are as yet made in the usual way.

Italian Shop Practice.

During the visits to several of the large automobile shops in Italy the writer had an opportunity to see some of their working methods. It was found that these were very similar in the different shops. A few remarks as to the practices in vogue will give an idea of the present standard of Italian shop practice. The first operation in finishing the cylinders was, of course, to finish the two end surfaces. This was done in a planer. Six to eight cylinder castings are clamped in a line on the planer table, and these are finished by taking one roughing and one finishing cut. When the two end surfaces are finished, the cylinder is set up in a vertical boring mill, where the cylinder proper is bored out to about 0.01 inch below the correct size. This operation is performed by using a special boring tool consisting of a main body, fastened in the toolholder, in which are inserted three single cutting tools arranged at angles 120 degrees apart. The cutting points of these tools are not at the same distance from the center, but arranged so that the first tool takes the first roughing cut in the cylinder, the second tool the second roughing cut, while the third tool takes the final finishing cut. The use of a three-pointed tool with 120-degree angle between the points produced a good balance of the cutting resistance, and the roughing cut, being divided up into two cuts, does not need to be very heavy.

From the boring mill the cylinder was taken to the grinding machine, where the bore was ground to the true size. The internal grinding machine used for this purpose was built so that the cylinder could be placed stationary on the machine, the center of the grinding spindle having a circular or planetary motion around the axis of the cylinder, so as to bring the wheel in contact with each point of the cylinder bore. The next operation is to finish the valve seats. This is done in a vertical boring mill by a double cutting tool, which is made according to the angle of the seats. The tool is marked so as to indicate the depth to which it should be fed down in order to get the seats accurate. Afterwards the sides of the flanges are milled in a horizontal milling machine, the necessary holes drilled, and the other small operations carried out in turn.

The turning of the crank-shafts always involves some difficulties. In the Fabbrica Automobili Itala the crank-shafts were turned in the following way. The first operation was to center the shafts for turning the journals. These were then turned, and the outer plain surfaces of the cranks and the outer ends of the cranks faced. In order to get the centers for turning the four crank-pins, a round fixture was put on at each end of the shaft, these fixtures having the centers drilled into them. With these fixtures on, the shaft was placed between the centers in a lathe, and one of the fixtures was clamped by means of an independent chuck. With the shaft thus fixed, one crank-pin after the other was turned, and the inner sides of the cranks faced. The remaining flat surfaces, which could not be finished in the lathe, were later finished by milling. The journals and the crank-pins were turned somewhat oversize, leaving enough for grinding the crank-shafts, which were held in the grinding machine in the same manner as described for the turning operation.

These indications of Italian shop practice show that work is done very much in the same way as in American shops.

Prospects of the Italian Automobile Manufacture.

It is interesting to note the opinions of a large number of leading machine tool dealers and other persons of technical standing in Italy, regarding the future of the Italian automobile industry. Most of these people do not seem to believe

that Italian automobiles are actually superior to American cars, but answered questions regarding this subject with a smile, saying that Italian automobiles had had "good luck" in contests, but expected that within a few years American motor cars would be imported to Italy.

Wages in Italy.

The wages paid to the average skilled workman in Italy—the machinists, molders, pattern-makers, etc.—vary from 4 to 6 lire ($0.80 to $1.20) per day, and men of more than average skill, such as tool-makers, are paid from 6 to 8 lire ($1.20 to $1.60) a day, all based on a ten-hour day. These figures are as stated by the automobile factories. These used to be the best paying shops in Italy, but on account of the crisis, the wages in the automobile shops were reduced a short time ago, so that the figures given can be considered to be reasonably accurate for all Italian machine shops. Compared with American wages, these are very low, but living expenses are also lower here, and another point to be considered is that the working man is here insured for sickness, and an old age pension is provided, the premiums for which are paid partly by the employer. The regular straight piece-work system seems to be favored in all the shops visited here.

World's Fair in Turin, 1911.

It is, as yet, entirely too early to say anything regarding the contemplated World's Fair in Turin in 1911. The leading men of the industries in Italy, who were interviewed on this subject, did not seem to be very optimistic about the enterprise, but rather the opposite. Their view was, that as far as Italy is concerned, not much could be gained by an exposition, but a great deal of money would be required for the arrangements, and Italy can hardly afford to spend the money for purposes of this kind at the present time. Aside from this, the exhibiting machine manufacturers have to go to a large expense, and are doubtful about whether they afterwards will be amply repaid for this in increased trade.

Trade Conditions in Switzerland.

The industrial conditions which have been noted as existing in the eastern part of Germany and in Italy can also be observed in Switzerland. The manufacturers of machine tools, as well as of other kinds of machinery, have apparently a fair amount of work on hand and are working with full or nearly full force, while the dealers in machine tools complain that business is very dull, and that no improvement in the conditions worth mentioning has taken place. The watch industry in the eastern part of Switzerland, which is of great importance, is at present very dull, largely owing to the fact that on account of the financial depression in the United States no export of watches takes place to this country. In fact, dealers in machinery in Switzerland seem to be more pessimistic about the future than are those in Germany and Italy.

After having visited Germany, Austria, and Italy, the differences in conditions in Switzerland are striking. It appears that the republican form of government has here had an influence on the general spirit even in the machine shops. The pay is somewhat, although not much higher here than in the neighboring southern Germany. Skilled machinists receive on an average 7 francs ($1.37) a day; but more than in the matter of pay does it here appear that the democratic form of government has influenced the ideals of the shop in regard to the relation between the foreman and the men under him. When talking to his foreman, the employe neither is required to, nor does he, assume that attitude of subordination created by the military spirit of discipline which is so commonly observed in Germany. More of the democratic equality is in evidence, and the same spirit is exhibited as is found in most American shops. The visitor realizes this as soon as he is inside the shop, and it becomes still more apparent to him as he is walking around, inspecting the machinery, and watching the men at their work.

* * *

According to a note in *Mercator*, a brick-yard is at the present time being established at Skutskär in Sweden for making "brick" from the refuse from sulphite mills. It is stated that the "brick" thus manufactured possesses all the qualities of ordinary brick.

MISCELLANEOUS FOREIGN NOTES.

German Imports and Exports of Machine Tools.—According to statistical tables published in the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, issue of March 25, 1908, the exports of German machine tools in 1907 amounted to 58,051 metric tons, as compared with 22,743 metric tons five years ago. The increase over the previous year amounted to 12,743 tons. The imports in 1907 amounted to 8,175 tons, being a decrease of 5,974 tons, as compared with 1906. Of the imports, nearly 70 per cent came from the United States, and about 11 per cent from Great Britain. The decrease in the imports from the United States, as compared with the previous year, amounted to about 4 per cent. As regards exports, Italy is the largest customer of Germany in the machine tool line. Austria-Hungary, France, Switzerland, and Belgium come next, in the order mentioned. The exports to Italy alone amounted to 12,580 tons, or more than one-fifth of the total exports.

Growth of Russian Industries.—Russia, which until lately imported nearly all her supplies of machinery and other iron products, has of late become an exporting country, the industries of Russia having, during the last years, developed on a large scale. The iron industry has begun to play an important part in the country's exports. Rails and railroad cars, particularly freight cars, have been exported; rails to Servia, Roumania and Argentina, particularly, and railroad cars to Italy. Russia has immense possibilities for industrial extension, having unlimited resources in nearly all directions. Fresh naphtha and coal deposits are constantly being discovered, and mining and manufacture are steadily becoming better organized, and made rational. The primitive methods of the Russians so often referred to, excepting perhaps in agriculture, will soon be a thing of the past. Immigration from European Russia to Siberia is increasing tremendously, and the vast resources of northern Asia are likely to be greatly developed during the next decade.

The Neville Machine & Tool Co., Ltd., 7 James St., Liverpool, England, has brought out an interesting portable radial drilling machine. The base of the machine is mounted on four small wheels, and is also provided with four resting blocks, secured to screws passing through brackets in the base. When the machine is in use, the screws and resting blocks are so adjusted that the base rests on these, instead of on the wheels, and the weight of the machine provides enough stability for any ordinary drilling operation. When the machine is to be moved, the screws securing the resting blocks are turned, thereby lifting the blocks so that the base will rest on the wheels. The radial arm is so mounted that it can be turned through an angle of 360 degrees. The maximum length of the arm is 3 feet 7 inches, having a vertical adjustment over the base plate of 4 feet 11 inches. The base plate is 6 feet 6 inches by 2 feet, and the traverse adjustment of the tool-carrying head is 2 feet.

Trade Conditions in Belgium.—It is reported from Belgium that the iron, steel, and machinery industries are not as crowded with orders as they have been for some time past, and that prices, which have been for some time rather abnormally high, have a tendency to return to a more normal level. Foreign competition, particularly from Germany and Great Britain, is becoming more keen, since in these countries there has been a somewhat smaller demand placed on the industries by the home market during the last few months. It is also likely that before long American competition in Belgium will also influence local conditions, since American manufacturers are likely to have an opportunity for some time to come to devote themselves to foreign trade. The keen competition at home, however, has caused Belgian exporters to make efforts to form a syndicate for promoting their foreign trade. This syndicate is intended to have representatives and selling agents in all the important centers all over the world. Being only a selling syndicate, the proposed capital of $5,000,000 is rather a large one, and the combination may have some future ahead of it. The organization is well systematized, and intends to do banking business and take care of transportation for its members, as well. In general, it might be said that the outlook for the Belgian machinery industry is satisfactory.

MACHINERY AND SUPPLY CONVENTION.

The joint convention of the Southern Supply and Machinery Dealers' Association, the National Supply and Machinery Dealers' Association, and the American Supply and Machinery Manufacturers' Association, met in Richmond, Va., May 13, 14, and 15. Manufacturers and merchants from all parts of the country, engaged in the manufacture of machinery and supplies, and in its distribution, were represented. The three organizations went on record as opposing any reduction of prices at this time. Action was taken looking toward influencing the United States Government in requiring that all goods purchased by the Government should be marked with the name of the manufacturer. Resolutions were passed opposing legislative action in behalf of so-called "anti-trust" and "anti-injunction" measures, and requesting legislation sanctioning the combination of manufacturers and merchants, where such cooperation proves beneficial to the industries and trades, and is not harmful to the public.

A number of addresses were made, among which may be mentioned one by Mr. F. A. Hall, of the Yale & Towne Mfg. Co., New York, who spoke on the subject of "Resale Prices." In connection with this, it may be mentioned that the associations reaffirmed their endorsement of the minimum resale price system. The dealers' organizations pledged themselves to assist the manufacturers in the rigid enforcement of this system wherever adopted. Other addresses of interest were: "Salesmanship," by Mr. W. E. Gerow, of the Atlantic Supply Co., Jacksonville, Fla., and "Commercial Fraternity," by Mr. C. A. Moore, president Manning, Maxwell & Moore, New York City. Mr. D. K. Swartwout, of the Ohio Blower Co., Cleveland, Ohio, gave a "Plain Talk to Jobbers," and Mr. W. M. Pattison, of the W. M. Pattison Supply Co., Cleveland, Ohio, spoke on the "Advantages of Cooperation in Machinery and Supply Business." Finally, Mr. Robert Wuest, commissioner of the National Metal Trades Association, Cincinnati, Ohio, spoke on the "Benefits Derived from Trade Organization," and Secretary Wm. H. Taft, who was invited to address the joint convention, delivered an address on "The Value of Trade Organization." The committee in charge of the convention had arranged for several entertainments, including a smoker and vaudeville performance, at the Jefferson Auditorium, and a banquet.

Mr. J. C. Miller, of Huntington, W. Va., was elected president of the Southern Supply and Machinery Dealers' Association, and Mr. Alvin M. Smith, of Richmond, Va., secretary and treasurer. Mr. George Puchta, of Cincinnati, Ohio, was elected president of the National Supply and Machinery Dealers' Association, and Mr. A. T. Anderson, of Cleveland, Ohio, secretary and treasurer. Mr. Chas. F. Aaron, of New York City, was elected president of the American Supply and Machinery Manufacturers' Association.

* * *

OPENING OF THE MACHINERY CLUB OF NEW YORK.

The Machinery Club of New York, the movement for the organization of which was commenced over a year ago, opened its quarters on the 21st and 22d floors of the Fulton Terminal Building, corner of Fulton and Church streets, on May 21. The purpose of the club is to bring into closer contact the great number of men who are engaged in the machinery business in New York City, and those otherwise interested in the machine industry. The club is also intended to be the headquarters for out-of-town members, and while it will be primarily a lunching club, it is expected that the convenient location and the excellent and pleasant quarters will make it a general meeting place for the machinery trade in New York, and a home-like stopping place for those residing elsewhere, whose business takes them to New York at intervals.

The main feature of the opening was an address by Mr. George A. Post, president of the Standard Coupler Co., who, in some well-chosen remarks, explained the purpose of the club and the intentions of its organizers. A luncheon was also served. The number of people present at this occasion, and the general appreciation expressed of the efforts of those who have been most active in the organization of the club, seemed to indicate the complete success of the undertaking.

The movement for the organization of the Machinery Club was begun on April 1, 1907, when Mr. F. H. Stillman, president of the Watson-Stillman Co., called a meeting of the trade at the rooms of the Board of Trade and Transportation. At this meeting more than two hundred men engaged in the machinery and metal trades and allied industries were present, and a committee was appointed to form an organization. The efforts of the organizers have been well rewarded, 1,100 members having been enrolled before the opening of the new quarters, and there are now more than 500 resident members.

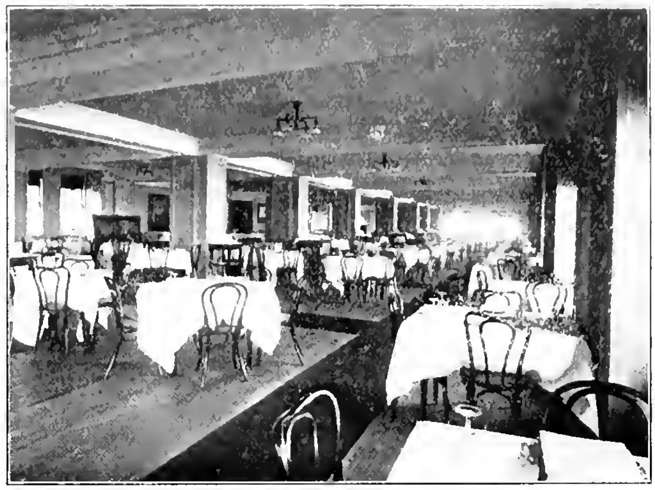


Fig. 1. Main Dining Room, 50 x 150 feet.

The club occupies the entire 21st and 22d floors of the Fulton Building. The main dining room is located on the 21st floor and its dimensions are 50 x 150 feet. Besides this, there is, on the same floor, a large furnished lobby, a grill room, 38 x 54 feet, and a reception room, 26 x 63 feet. A unique feature of the grill room, and one which undoubtedly will be appreciated by out-of-town members, is a large round table placed in a conspicuous place, which is called the club's "open table." The out-of-town members, and others who have but a limited acquaintance in New York, will there find members who will join in conversation with them, as it is an established rule that diners at this table may engage each other in conversation without the formality of an introduction.

Fig. 2. Reception and Reading Room.

On the 22d floor are located an unusually attractive smoking room, an equally attractive ladies' dining room, and several private dining rooms. The 22d floor is the top floor of the building, and a spacious roof-garden will be one of the prominent features of the club arrangements. Much credit is due to the house committee, to which has fallen the task of furnishing the club rooms, and supervising and arranging for the purchase of furniture, etc. The foremost idea of this committee seems to have been to furnish the place in a manner so that it would be comfortable, at the same time avoiding unnecessary luxury or mere useless ornamentation. The

club rooms have the general appearance of being in harmony with the business for which they will become a common gathering place.

A feature that makes the location unusually attractive, aside from its very central position in the machinery district, is the unequaled transportation facilities for reaching the uptown hotel district of New York and the outlying manufacturing districts of Newark, Jersey City, and Brooklyn. The Hudson & Manhattan R. R. connecting with the Subway and joining New York with New Jersey by a great tunnel system, will have its principal station in the sub-basement of the

Fig. 3. Smoking Room.

twin Fulton and Cortlandt Terminal structures. The Cortlandt Terminal Building is also the home of a large club, the rooms of the Railroad Club being on the 21st and 22d floors.

The officers of the Machinery Club are F. H. Stillman, president; R. C. McKinney, vice-president; Walter L. Pierce, treasurer; W. Seton Henry, acting secretary.

* * *

SPRING MEETING OF THE NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION.

The spring meeting of the National Machine Tool Builders' Association was held at the Hotel Chalfonte, Atlantic City, N. J., May 19-20, and was conducted by President Fred L. Eberhardt of Gould & Eberhardt, and Secretary P. E.

Group of Machine Tool Builders and Guests at Atlantic City, May 19, 1908.

Montanus of the Springfield Machine Tool Co. Forty-nine of the ninety-one concerns having membership in the association were registered. Five new members were enrolled, these being the T. C. Dill Machine Co., Philadelphia, Pa.; Edwin Harrington Son & Co., Inc., Philadelphia, Pa.; Ingersoll Milling Machine Co., Rockford, Ill.; International Machine Tool Co., Indianapolis, Ind.; and the Sibley Machine Tool Co., South Bend, Ind.

The more important matters discussed, of general interest, were uniform cost accounting, machine tool prices, cancelation of orders, uniform sale contracts, apprenticeship and readjustment of railway rates. The report of the committee on uniform cost accounting, presented by Mr. C. Wood Walter of the Cincinnati Milling Machine Co. in the absence of Mr. F. A. Geier, the chairman, was accompanied by a pamphlet prepared for the association by the Miller & Franklin Co., Boston, Mass., which explains the system in detail.

It was unanimously agreed that there was no good reason for changing the present prices of machine tools. The cost of materials has undergone little or no reduction, pig iron being almost the only exception, and wages are practically unchanged. With the resumption of business, machine tools will actually cost more than before the panic because of the inefficiency of new help that must be taken on and trained to replace the men laid off. The association placed itself on record in favor of arbitration among its members, it being recommended that the parties in dispute each choose a representative and these choose a third to act as a board of three to settle the matter. It was the sense of the association that differences in patent matters could be adjusted in this way very much more satisfactorily and cheaply than by recourse to the courts.

The cancelation of orders by buyers of machine tools is a particularly sore subject just now, and much warmth of feeling was displayed in this discussion. The injustice of the present custom which permits an intending purchaser to cancel any or all orders for machine tools at will was pointed out, and resolutions were adopted to discourage the practice. Other lines of manufacture do not countenance cancelation of orders, the purchaser being unable to break contracts without the consent of the manufacturer or without forfeiting a certain part of the purchase money deposited when the contract was made. In the report by Mr. C. A. Johnson of the Gisholt Machine Co., a uniform contract was recommended that should cover cancelation and provide that title to all machinery sold should not pass to the purchaser until the full purchase money had been paid. The defective business practice of jobbing foundries which supply machine tool castings was caustically referred to by Mr. C. H. Norton of the Norton Grinding Co. in a minority report, and American practice was compared with European practice, much to the advantage of the latter.

Mr. J. H. Cone, of the National Metal Trades Association, of Cincinnati, addressed the meeting just before adjournment on cooperative engineering education, and noted the remarkably good results that have come from the innovation in the Cincinnati University. Not only have the students who took the coöperative engineering course been able to keep abreast of their classes, although in school but half time, but their examinations were higher in average rating than those taking the full time course. More remarkable has been the effect on the system of teaching. The practical knowledge obtained by the boys alternately working one week in the Cincinnati shops and one week in the university shows the weaknesses of much mechanical engineering instruction. It is believed that this system of mechanical education will spread, as its practical benefits become known.

* * *

PERSONAL.

John E. Willard has been made manager of the Union Gas Engine Co., San Francisco, Cal.

Norman G. Meade, electrical expert and occasional contributor to MACHINERY, is now with the New York Edison Co. in charge of the editorial work on the *Edison Bulletin*.

G. O. Gridley, manager of the Windsor Machine Co., Windsor, Vermont, will sail for England the first week in June. Mr. Gridley expects to be gone about six weeks.

Herbert C. Petty has been elected a director of the Crocker-Wheeler Co. Mr. Petty entered the service of the company in 1903, and advanced rapidly to the position of contract manager.

Edward B. Busby, formerly with the Midvale Steel Co., is now employed in the selling department of the Electric Welding Products Co., Cleveland, Ohio, formerly the Cleveland Cap Screw Co.

J. E. Merrill, foreman pattern-maker of the Waterbury Mfg. Co., Waterbury, Conn., has left that concern to take charge of the pattern shop of the Bridgeport Foundry and Machine Co., Bridgeport, Conn.

Russell A. Stinson, vice-president of the Canadian Crocker-Wheeler Co., Ltd., Montreal, recently organized, has been identified with the manufacture, construction and sales end of the electrical trade in Canada for the past fifteen years.

T. W. Meachem, president of the New Process Raw Hide Co., has been elected president of the Chamber of Commerce of Syracuse, N. Y., which is a merited recognition of business ability from a community where Mr. Meachem is well known.

F. E. Lovell, president of the Canadian Crocker-Wheeler Co., Ltd., Montreal, is a member of the old-established lumbering firm of H. Lovell & Sons, Coaticocke, Quebec, which has extensive interests in mills and timber lands throughout the province of Quebec.

F. John Bell, secretary-treasurer of the Canadian Crocker-Wheeler Co., Ltd., has been identified with the electrical trade in Canada for the past fifteen years, and is well-known in Montreal, where the head office of the company has recently been opened.

Dr. Schuyler Skaats Wheeler, past president of the American Institute of Electrical Engineers, and president of the Society of Engineers, addressed the engineering society of Columbia University, May 4, on the subject of engineering honor. Dr. Wheeler mentioned the three great duties of the engineer in the order of their importance: First, the engineer's attitude to his client; second, to the public; and third, to his engineering society. He strongly condemned the publication of all fake scientific and engineering statements, and insisted that discoveries and inventions should be announced not in the daily papers, but through technical societies or through the technical press.

The many friends and admirers of Prof. William Kent, dean of the College of Applied Science, Syracuse, N. Y., and compiler of Kent's "Mechanical Engineer's Pocket Book," are much interested in the controversy raging between him and Chancellor James R. Day, of the university, over the former's action in regard to the alleged perilous condition of certain of the university buildings. Following the terrible school building fire in Collinwood, Ohio, March 4, in which 165 children died, Dean Kent called attention to the lack of fire escapes and fire protective construction in the College of Applied Science building, claiming that the conditions were extremely hazardous, but was ridiculed for his pains. He applied to the public authorities of Syracuse for an investigation, the result being that his claims were sustained. As a result of going over the chancellor's head, Dean Kent's resignation has been demanded. This he has refused to give because his actions were dictated by motives of public policy, being what any citizen had a right to do. No reflection has been cast on his ability as an educator or engineer, the demand for resignation being made because of disregarding the opinion of the chancellor on a matter of safeguarding human lives.

* * *

OBITUARY.

Arthur Koppel, head of the Arthur Koppel Co., New York, died suddenly of heart disease at Baden-Baden, Germany, May 13. Mr. Koppel was fifty-six years old. He leaves a wife, three sons, and a daughter.

We announce with deep regret the sudden death of our Paris representative, Mr. Eloi Delmouly, who was asphyxiated by the gas from a stove set up for heating purposes. Mr. Delmouly was well known as an engineer in his special field. He was a bachelor with no relatives in Paris, and will be buried at his native place, Agen, in the southern part of France.

Francis B. Stevens died at his home at Castle Point, Hoboken, N. J., May 23, at the age of nearly ninety-four years. Mr. Stevens was born at Trenton, N. J., October 16, 1814. He was educated in the New York University and became a civil engineer. He made a number of inventions, the best known of which is the Stevens cut-off, first applied to the steamboat *Albany* in 1840. His uncle, Edwin A. Stevens, was the founder of Stevens Institute.

William Dana Ewart.

WILLIAM DANA EWART.

The death at Rome, Italy, on Sunday, May 3, of William Dana Ewart, will be noted with more than ordinary regret by those whom his genial disposition had made his friends and by the many others to whom his most prominent invention has made his name familiar. Mr. Ewart was born in Ohio about fifty-six years ago, and at a comparatively early age gave evidence of an inventive mind and rare mechanical ability. He was the inventor of the malleable-iron detachable drive chain, first known under his name and in later years as link-belt, which has formed an important part of agricultural and other interchangeable machinery, and has, to possibly a greater extent than any other single invention, helped the wonderful progress in the development of elevating and conveying machinery during the past thirty years. This drive chain has been continuously manufactured by the Ewart Manufacturing Company and exploited by the Link-Belt Machinery and Link-Belt Engineering Companies till, in 1906, all three companies were consolidated into the Link-Belt Company, a corporation in which he was largely interested, and whose fortunes are still largely directed by his former associates. Mr. Ewart, whose abilities brought their proper reward, was not only an inventor, but a man of executive capacity, possessing a rare gift for harmonizing differences and securing cooperation. His health becoming impaired, he retired in his early prime from the activities of business and sought renewal of physical strength under more favorable climatic conditions abroad.

* * *

From time to time we have mentioned in these columns some experiments that have been carried on in Europe to perfect the process for the production of alcohol from peat, initiated nearly forty years ago. It is now stated that important progress has been made in the last two years by a Frenchman, Raynaud, and that the results obtained are so encouraging that a plant for manufacturing alcohol from peat on a commercial scale will be erected in northern Germany. According to statements made by Professor Ramsay, one ton of dry peat will furnish 42½ gallons of pure spirits, giving as a by-product about 66 per cent of sulphate of ammonia. Owing to the fact that the only obstacle to the more extended use of alcohol at the present time is its price, this process, if successful, will tend to solve an important power problem of the future, it being asserted that the manufacturing cost of one gallon of 97 per cent alcohol will be only about ten cents.

A WARNING TO MACHINERY DEALERS AND MANUFACTURERS.

Iron and steel companies, machine manufacturers, hardware dealers, etc., are cautioned against transacting business with a party who is at the present time floating worthless checks. His methods of operating are first to write to a certain concern for a catalogue, etc., from an address in almost any part of the country. Later he calls upon such firm with said catalogue and certain articles marked, asking to see these goods and places an order for same, giving a fictitious address. He then asks if a deposit is desired on the transaction and fills out a blank check in sums ranging from $200 to $1,500. Sometimes he gives a large check in part payment and asks for a certain amount, probably one-third or less, to be given him in cash for necessary expenses as he has no one in the vicinity who can identify him in order to have a check cashed.

He may use almost any name, but is known to have operated under names of: K. S. Miller, H. B. Miller, P. P. Hilliard. He is described as being an American, 28 years of age, 5 feet 7 inches tall, 160 pounds in weight, good build, dark hair, smooth shaven and has a large burn scar on the left side of his face. Any information relative to the operations of this party that will be referred to the American Bankers' Association or their agents, Pinkerton's National Detective Agency, New York, will receive prompt attention.

* * *

THE TWO-JAWED LATHE CHUCK PATENTED.

An article was published in the May issue by Mr. Ethan Viall describing a two-jawed lathe chuck used by the H. Mueller Mfg. Co., Decatur, Ill., with the statement that the chuck was patented in 1889 and, therefore, that the patent had expired. We are informed by the patentee, Mr. Edward Marcille, Peoria, Ill., that this statement is an error, the chuck having been patented January 3, 1899, instead of in 1889. Consequently our readers will know that this interesting and valuable chuck construction is not open to the public.

* * *

Beginning with the issue of June 5, the *Railroad Gazette* of New York and the *Railway Age* of Chicago, will be issued as a single combined weekly periodical, under the name of the *Railroad Age Gazette*, with the publication office in New York. Both papers have been long established, the *Railroad Gazette* for more than fifty-two years, and the *Railway Age* for thirty-two years. The changed conditions in railway business have made the advertising support inadequate for two expensively conducted journals in the field.

* * *

NEW BOOKS AND PAMPHLETS.

HANDBOOK OF MATHEMATICS FOR ENGINEERS. By L. A. Waterbury. 91 pages, 2¾ x 5½ inches. Published by John Wiley & Sons, New York. Price $1.00.

This little work is intended to be a vest-pocket handbook of mathematics for engineers. It treats of algebra, trigonometry, analytical geometry, differential calculus, integral calculus, theoretical mechanics, mechanics of materials. A thumb index is provided for convenient reference and a special index makes the work very convenient for reference.

STRENGTH OF CHAIN LINKS. By G. A. Goodenough and L. E. Moore. 73 pages, 6 x 9 inches, illustrated. Published by the University of Illinois, Urbana, Ill.

This bulletin, No. 18, records results of a series of tests to determine the strength of chain links, and to verify the laws and formulas for the strength of chains. The appendix gives at length the theory of stresses in curved bars, analysis of the open link, derivation of theoretical formulas for the change of length in the axis of the link, and analysis of stud link. The pamphlet is one of much practical value to designers and engineers having use for chains in machinery or for handling materials.

AUTOGENOUS WELDING OF METALS. By L. L. Bernier. 45 pages, 4½ x 6½ inches. Published by the *Boilermaker*, 17 Battery Place, New York City. Price $1.00.

This pamphlet is a description of the application of autogenous welding to the manufacture of tanks and other receptacles made of plate metal. The autogenous process is essentially a welding process, the heat of the oxy-acetylene flame being so great that the metal at the joint is fused and joined together into a perfect weld. The flame may be made oxidizing or non-oxidizing to suit the requirements of the case. In welding it is of course made non-oxidizing and when used for cutting metals apart it is preferably oxidizing. The importance of the process for tank making is obvious.

THERMODYNAMICS OF TECHNICAL GAS REACTIONS. By F. Haber. 356 pages, 6 x 9 inches. Published by Longmans, Green & Co., New York. Price $3.00, net.

This book is made up of seven lectures on chemical reaction and its relation to reaction energy; entropy and its consequence in gas reactions; derivation of formula, and its effect on reactions of solids; examples of reactions which proceed without change in the number of molecules; examples of reactions involving a change in the number of molecules; the determination of the specific heats of gases; and the determination of gas equilibria, with the theoretical and technical discussion of related questions. The work is technical and of interest to those only concerned with the chemical and technical problems of thermodynamics.

TABLES AND OTHER DATA FOR ENGINEERS AND BUSINESS MEN. Compiled by Chas. E. Ferris, Professor of Mechanical Engineering, University of Tennessee. 160 pages, 2½ x 5½ inches. Published by the University Press, Knoxville, Tenn. Price 50 cents.

This little vest-pocket manual for engineers was issued primarily to advertise the University of Tennessee. The large demand for it shows that it meets a common want, the present issue being of the tenth edition. It contains metric conversion table, tables of areas and circumferences of circles, tables of squares, cubes and reciprocals, weights of rivets and round head bolts; weights and areas of square and round bars; weights of sheet or wrought iron, steel, copper and brass; tables of sines, tangents and secants, hyperbolic logarithms, and many other tables of common use among engineers.

THE STEAM TURBINE. By Robert M. Neilson. 604 pages, 6 x 9 inches, 387 illustrations. Published by Longmans, Green & Co., New York. Price $4.20, net.

The first edition of Mr. Neilson's work was issued in 1902. This book is of the second edition, in which the descriptions of Parsons and De Laval steam turbines have been considerably enlarged, as well as the chapter on marine propulsion. A new chapter has been added, in which the Parsons, Stumpf, Schulz, Curtis and Seger turbines are described. The book treats of the fundamental notes and definitions of the steam turbine, the conversion of heat energy and steam into kinetic energy, types of steam turbines, losses and efficiency, steam turbines of five classes, low pressure steam turbines, effects of steam pressure, superheat and vacuum on efficiency, etc. An appendix contains a list of British patents on steam turbines from the earliest records up to the end of 1905. The work will be found a very satisfactory treatise on the subject and can be recommended to those interested in mechanical construction and theoretical treatment.

BETTERMENT BRIEFS. By H. W. Jacobs. 240 pages, 6 x 9 inches, 132 illustrations. Published by the author, Topeka, Kansas.

The work is a collection of some contributions on railroad betterment that have been published from time to time, and are now brought together and bound in book form. The author is assistant superintendent of motive power of the Atchison, Topeka & Santa Fe Railway System, Topeka, Kansas, and has had an unusual opportunity of studying the organization and efficiency of the railway machine shop. It illustrates many time-saving devices that are in daily use and gives particular attention to the use of high-speed steel on the lathe, planer, milling machine and other machine tools. An example of motion pictures is given on page 158, which were taken for the instruction and the entertainment of the men. These pictures show examples of machine work, firing locomotives, etc., and help to enlist their interest and co-operation in the promotion of more efficient methods. The work as a whole is one that can be most highly recommended to railway shop master mechanics, superintendents of motive power and all concerned in the increase of the efficiency of railway repair shops.

MACHINE DESIGN, CONSTRUCTION AND DRAWING. By Henry J. Spooner. 691 pages, 6 x 9 inches. About 1,500 figure numbers and 4 folding plates. Published by Longmans, Green & Co., New York. Price $3.50.

Sixty-five pages of the work are devoted to the subject of drawing, being on drawing instruments, materials, scales, and drawing to scale; how to draw straight lines and simple figures; circular arcs and lines, and how to commence a working drawing. Then follow chapters on machine details, including leather collars, shafting, crankshafts, cranks, journals, couplings, clutches, key and keyway, riveted joints, bolts, nuts, screws, pipe and pipe connection, cotters and cottered joints, bearings, journals, hangers, roller and ball bearings, toothed gearing, friction gearing, wire rope gearing, chains, crane hooks, steel and iron cranks, pistons and piston rods cross-heads, guides, connecting-rods, engine eccentrics, machine handles, materials used in construction of machines, strength of beams, hints on designing machines and machine parts, springs, miscellaneous. The work is voluminous, and certainly covers a large amount of engineering matter. It should be of general value to students, draftsmen, engineers and others concerned in machine construction and detail.

BRENNAN'S HAND BOOK. A compendium of useful legal information for business men. By B. A. Brennan, contract manager of the Westinghouse Machine Co. 571 pages, 4 x 6½ inches. Published by *The Electric Journal*, 422 Sixth Ave., Pittsburg, Pa. Price $6.00.

This book was compiled to meet the wants of the author, who is the contract manager of the Westinghouse Machine Co., and contains a synopsis of the statutes bearing on the collection laws of the different states and useful legal forms. The work by sections is: I. Contracts in general; II. Sale Contracts; III. Property, Deeds, Mortgages, Liens, Interest; IV. Acknowledgments, Power of Attorney, Licenses, Guarantees, etc.; V. Notes, Checks, Interest; VI. Negotiable Instruments; VII. Synopsis of Statutes on Conditional Sales, Chattel Mortgages, Bills, Notes, Forms of Acknowledgments; VIII. Collection Laws Tabulated; IX. Legal Forms. It is obvious that this publication of legal lore, presented in everyday language, is of the greatest value to manufacturers, shop managers, merchants, dealers, and others doing business in various states. The book is well printed and bound in flexible leather, with gilt-edged pages, being suitable for the library, desk or traveling purposes.

POWER AND POWER TRANSMISSION. By E. W. Kerr. 366 pages, 6 x 9 inches. 263 illustrations. Published by John Wiley & Sons, New York. Price $2.00.

This book is made up largely of the subject matter of lectures delivered by the author, who is professor of mechanical engineering, Louisiana State University. The present issue is of the second edition, in which the chapters on steam turbines and valve diagrams have been rearranged and added to. A valuable feature is practical problems; 175 problems and 10 pages more of matter have been added. The work defines the terms used in machinery and mechanics, and treats of shafting, bearings, frictional lubrication of bearings, friction wheels, pulleys, bevel gearing, screws, cams, the lathe, pipe fittings, heat, steam, simple steam engines, automatic cut-off engines, indicators, compound engines, valves, valve gearing, valve diagrams, rotary engines, steam turbines, pumping machinery, gas engines, compressed air and hot air engines. The book has one fault common to many otherwise excellent American technical books, and that is the liberal use of manufacturers' electrotypes of a style and size totally unsuitable to the general character of the work. The book is well suited to the needs of students in mechanical and engineering courses.

ELEVATOR SERVICE. By Reginald Pelham Bolton. 69 pages, 7½ x 10¾ inches. Published by the author, 527 Fifth Ave., New York. Price $5.00.

This work treats of the conditions and proportions of elevators, and gives diagrams, formulas and tables for passenger travel, relation of the elevators to the building, and proportions and loads of cars. Its contents by chapters are: I. Problem of Vertical Transportation; II. Conditions; III. Passengers and Operators; IV. Rating the Work of the Elevator; V. Computing the Average Work; VI. Shape and Size of the Car; VII. Load and Speed Conditions; VIII. Building Its Prearranged Surface; IX. Examples of the Use of Large Chart Giving the Relation of Elevators to Area of Floors; X. Definitions of Some Terms Used in Connection with the Elevators. The problem of vertical transportation has become one of the most serious that the constructing engineer has to deal with in the modern office

MACHINERY.

July, 1908.

CAM APPLICATIONS.*

MECHANISMS EMPLOYED IN CONNECTION WITH CAMS.

GEORGE W. ARMSTRONG.†

George W. Armstrong.‡

Cams and their attendant levers, considered merely as simple machine elements, are without doubt the most versatile of mechanisms; and, when subjected to the designer's consideration, may be developed along such diverse lines, and made to exhibit such limitless possibilities, as are shared in no comparable degree by any other elementary mechanical principles at his command. Even with all their inherent adaptabilities, however, their field may be greatly extended by conjunctive appliances devised to control or modify their motions and applications in various ways. It is the purpose of this article to illustrate several such devices designed by the writer. Some of these performed their functions very satisfactorily, and appear as features in patented machines, while others never reached the stage of practical application, although this need not detract from their interest as theoretical mechanical movements.

Cam Combination Movement No. 1.

Figs. 1, 2, and 3 represent the solution of three inter-dependent problems. The requirements of the one illustrated by Fig. 1 were that two bell crank levers, working oppositely,

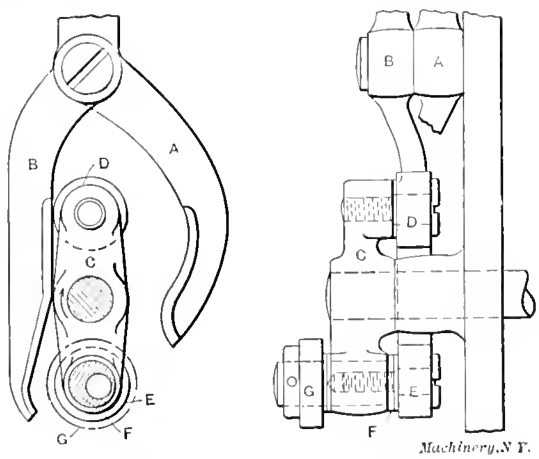

Fig. 1. Cam Combination Movement No. 1.

should transmit to other machine elements a variable motion, differing in each lever (the kind of motion, length, or time not being pertinent to this discussion). Every other vibration of each lever must be through a certain angle a; the alternate vibrations of each lever must have the angle a varied through a cycle of twelve vibrations from a maximum to a minimum, and vice versa, in harmonic ratio, a being the mean.

Levers *A* and *B*, with properly shaped cam arms, are operated by the rolls on arm *C*, which alternately engage the lever cam surfaces. The roll *D* gives the angle a. Roll *E* is eccentrically fastened to the bushing *F*, which is rotated in its seat by the star wheel *G* one-twelfth of a revolution per revolution of arm *C*, thereby carrying the roll to and from the center to vary the angle of vibration according to the imposed conditions.

Cam Combination Movement No. 2.

Another mechanism, acting with the above, presents to a certain extent somewhat similar conditions. An irregular vertical line *G*, Fig. 2, is desired reproduced by the upper end of a lever as follows: For one vibration the line must be re-

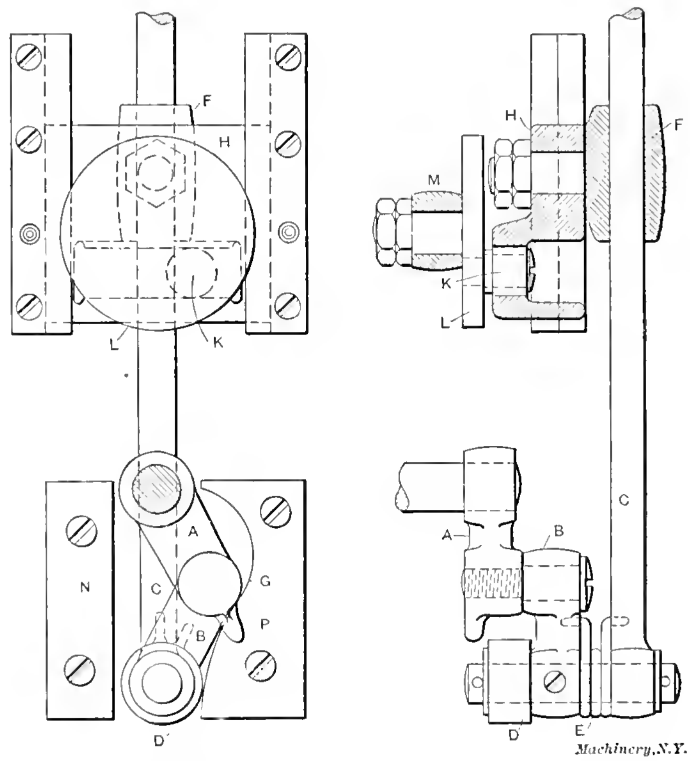

Fig. 2. Cam Combination Movement No. 2.

produced exactly; this is the mean vibration of a cycle of twelve, in each of which the line is reproduced to an increased or diminished scale, to the maximum or minimum, or vice versa. The amplitude of variation of the reproduced line per vibration must be by harmonic ratio. Further, the lever must return in a straight line.

Crank *A* and connection *B* reciprocate the lever *C* and the roll *D* which is kept in contact with *G* by spring *E*. The lever *C* is fulcrumed and slides in the oscillating bearing *F*, which is supported by the slotted cross-head *H*. This is operated by roll *K*, fastened off center on a twelve-tooth ratchet *L*, supported by a bridge-bearing *M*, over the cross-head ways.

In action, the crank throws the connection *B* out of line with the lever *C*, which results in the spring *E*, by reason of the introduced tension, forcing roll *D* to follow the outline of *G* till the highest point is reached, whereupon the connection becomes out of line on the opposite side, and constrains the spring to hold the roll against the straight return guide *N*. During every revolution, the pawl *P* turns the wheel *L* one tooth, raising and lowering *H* and *F*, thereby assuring the proper magnification and diminution of *G*.

Cam Combination Movement No. 3.

Fig. 3 represents the third problem. A horizontal lever must be given a transverse movement along a bar, upon

* For additional information on this subject see "Laying Out Cams for Rapid Motions," February, 1908, and other articles there referred to.

† Address: 33 Fourth St., Norwich, Conn.

‡ George W. Armstrong was born in 1876 in Norwich, Conn., and was educated at the Norwich Free Academy. He took a post-graduate course in science, and was assistant instructor in manual training. He studied the International Correspondence School Course in mechanical engineering, and has had experience as machinist, pattern-maker, tool-maker and draftsman in various shops. His specialty is designing special machinery.

which it is fulcrumed, during the 90-degree dwell of its operating cam; the speed of the movement must decrease by harmonic ratio as it approaches the middle of its travel from each end, and increase as it recedes; while the lever must be vibrated through smaller angles as it approaches the middle, and greater angles as it recedes.

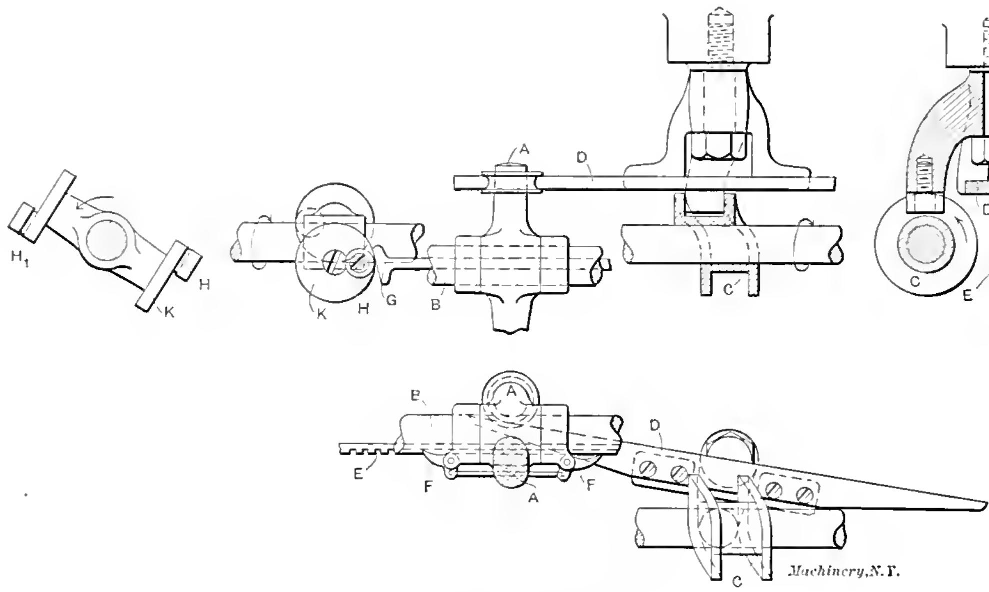

Fig. 3. Cam Combination Movement No. 3.

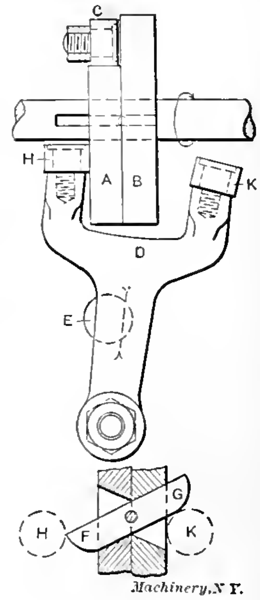

Fig. 4. Cam Combination Movement No. 4.

Lever A, pivoted upon B, is vibrated by means of cam C and rocking bar D. Bar B is splined to accommodate a ratchet E, with which one of the pawls F engages. At each end of the travel, the pawls strike, change positions, and automatically reverse the feed. The ends G of the ratchet are reciprocated by roll H, which is mounted eccentrically upon a twelve-tooth star wheel K. At each revolution, as the star wheel comes opposite the ratchet, a stationary pin turns it one tooth, throwing the roll out from center and moving lever A along. When the lever is farthest to the left, the roll H is in line with the ratchet and star center, and between them. This position gives the maximum movement to the ratchet. The roll is thereafter thrown further out of line, decreasing the feed until the lever reaches the middle distance, after which the roll H_1, on the opposite end, comes into action to complete the movement in an increasing ratio. Another set of star wheels and rolls on the other end of the shaft, gives positive motion and return to the ratchet in both directions.

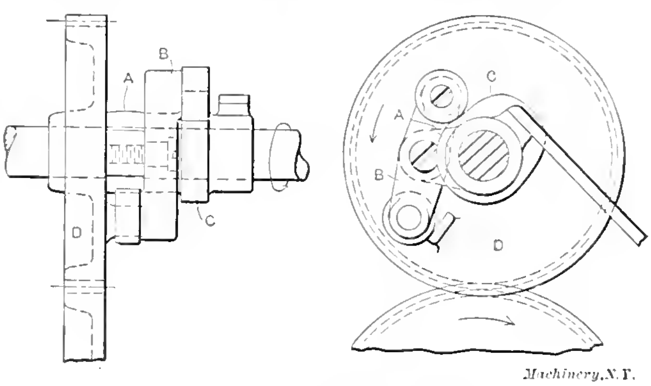

Fig. 5. Cam Combination Movement No. 5.

Cam Combination Movement No. 4.

Fig. 4 shows an arrangement where two revolutions of a cam are necessary to give the required movement to the lever. The rise and the dwell require one revolution each. Two cams A and B, fastened together, can slide upon the shaft a distance equal to the face of one, by reason of a spline and a key. The motion is taken off by roll C, which is shown in the engraving resting on spiral cam A. Cam B is an entire circular disk. The shifting lever D is operated on the "load-and-fire" principle, E being a spring plunger. In the cams, and pivoted between them, above the key, is a double-ended cam F and G, omitted for clearness from the large figure. This swings until it rests against the sides of the opening.

In operation, the cam A lifts the roll to its highest point, when lever D slides the cam along, leaving the roll C upon cam B for the dwell of one revolution, when the cam is immediately shifted in the opposite direction for an instantaneous drop. With the lever and cams as shown, F engages roll H and forces it to the left until E acts to throw the lever and the cam the full distance over. If F and G were stationary, they would interfere with the rolls H and K, and be inoperative, but being pivoted, the end out of engagement is swung forward to clear its roll before the other end throws the roll on this side over.

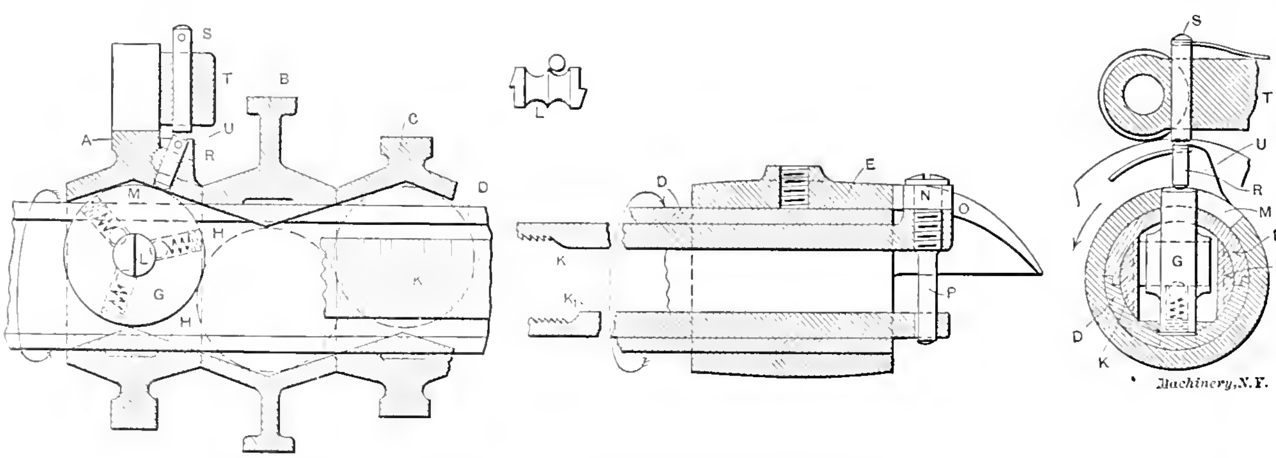

Fig. 6. Cam Combination Movement No. 6.

Cam Combination Movement No. 5.

Fig. 5 shows a method whereby a shaft, making the same number of revolutions as its driver, is rotated at variable

speeds. The driving shaft carries the casting *A* to which is fulcrumed the lever *B*, which in turn has a roll on each end. One roll engages a cam *C*, supported upon the shaft, but not revolving with it. The other roll bears upon a lug on the side of gear *D*, which is also free upon the shaft, but is constrained to revolve with it either faster or slower, according to the relative positions of lever *B* and cam *C*.

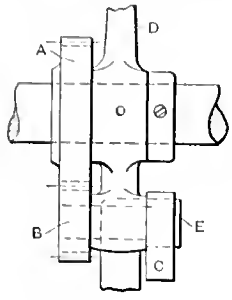

Fig. 7. Cam Combination Movement No. 7.

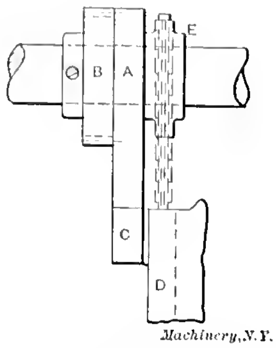

Fig. 8. Cam Combination Movement No. 8.

Cam Combination Movement No. 6.

A problem entailing a group of five dissimilar cams upon one shaft presented these requirements: The cams must operate their respective levers successively back and forth from end to end of the group; that is, while any one operates its lever, all the others must remain stationary with their lever-rolls on a 90-degree low dwell. It requires eight revolutions of the shaft to complete one cycle.

The design adopted to carry out these provisions is shown in Fig. 6, in which the hollow shaft *D*, carried in bearings *E*, supports the cams *A*, *B*, *C*, etc. A roll key *G* is caused to move inside of the shaft from end to end. The roll is constrained to follow the inclines *H*, and is drawn along its sinuous course by ratchets *K* and K_1, and a pawl *L*, it being obvious that *G* will key each cam in succession to the shaft as it enters its respective keyway *M*. Within *G* a double-ended pawl *L* is held in engagement with either ratchet *K* or K_1 by balls and springs. The ratchets are cut oppositely and are reciprocated by roll *N* and cam *O*. Roll screw *P* constrains both ratchets to reciprocate together, and a similar equipment on the opposite end makes the motion positive. When the roll has keyed the last cam, the return of the ratchet causes the pawl to rise onto a higher surface, thereby throwing it into mesh with the other ratchet, and effecting the reversal. It will be noticed that, in the engraving, the part of the longitudinal section to the right is turned around 90 degrees in relation to the portion at the left. This was done to show more clearly the construction.

To hold the cams positively while they wait their turn, knock-out pin *R* is resorted to in connection with the catch-pin *S* in lever *T*. Just as roll *G* starts to drive the cam, it pushes out *R* and raises *S* above the lug *U*, freeing the cam from the lever.

Cam Combination Movement No. 7.

A lever is to be vibrated twice per revolution of a shaft, which shaft is to be the fulcrum of the lever. A gear *A*, Fig. 7, upon the shaft drives the pinion *B* and cam *C* which have a bearing in the end of lever *D*. The cam runs over a stationary roll *E*, and vibrates the lever about the shaft as a center.

Cam Combination Movement No. 8.

Fig. 8 shows how a shaft may be rocked by a cam which is located upon itself. The cam *A*, fast to gear *B*, is driven from an outside source, and reciprocates the roll *C* and the radial slide *D*. A chain passes over a sprocket *E* which is fast on the shaft. One end of the chain is fastened to the slide *D*, the other is fastened to a tension spring beneath the slide.

Cam Combination Movement No. 9.

Referring to Fig. 9, it was desired that lever *A* should have an angular displacement of 45 degrees, but it was found that a cam to accomplish this with the given center distances would not swing inside the rods *B*. The idler lever *C* was resorted to, and, as first designed, was connected to the lower arm of *A* by a link. As made, however, the roll *D* on *C* ran between the cam *E* and the lever roll *F*, allowing a much smaller cam and giving a very smooth movement.

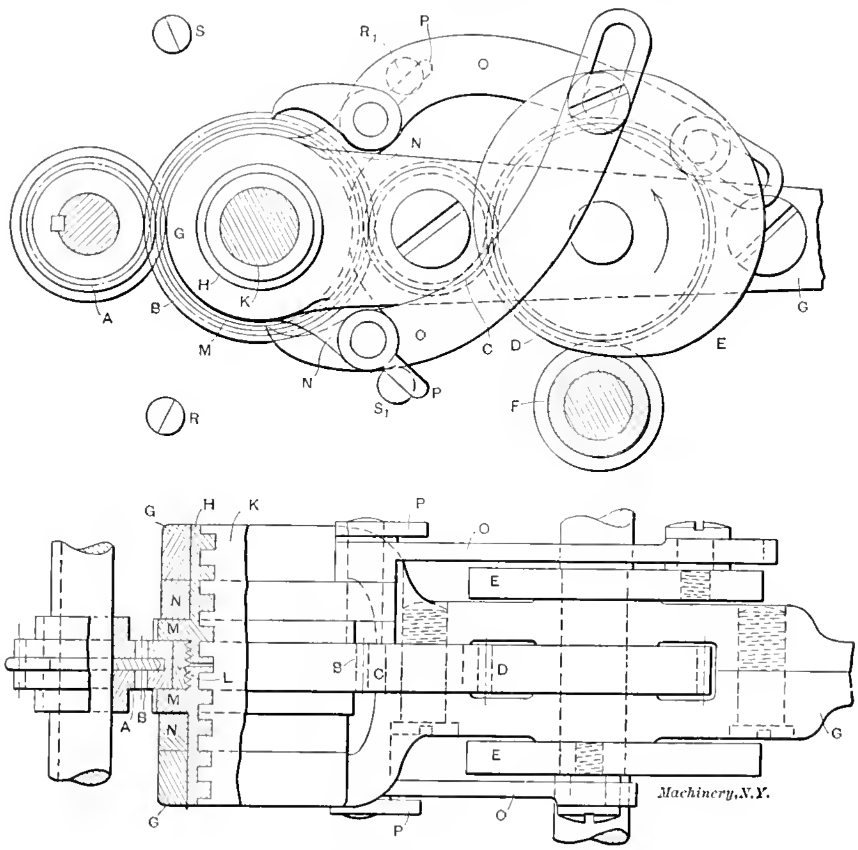

Fig. 11. Cam Combination Movement No. 11.

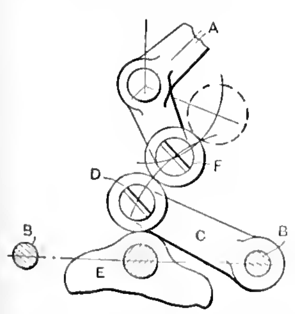

Fig. 9. Cam Combination Movement No. 9.

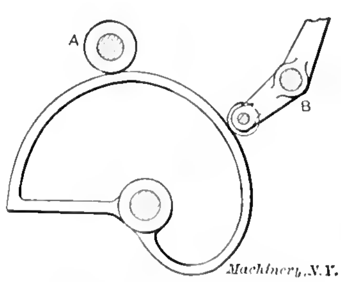

Fig. 10. Cam Combination Movement No. 10.

Cam Combination Movement No. 10.

How one cam was made to operate two machine elements is shown in Fig. 10, where the cam was designed to reciprocate the roll *A* and its slide, giving it a 90-degree dwell after the rise and while lever *B* was vibrated. By properly positioning the fulcrum and proportioning the arms of lever *B*, the necessary motion for it was taken off the last part of the rise of the cam. Roll *A* is shown at the beginning of dwell and the cam is about to throw lever *B*.

Cam Combination Movement No. 11.

A cam is desired to vibrate a third-class lever, and while at its lowest dwell (100 degrees), the lever must be given a lateral translation of 1/16 inch. The total travel each way is 6 inches, and the feed must be automatically reversed at each end.

The manner of accomplishing this is delineated in Fig. 11, in which pinion A drives idlers B and C and cam gear D. The pinion is keyed on the shaft, and is built up with a flange which engages a groove in gear B, causing it to follow the gear. Two like cams E are driven by D, and bear against flanged roll F. The lever G swings about its fulcrum H which is a two-part nut upon the stationary screw K. The nut is divided, the halves being united by sleeve L. The flanges M on each nut are provided with oppositely cut ratchets. Rockers N carry the pawls being actuated by the connections O. In order that the required translation may be imparted to the lever by the four pitch nut, the pawls must swing through an arc of 90 degrees. The engraving shows the parts in position to do this.

The reversal is accomplished by the projections P on the pawls and two pair of spring plungers; R and R_1, being on one side of the frame, and S and S_1 being on the other side. As the lever travels away from us, the pawls approach R and R_1. At the last 1/16 feed, R recedes to let its pawl pass, but throws it into the ratchet on its return. Plunger R_1 recedes to allow the pawl to pass by, but immediately lifts it out of its ratchet.

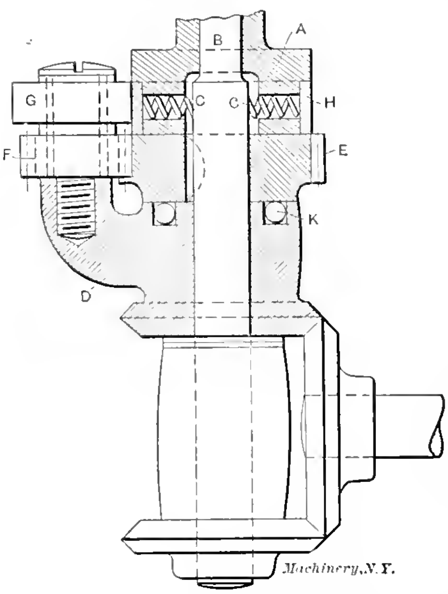

Fig. 12. Cam Combination Movement No. 12.

Cam Combination Movement No. 12.

The accompanying Fig. 12 shows how a circular part making thirty revolutions per minute clockwise, in a horizontal plane, was vibrated from and to its center twice per second, the vibrations being applied progressively counter clockwise around its center, and the part being vibrated vertically sixty times per minute. The part A to be vibrated is revolved by shaft B,

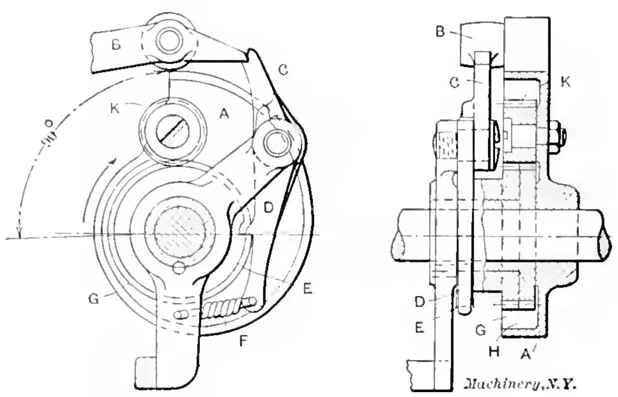

Fig. 13. Cam Combination Movement No. 13.

and centered about it by three springs C. The arm D revolves in the opposite direction to A and the gear E of twenty teeth, which results in the pinion F revolving four times per revolution of arm and part A. The pinion carries a cam G which is made of rubber. It presses against the slip ring H and vibrates the part A. The ring is provided to prevent any drag by reason of the opposite directions of rotation. The balls shown at K serve to reciprocate the part A vertically by reason of the annular groove having two barriers against which the balls stop, and part E having two cam projections which enter the groove and roll up over the balls.

Cam Combination Movement No. 13.

The cam A in Fig. 13, elevates lever B during three-quarters of a revolution. The latch C holds it up during 90 degrees dwell. This latch is controlled by the pawl D, cam E, and spring F. Cam E has ratchet-like notches in its edge, and is made in one piece with a 24-tooth gear G. The pair is rotated upon the hub of a 25-tooth stationary gear H by the planetary pinion K, once every twenty-four revolutions of cam A.

It is desired that the lever B should have 90 degrees dwell the first revolution; thereafter the dwell should increase 360 degrees after each rise to the fourth period (which gives 1,530 degrees dwell), when the dwell should decrease till it is 90 degrees again; that is, during the fourth period the rise is three-quarters of a revolution, and the dwell is $\frac{1}{4} + 4$ revolutions.

This requires 24 revolutions per cycle, and cam E should be indexed for 24 divisions, but only cut at these divisions: 1—2—4—7—11—16—20—23. When pawl D drops into a notch, latch C is thrown out, giving a sudden drop to lever B.

Cam Combination Movement No. 14.

Five levers equally spaced are fulcrumed upon one bar. Four different positive motion side cams operate the four outside levers. The fifth or middle lever is to have the resultant motion of the others at all times; that is, the forces acting on the other four are to be automatically resolved, and their resultant in magnitude and direction is to be transmitted positively to the fifth lever.

As it is not necessary to show the cams or levers to illustrate the principles involved, a horizontal section, merely, of the resolving apparatus will be shown. The four levers are suitably connected by knuckle-joints, one to each of the racks L, M, N and O, Fig. 14. These racks are free to slide up and down independently, and are arranged in two pairs. One pair meshes with pinion A_1, the other with A_2. As the arrangement is symmetrical, the description of one side will suffice. Any movement of levers L and M will be transmitted to pinions A_1 and B_1, which are constrained to travel together by reason of a stud through both. A stationary rack C_1 and a sliding rack

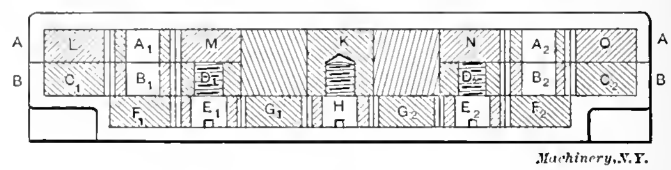

Fig. 14. Cam Combination Movement No. 14.

D_1 engage pinion B_1. Sliding rack D_1 carries a pinion E_1, which in turn engages stationary rack F_1 and sliding rack G_1. The last, and also rack G_2, engage pinion H upon sliding bar K, to which is attached the fifth lever.

To illustrate the action, we will assume that lever L lifts one inch, lever M drops ½ inch, lever N is stationary, and lever O lifts ¼ inch. The resultant is a ¾-inch rise. We know that a pinion moved along a stationary rack will cause a movable rack on the opposite side to travel with twice the velocity of the pinion's periphery. This fact and its converse is here applied.

Lever racks L and M acting upon pinion A_1 will cause it to rise $\frac{1}{2}(1 - \frac{1}{2}) = \frac{1}{4}$ inch. This travel is doubled in sliding rack D_1, producing a movement of ½ inch, and doubled again in sliding rack G_1, throwing the latter 1 inch. As G_1 has teeth on both sides, it, in turn, moves pinion H, and the fifth lever slide K, ½ inch. Lever racks N and O traced out as above give a movement of ½ inch to G_2 and ¼ inch to H and K, which totals ¾ inch rise for the fifth lever. When all cams drop 1 inch together, the resultant is 4 inches drop for the middle lever.

* * *

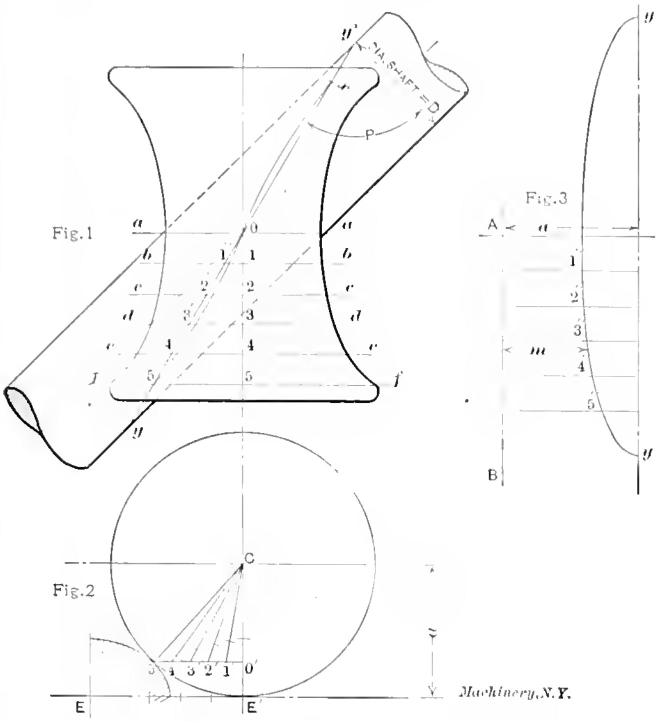
It is mentioned in the *Times Engineering Supplement* that a new steam turbine of novel design has been brought out by Mr. John Ogg, Aberdeen, Scotland. The turbine consists of a metal wheel or disk mounted on a hollow shaft perforated by holes passing from the center to the inside of the wheel, radially. The holes are tapered from the center outward and form expanding nozzles for the steam, which is supplied through the hollow shaft. The steam, on issuing from the nozzles, strikes against blades fixed to the rim of the wheel at a suitable angle. Several wheels may be mounted on the same shafts and the blades on some of the wheels may be set for the forward motion and others for reverse motion.

GRAPHICAL SOLUTION OF CROSS-ROLL CURVE PROBLEM.*

SIDNEY C. CARPENTER †

In the present article the writer offers a method of constructing the cross-roll curve. This method will be found fully as accurate, and far easier to handle, than the more complicated formulas which have been suggested for the same problem.

After laying out the shaft and the center line of the roll, as in Fig. 1, the first step is to determine the line of contact between the roll and shaft. Taking a section on the line *ff*,



Graphical Solution of the Cross-roll Curve.

at the end of the roll, draw the ellipse forming the section of the shaft on this plane, as shown in Fig. 2. From C, the center of the roll, draw a circle tangent to the ellipse, and locate the point of tangency 5′, as closely as possible. This point is the point of contact between the roll and the shaft on the plane *ff*. Projecting 5′ to Fig. 1 we obtain the point 5″. The straight line from 5″ to 0 represents the average direction of the line of contact. Produce 5″ 0 in both directions till it cuts the sides of the shaft at y and y', and draw the ellipse which represents the section of the shaft on yy', as shown in Fig. 3. This ellipse should be constructed as accurately as possible. The minor axis, of course, equals the diameter of the shaft, and the major axis equals $\frac{D}{\cos a}$.

At a distance a from the major axis of the ellipse, equal to the vertical distance between the center lines of the roll and shaft, draw AB parallel to the major axis. In Fig. 1 divide 05 into a number of equal parts, and through these points draw *bb*, *cc*, etc., cutting yy' in 1″, 2″, etc. These are the points of contact on the sections *bb*, *cc*, etc., assuming the contact line to be straight. Now revolve the ellipse yy' into the plane of the roll axis. Points 1″, 2″, etc., will take the positions shown in Fig. 3, and AB will be the center line of the roll. Erect ordinates on yy' passing through 1″, 2″, etc., and produce them to AB. Under the conditions assumed it is evident that the distance m, on any ordinate, from AB to the curve of the ellipse, is equal to the radius of the roll section at that point. Revolving the ellipse back to its real position, point 5″ will assume position 5′ in Fig. 2; the real radius of the section will be $C5'$, and the distance between 5″ and AB, Fig. 3, will equal $C0'$. But $C5'$ equals $\frac{C0'}{\cos 5'C0'}$. Therefore, denoting the distance from AB to the curve of the ellipse by m, angle $5'C0'$, $1'C0'$, etc., by F, and the radius of the roll section by R,

$$R = \frac{m}{\cos F}$$

Angle F can be obtained by dividing $5'C0'$ into angles corresponding with the other points of division, and m must be measured from Fig. 3. The formula, however, is not exact, though it is very close. The method of obtaining F gives the correct angle, but m is slightly too small, for the real point of contact, instead of being on the straight line 5″0, is on the curved line 5″0. A little consideration will show that the real line of contact is an arc over the surface of the shaft, as represented by the curve 5″0x, while the straight line 5″0x represents the chord *through* the shaft.

If the construction is very carefully done, the following method gives very close results. After obtaining 5′, Fig. 2, the point of contact on the section *ff*, draw 5′0′ perpendicular to $C0'$ and divide it into equal parts, corresponding to the divisions on 05. Draw $C1'$, $C2'$, etc. Now divide EE' into the same number of parts. The division points represent the center of the shaft section on the planes *aa*, *bb*, *cc*, etc. For each position, draw that portion of the ellipse which is normal to the corresponding line from C. The point of intersection will be the point of contact for the corresponding plane in Fig. 1, and the radius can be measured directly, or transferred to Fig. 1, and the curve for the outline of the cross-roll drawn. The accuracy of the result depends upon the care with which the ellipse is constructed for the different positions.

* For additional information on this subject, see the article in the December, 1907, issue, on the "Derivation of the Cross-roll Curve," and other articles there referred to.

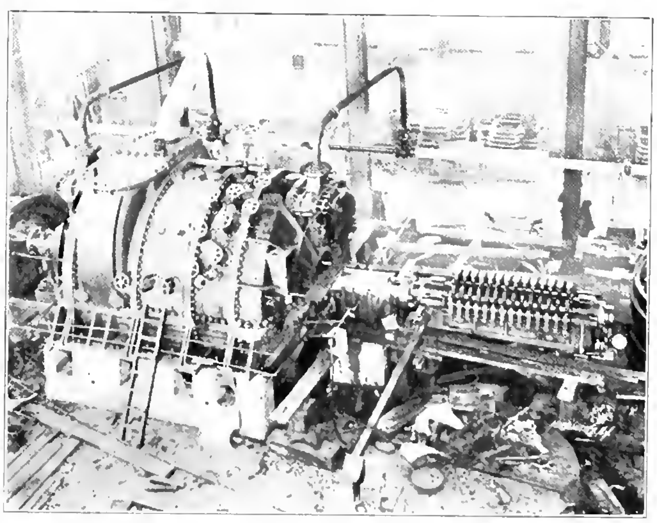
GIANT TURBINES FOR JAPANESE CRUISER.

There have just been completed at the Fore River Works, Quincy, Mass., a pair of giant turbines, destined for the new Japanese cruiser *Ibuki*, now building in a Japanese yard. These turbines will develop on aggregate of 27,000 horsepower, and the cruiser will have a speed of 23 knots, with 14,500 tons displacement. The turbines are 144 inches in diameter, with seven ahead and two reverse stages, contained in one casing. The reverse wheels will develop about 60 per cent of the full-ahead power, and reversing can be accomplished in eight to ten seconds from the time signals are given. These will be the first turbines ever installed in a Japanese ship, and are to be followed by two more of similar



One of the Turbines built at the Fore River Works, Quincy, Mass., for a Japanese Cruiser.

design for the battleship *Aki*, now under construction. The boxed weight of the turbines just finished was 150 tons. Each separate part was securely boxed, marked and numbered, so that the parts can be readily fitted together when Japan is reached. A diagram was made of the vessel which carried the parts of the turbines before the crates were hoisted aboard, in order that there might be no movement in the hold that would cause damage to any of the parts in rough weather. Several workmen from the Fore River Works are going to Japan to assist in setting up the turbines. The building and shipping of the turbines were under the direction of Commanders Yushida and Kamimura of the Japanese navy

ADAMS-FARWELL AERONAUTIC GASOLINE MOTOR.

The flying-machine inventor is not so much ridiculed nowadays as of yore, for attempting to accomplish mechanical flight. The Darius Green type of flying machine inventor, among whom was the ill-fated German, Otto Lilienthal, laid a foundation of practical knowledge of air resistance, air currents and the laws affecting the action of gliders and aeroplanes; and to-day the possibility of navigating the air looms before us. Lilienthal began his experiments in 1891, and was killed by an accident to his glider in 1896. Although his work was generally regarded with contempt at the time, Lilienthal's investigations were the start of work along the same lines that is of much interest and value now. It is with the advantage of the principles established by such men as Lilienthal that the present experimenters are enabled to attack the problem of "heavier-than-air" flying machines, intelligently. They are generally men of expert engineering and mechanical knowledge, such as the Wright brothers, Henri Farman and Leon Delagrange, and their work is regarded with respect, because we are beginning to understand what the requirements are and how they are to be met. The successful solution of flying, which is believed to be not far distant, will mean a tremendous change in light transportation and sport. The engineer is interested in the practical side. He knows that birds fly because of possessing great muscular power and wing surface, as compared with their weight. It does not necessarily follow, however, that a flying bird continually exerts great power; in fact, we have very good proof that it does not, but it must always have large reserve power to enable it to rise quickly from the ground and to suddenly change its course when the air currents do not favor progress. So it must be with the mechanical flyer; hence the need for powerful and light motors.

The accompanying half-tones, Figs. 1 to 4, show a new aeronautic motor developed for an Eastern inventor who is making secret tests of a new type of aeroplane. The motor is the design of F. O. Farwell, inventor and patentee of the revolving cylinder motor first used on the Adams-Farwell automobile. (See MACHINERY, November, 1904, for description.) The automobile engine described had three cylinders revolving around a stationary crank-shaft, and a 20-H.P. engine weighed 190 pounds, or $9\frac{1}{2}$ pounds per H.P. This design was afterwards changed to five cylinders, and the aeronautic motor shown herewith is built from the same patterns with the exception that the bore is $4\frac{1}{4}$ inches, instead of 4 inches. It is lightened by making some other changes also. The engine illustrated has five cylinders, $4\frac{1}{4}$ inches bore, $3\frac{1}{2}$ inches stroke, and runs at 1,800 R.P.M. Its weight is only $97\frac{1}{4}$ pounds, and figured by the Association of Licensed Automobile Manufacturers' rule, $\text{H.P.} = \frac{D^2}{2.5} \times N$, its rating is 36 H.P., or only 2.7 pounds per H.P. This weight includes everything necessary for operation, with timer, float-feed carbureter, automatic force-feed oil-pump and lubricating oil tank. With the spider shown in the half-tones, Figs. 2, 3, and 4, which secures the motor to four tubes, the motor and base weigh 104 pounds. The parts not included in this weight are the battery, coil and gasoline tank, which cannot be considered as parts of the motor.

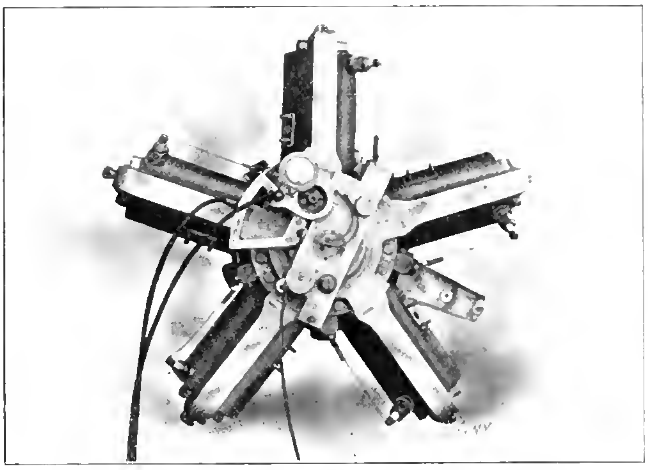


Fig. 1. Top View of Adams-Farwell Five-cylinder Motor for Air Ships and Aeroplanes.

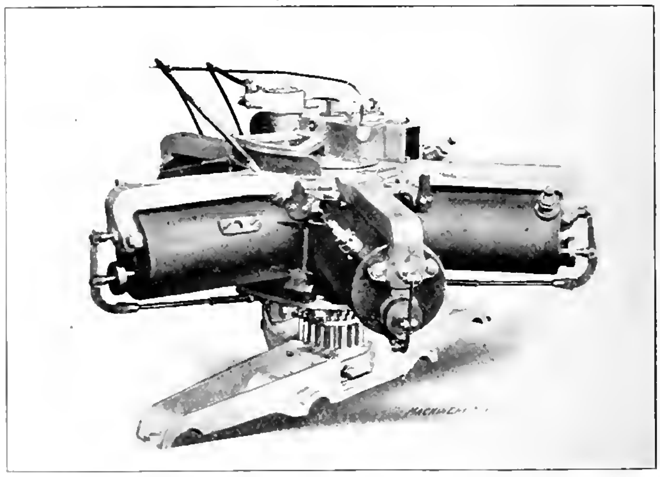

Fig. 2. Side View of Five-cylinder Motor, showing Spider for Attaching to Frame.

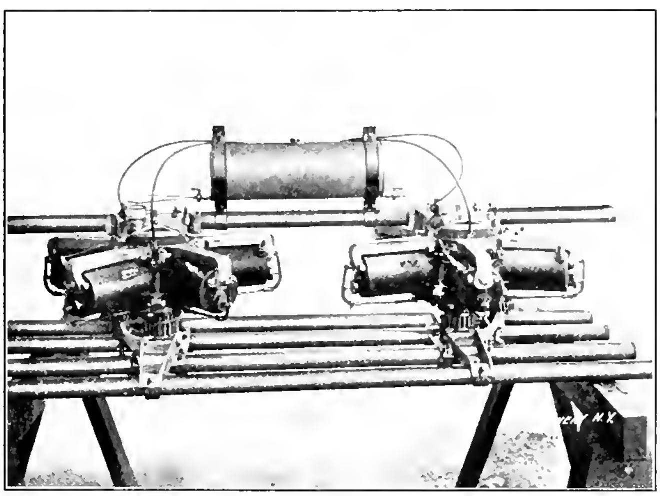

Fig. 3. Two Motors attached to a Frame of Tubes, with Complete Equipment

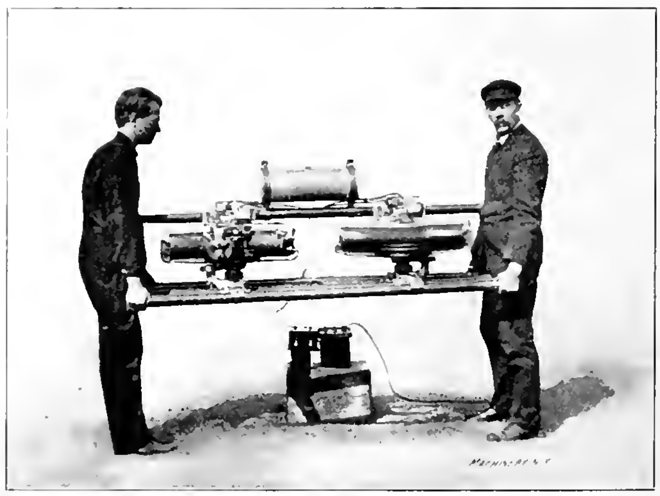

Fig. 4. Two Motors supported by Two Men. One Motor is shown running at High Speed, Illustrating Freedom from Vibration.

The above weight per H.P. developed is believed to be the lightest of any motor so far built in which practical utility was not sacrificed. The nearest approach is the Antionette eight-cylinder motor, made by the Adams Mfg. Co., Ltd., London, England. The weight of this engine for 31.71 H.P., by the A. L. A. M. rule, is 88 pounds or 2.77 pounds per H.P. The larger sizes are heavier per H.P. This motor is water-cooled, and requires considerable additional weight for the water, water pump, piping and radiator. Another very light motor, built by the G. H. Curtis Mfg. Co., Hammondsport, N. Y., weighs 150 pounds for 40 H.P. or 3.57 pounds per H.P.

The construction of the Farwell motor is peculiarly advantageous for aeronautic purposes. The cylinders form the fly-wheel, and this fact alone means a big saving in weight. Inasmuch as the cylinders revolve rapidly in the air, they are air-cooled, and no other air-cooling machinery is required. The cylinders act as their own fan, and the cooling effect has been found to be perfectly satisfactory. In the automobile motors, as first developed, longitudinal ribs were cast on the cylinders, but in 1907 these were discarded, it having been found that smooth cylinders as large as 5 inches bore and 5 inches stroke cooled perfectly working in this way. Another saving of weight comes from the fact that all five cylinders work on a common crank-pin, and all ten valves are operated by one cam.

Not the least difficult part of the design was the attachment of five connecting-rods to a crank-pin 1⅜x4 inches, so that the working pressure per unit of bearing surface would not greatly exceed the limits imposed by lubrication and durability. A longitudinal section of a cylinder, connecting-rod and the crank-shaft is shown in Fig. 5. Four of the connecting-rods have narrow forked bearings encircling the crank-pin, while the fifth rod has a single bearing double the width of one fork and, of course, equaling the width of two. The exterior of these bearings or forked parts is machined truly circular, and each connecting-rod is made with an extended part each side of the forked bearings which is machined to fit the exterior of the other connecting-rod forks. Inasmuch as the maximum pressures transmitted to the connecting-rod act to compress it against the crank-pin, the working bearing of each connecting-rod on the power stroke is the full length of the pin and about 60 degrees of its circumference.

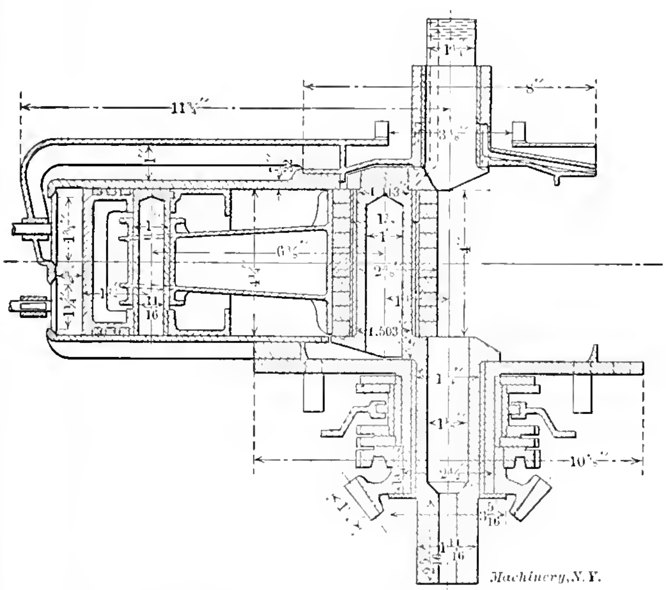

Fig. 5. Vertical Section through a Cylinder and the Crank-shaft, showing Method of attaching Connecting-rods to the Crank-pin.

Each cylinder is cast with the head and a part of the central crank case in one piece of steel of high tensile strength, each weighing only 7½ pounds. The five cylinders are bolted together and are bolted to a top aluminum flange, weighing 3 pounds, which forms the gas manifold. At the bottom the cylinders are bolted to a steel flange, which supports the valve cam and the transmission gear. These flanges have long bronze bushings, and form bearings around the vertical stationary crank-pin. The pistons are made of cast iron and weigh 2½ pounds each. The connecting-rods are made of bronze.

As before stated, the valves, ten in number, are operated by one cam. These valves have no springs to close them, but being in the heads of the cylinders and closing outwardly, they are closed by centrifugal force. The higher the speed of the motor, the greater the centrifugal force, and the greater the necessity for a strong force to close the valves quickly. Centrifugal force also puts the gas in each cylinder under pressure, which is an advantage in a high speed engine. The engine operates under the variable compression system, used for several years on the Adams-Farwell automobile motors. It consists in mechanically holding the inlet valve open for a part of the compression stroke, and closing it after a part of the gas has been blown back, and taken in by another cylinder, which at that time is under the suction stroke. The compression is relieved and the motor runs with little compression resistance when starting or running slowly. It may be gradually increased until maximum speed and power is obtained, and may be as gradually reduced when stopping the motor. Therefore, there is not the abruptness in starting or stopping, which characterizes the ordinary gasoline motor, and this is another feature of considerable importance in aeronautical work.

The wiring for the ignition system is as simple for this five-cylinder motor, as it could be for a single-cylinder motor. There is but one spark coil, one timer and contact, one primary, and one secondary current. Fig. 1, showing the top view of the motor, makes the arrangement clear. The wire is attached to a flat steel spring. This is insulated for the remainder of the timer by a fiber block. A hardened steel wheel is mounted freely on the concentric or crank end of a short shaft, which is geared to the motor, and which makes one revolution to each two-fifths revolution of the motor. A distributor for the secondary current is formed by a strip of brass on the lower edge of a fiber segment, supported by a bracket shown. A short, bare wire leads from the spark plug, on each cylinder, to a fiber insulator, near the crank case. In the top of this insulator is a screw, which, when the motor turns, passes under the distributor, but does not touch it. When the cylinder, which is to be fired passes under the distributor, the timer wheel makes contact with the springs and the secondary current passes to the spark plug of that cylinder. Each alternate cylinder is on the power stroke as it passes the dead center of the crank. There being five cylinders, the power strokes are in perfect rhythm. After the motor is started, the timer case is swung around to the left, which advances the spark to its maximum.

The same shaft that turns the timer wheel revolves the force-feed oil pump by means of a worm gear. The rectangular block shown at the top, which is clamped to the upper tube, not only forms a support to the upper end of the crank-shaft, but makes an oil tank holding one-half pint of lubricating oil. It supports the timer and oil pump, and in one end is formed a carbureter with float-feed chamber. The complete device weighs only 2½ pounds. To recapitulate the advantages claimed for the Farwell motor, for aeronautic purposes are:

Gyroscopic force, utilized to steady aeroplanes in flight; the entire motor revolves around the stationary crank-shaft, giving maximum fly-wheel effect for given total weight; the lightest motor of this power that has ever been constructed (97¼ pounds, rated at 36 H.P.); motor has no fly-wheel, no muffler, and no cooling device, other than that made by the revolving cylinders; valves close by centrifugal force, instead of springs; ten valves actuated by a single cam; simple ignition system identical with that used on single-cylinder motors of ordinary design; gas injected into the cylinder under pressure by centrifugal force; absolute freedom from unbalanced forces and vibration. The motor is built by the Adams Co., Dubuque, Iowa.

* * *

Electric welding enables certain manufacturing operations to be accomplished easily, simply, and, therefore, cheaply, which, if conventional old-time methods were used, would be very costly and difficult. Take for example the case of multiple-throw automobile crank-shafts. Every one knows how hard it is to drop forge such work satisfactorily beyond two throws in one piece, following common practice. It is made comparatively easy if electrical welding is employed as an assembling process. Four-throw and six-throw shafts are now built up by electrical welding in the rough, using single-throw or double-throw units until sufficient throws have been united. The advantage of the method has been recognized as making possible a still further advancement. If the single-throw drop forgings are rough-turned and rough planed before being electrically welded together, the finishing operations of the assembled shaft are greatly simplified and cheapened.

MAGNALIUM.

VALUABLE CHARACTERISTICS OF AN ALUMINUM ALLOY.

Magnalium is an aluminum and magnesium alloy which promises to fulfill the expectations based in the past on aluminum, but never realized on account of its softness and other unfavorable qualities, which have been overcome by the development of magnalium. For the following interesting notes on its characteristics we are indebted to Mr. Morris R. Machol, 32 Park Place, New York, who is the American agent of the Magnalium Syndicate of Berlin, Germany.

Magnalium like pure aluminum can be cast in a liquid condition. The castings can be machined about the same as brass. The machined surfaces are of a mirror-like smoothness and silvery color. Perfect screw threads can easily be cut in the metal, and bored holes can be made smooth and true. Filing it results in fine, regular, clean-cut surfaces without tearing up the metal or clogging up the file as does aluminum, and the action is accompanied by the usual typical sound which is heard when filing. Only rough or medium fine files can be used on aluminum, preventing, of course, any exact work, while magnalium will allow the use of even the finest kind of files.

Magnalium can be cast by any ordinary foundryman, the only precaution necessary being the use of *clean* graphite crucibles, and care must be taken not to increase the temperature too far above the melting point (1185 to 1250 degrees F.) as this weakens the metal. If cast in an iron chill the tensile strength is greatly increased and is at a maximum if the chill is water-cooled. Cast in dry sand, the usual quality of magnalium has a tensile strength of 18,000 to 21,000 pounds per square inch, and shows reduction of area of 3¾ per cent; cast in iron chills, 22,000 to 25,000 pounds per square inch; reduction of area, 5 to 8 per cent. The tensile strength of a quality containing a somewhat smaller percentage of aluminum equals about 34,000 pounds per square inch, but can be increased to about 42,500 pounds per square inch by proper treatment. By drawing, rolling, pressing, etc., the tensile strength obtained by quick cooling is still further increased. Wire drawn from one quality of the alloy has a tensile strength of 41,000 pounds and 10 per cent reduction of area, while it will stand 53,000 pounds if the raw material has been forged before drawing. Soft rolled sheets of alloy "Z" have a tensile strength of 42,000 pounds and 15 per cent reduction of area; hard rolled sheets, about 52,000 pounds and 3 per cent reduction of area.

Magnalium containing less than a certain percentage of aluminum cannot be rolled but can readily be drawn. The tensile strength of a drawn bar tested was 60,000 pounds, and that of a tube, 74,000 pounds per square inch.

Another advantage of magnalium is that it is extremely close grained, so that the polishing can be done without previous treatment. Furthermore, in lathe work the tool speed can be twice as great as with aluminum, thus making a saving in labor. Transparent or colored lacquers can be readily applied; polishing, etching, engraving, etc., can be easily done.

Pure aluminum being soft, can be cut with a knife like zinc or lead, while magnalium is hard. Some magnalium alloys, however, are very ductile and can be forged, rolled, drawn, etc., as intimated in the foregoing, sharing all advantages of aluminum in this direction. Annealed magnalium "Z" is so ductile that it can be rolled or beaten like silver. The elasticity of cast or annealed magnalium is small, but in the forged, hard-rolled or drawn material it is much greater. It attains and maintains a high polish and shows excellent resistance to atmospheric conditions. The color of magnalium is silvery white in contrast to the grayish aluminum. Besides all this, magnalium has the advantage that its specific gravity is less than that of aluminum. While the specific gravity of pure aluminum is 2.64, magnalium shows 2.4 to 2.57, according to the percentage of alloy. Other aluminum alloys have a greater specific gravity than aluminum, the most of them being between 3 and 4.

Magnalium has no odor. It resists oxidation better than aluminum or any other light metals and is almost unaffected by dry or damp air, water, gaseous ammonia, carbonic acid, sulphureted hydrogen and most organic acids. It is very slowly affected by saltpeter or sulphuric acid and more rapidly by alkalies or strong alkaline solutions. Salt water attacks magnalium slightly, and where exposed to sea water the metal should be lacquered, which will protect it so that it will give excellent satisfaction.

Magnalium shows almost no magnetic influences, but its electric and thermal conductivity is about 56 per cent of that of pure copper. The specific heat of magnalium is 0.2185.

Magnalium, especially alloys "X" and "Y," can be forged with good results most easily by heating the metal and then working about the same as Swedish steel. The metal must not glow red, but must be hot enough to char a piece of wood. Of course, the casting should be clean before forging to avoid cracks in the metal.

The great ductility of magnalium, especially alloy "Z," makes it possible to produce plates of any thickness. The ingot is first heated to between 570 and 660 degrees F. and rolled so that the reduction at the first pass is about 20 per cent. Then the plate is again heated. After the first two passes the plate is turned 90 degrees and passed through the finishing rolls until it reaches the required thickness. As magnalium rapidly loses its ductility in rolling, it has to be annealed repeatedly.

Magnalium should be annealed in a muffled furnace in order to keep the flame and gases away from the metal. The annealing furnace must be kept at an even heat. The metal must appear dark red and char a pine wood stick so that carbon particles separate from it. To anneal plates does not require as high a temperature. If plates are chilled in cold water, they will be very tough and ductile. The thinner the plates, the lower should be the temperature of the annealing furnace. Plates of less than 0.01 inch thickness can be heated in boiling oil or water and allowed to cool slowly. If the magnalium is gradually heated to a temperature of less than 750 degrees F. and slowly cooled, the metal gets so hard and elastic that it can be worked into springs.

Magnalium is a very ductile metal and in this respect is only surpassed by gold, silver, platinum and copper. When drawing, the diameter of the cast ingot should be reduced very slowly at first. Best results are obtained if the ingot is forged before drawing. Perfectly smooth wire as fine as silk threads has been made with astonishing tensile strength. Tubes made from plates or from cast hollow pieces are treated in exactly the same way as rods, namely annealed repeatedly, chilled and afterwards drawn cold over a mandrel.

Magnalium is remarkable inasmuch as that it can be tooled at high speed, about like steel. Screw threads of length can be easily and cleanly cut. The tools have to be very sharp and the surfaces (both metal and tools) must be kept lubricated with either kerosene, turpentine, paraffin, benzine, vaseline, soap-water or even clear cold water. Excellent surfaces will result and perfect screw threads or holes will be obtained. To cut magnalium, a fine-toothed saw, lubricated with kerosene, is recommended. Magnalium can be punched, drop-forged and pressed without any difficulty—about the same as silver, brass or steel plate—provided that it has been well annealed.

Weight for weight, magnalium is stronger than Siemens-Martin steel with 2 per cent aluminum alloy. This steel has an ultimate tensile strength of about 114,000 pounds per square inch. Magnalium "Z" is rated at 52,200 pounds per square inch. Dividing each by its specific gravity yields 14,400 and 20,800, or nearly 50 per cent advantage of strength for the same weight in favor of magnalium. The value of the new alloy for aeroplanes, automobiles, army equipment and many other uses in which cost is not so important as lightness, is quite apparent. The price per pound is about two times that of aluminum.

* * *

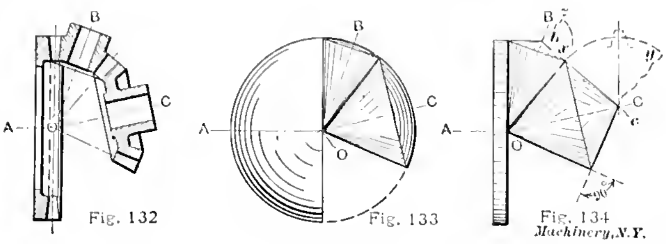
An advantageous system for lighting at the milling machines is in use in the Kearney & Trecker Co.'s shops, Milwaukee, Wisconsin. A small bracket of cast iron is screwed to the top of the milling machine at the front end, over the bearing for the overhanging arm, and into this is screwed a piece of ordinary Almond tubing, through which the wire is carried. This gives a very satisfactory flexible arrangement, and permits the light to be brought into the best position.

GEAR-CUTTING MACHINERY 7.

RALPH E. FLANDERS.*

MACHINES FOR FORMING THE TEETH OF BEVEL GEARS.

In studying methods and machines for cutting the teeth of bevel gears, we come to the most fascinating branch of the whole subject which we have been considering. It will be impossible in the comparatively short space we are able to devote to the subject to do more than give the bare outlines of the ingenious mechanisms which have been devised for this work. Almost any one of the machines we describe, operating on the templet or the molding-generating principles, would



Figs. 132, 133, 134. Illustrating the Spherical Basis of the Bevel Gear, and Tredgold's Approximation for Developing the Outlines of the Teeth on a Plane Surface.

require several pages and many illustrations to explain the details of its construction. We can, however, in the comparatively short descriptions here given, get an understanding of the principles of operation of each of them. This will best be done by analyzing the various principles of action and methods of operation applicable to the cutting of bevel gear teeth, as was done for spur gears in the introduction of this series of articles, following the same classification there given, but making the necessary changes in the mechanisms shown in Figs. 1 to 10 to fit them for the work of cutting bevel gears instead of spur gears.

The changes required in the spur gear cutting devices to adapt them for cutting bevel gears, made necessary by the difference in the nature of the two forms of gearing, are explained in Figs. 132, 133, and 134. The action of a pair of mating spur gears may be seen and studied on the plane perpendicular to their axes. To be understood correctly, the action of bevel gearing must be observed on a spherical surface. In Fig. 132 are shown three bevel gears with axes OA, OB, and OC. The bevel gear on axis OA is of the form known as the "crown gear." It is practically a rack bent in a circle about center O. Pinion OB and gear OC are familiar types of bevel gears. In Fig 133 are shown the pitch surfaces of the gears in the preceding figure. It will be seen in that figure that the pitch lines of the gear on the axis OC, for instance, converge at the center O. These pitch lines represent a conical pitch surface which is shown cut out from a sphere on axis OC in Fig. 133. In a similar way the cone about axis OB represents the pitch surface of the pinion in Fig. 132, while the plane face of the hemisphere at the left of Fig. 133 is the pitch surface of the crown gear of the preceding figure. If we wish to draw accurate representations of the teeth of the bevel gears in Fig. 132, in order to study their action in the same way that we can when drawing the teeth of spur gears on the plane surface of the drawing board, we would have to draw them on surfaces of the sphere from which the pitch cones in Fig. 133 are cut. The pitch circles, etc., of the various gears would be struck from centers located at the points where the various axes OA, OB and OC break through the surface of the sphere. Except for the different surfaces

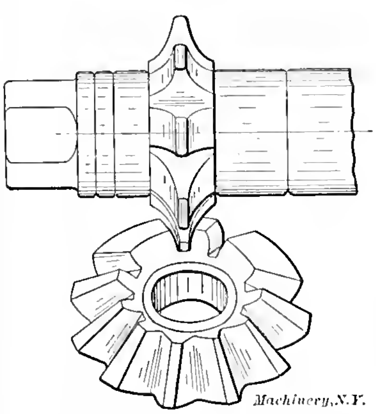


Fig. 135. Shaping the Teeth of a Bevel Gear by the Formed Cutter Process.

on which the drawing would be done, the procedure would be identical with that for spur gears. It should be noted that straight lines on spherical surfaces are represented by great circles—that is to say, by the intersection with the surface of planes passing through the center of the sphere.

Owing to the impracticability of the sphere as a drawing-board, an approximate process, known as "Tredgold's," is usually followed for laying out the teeth of bevel gears approximately. This is shown in Fig. 134 applied to the same case as in the two preceding figures. The conical pitch surfaces vanishing at the center O are identical with those in Fig. 133, as is also the plain circular face of the crown gear. For the bevel gear and pinion, however, the teeth are supposed to be drawn and the action studied on surfaces of cones complementary to the pitch cones—that is, on the cones with apexes at c and b. The surface of these cones can be developed on a flat piece of paper, as shown for that on axis OC in Fig. 134, in which case the pitch line becomes xy, as there illustrated. Teeth drawn on this pitch line, as for a spur gear, may be laid out on the conical surface and used as the outlines of bevel gear teeth. The difference in the shape of teeth obtained under the same system as the two methods shown in Figs. 133 and 134, is so slight as to be negligible, except perhaps, in gears having very few teeth. Whatever the method pursued for laying out or studying the action, all

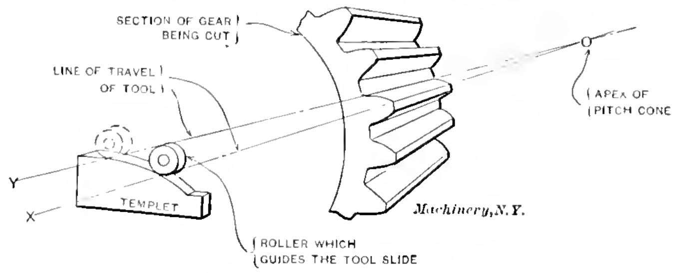

Fig. 136. Diagram illustrating the Templet Principle for Forming the Teeth of Bevel Gears.

the elements of which the teeth are formed consist of straight lines which meet at the center O of the pitch cones; consequently the teeth grow small toward the inner end, vanishing at the center if they are carried that far.

Five Principles of Action.

All of the five principles of action on which spur gear teeth may be formed (the formed tool, the templet, the odontographic, the describing-generating and the molding-generating principles) may be also applied to the cutting of bevel gears, though the describing-generating principle has never been so used, as far as the author's knowledge goes, so we will not give any time to its consideration.

The Formed Tool Principle: The use of this principle is illustrated in Fig. 135, where we have a bevel gear blank set

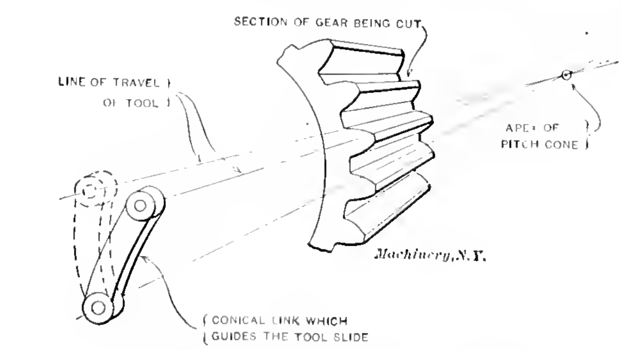

Fig. 137. Diagram illustrating the Odontographic Principle for Forming the Teeth of Bevel Gears.

in position to have the tooth spaces cut by a formed milling cutter. This method, though perhaps the commonest employed of all, is in its nature an approximate one only, it being impossible by it to form the tooth correctly. The reason for this may be seen in Fig. 135, where it is evident that the right-hand side of the cutter is reproducing its own unchanging outline along the whole length of the base of the tooth at the right. This form should not be unchanging, for, as previously explained, the teeth and the spaces between them grow smaller toward the apex of the pitch cone, where they finally vanish;

* Associate Editor of MACHINERY.

so it is evident that the outline of a tooth at the small end should be the same as that at the large end, but on a smaller scale—not a portion of the exact outline at the large end, as produced by the formed tool process and as shown in the figure. To make this error as small as possible, it is customary to use a cutter which gives the proper shape at the large end, and set the blank so that the tooth is cut to the proper thickness at the small end. This leaves the top of the tooth at the

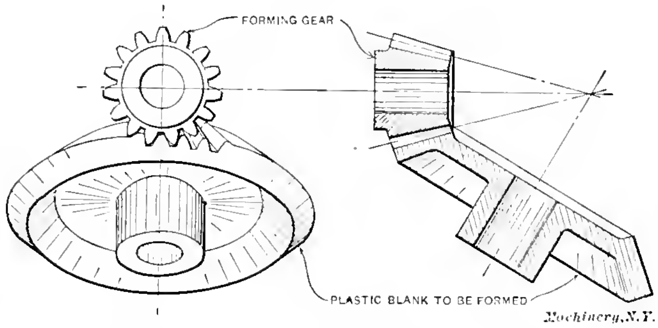

Fig. 138. The Impression Operation, applied to forming the Teeth of a Bevel Gear by the Molding-Generating Process.

small end too thick, an error which is often remedied by filing. Of course, the principle is the same with the formed planer or shaper tool as with the formed milling cutter, and the errors involved in the process are also identical. It is evident that but one side of the tooth space can be cut at a time, so that at least two cuts around will have to be taken.

The Templet Principle: This principle is illustrated in Fig. 136, in skeleton form only. A former is used which has the same outline as would the tooth of the gear being cut, if the latter were extended as far from the apex of the pitch cone as the position in which the former is placed. The tool is carried by a slide which reciprocates it back and forth along the length of the tooth in a line of direction (*OX*, *OY*, etc.) which passes through the apex *O* of the pitch cone. This slide may be swiveled in any direction and in any plane about this apex, and its outer end is supported by the roller on the former. With this arrangement, in the case shown, as the slide is

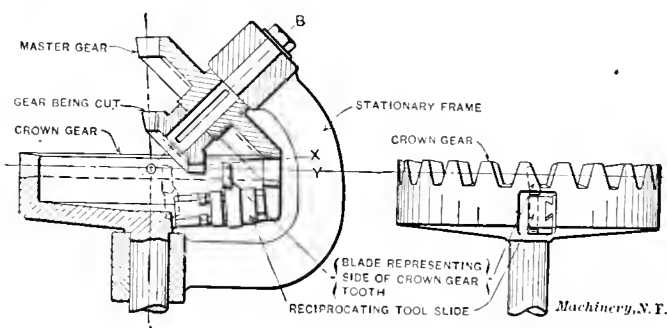

Fig. 139. Model illustrating the Shaping or Planing Operation, applied to the Molding-Generating Principle of forming the Teeth of Bevel Gears.

swiveled inward about the apex, the roll runs up on the former, raising the slide and the tool so as to reproduce on the proper scale the outline of the former on the tooth being cut. Since the movement of the tool is always toward the apex of the pitch cone, the elements of tooth vanish at this point, and the outlines are similar at all sections of the tooth, though with a gradually decreasing scale as the apex is approached—all as required for correct bevel gearing.

The arrangement thus shown diagrammatically is modified in various ways in different machines, but the movement imparted to the tool in relation to the work is the same in all cases where the templet principle is employed no matter what the connection between the former and the tool may be.

The Odontographic Principle: As explained for spur gears in Fig. 3, it is often possible to approximate the exact curves required for the teeth of gears by mechanisms which make use of circular arcs or other easily generated curves. In Fig. 137 is shown in diagrammatic form an arrangement for obtaining, by means of link work, a close approximation to the exact form of an involute outline, such as might be produced by the templet in Fig. 136, for instance. This true involute outline may be very closely approximated by a circle drawn on the surface of a sphere. To give this required circular movement to the point of the tool, the slide on which the tool reciprocates may be constrained by a link as shown, pivoted at the base to the frame of the machine, and at the upper end to the slide. The axes of these pivots should pass through the apex of the pitch cone, as required by the spherical nature of the bevel gear. This link work (which is thus of the "conical" type) if properly proportioned and located, will guide the tool slide and the tool point in very nearly the same way as a properly constructed templet, used as shown in Fig. 136.

The Molding-Generating Principle: The counterpart of the spur gear process shown in Fig 5 is illustrated for the bevel gears in Fig. 138. Here a correctly formed gear is being rotated in the proper position and in the proper ratio with a plastic blank. This operation, as in the case of the spur gear, forms teeth in the plastic blank which are properly

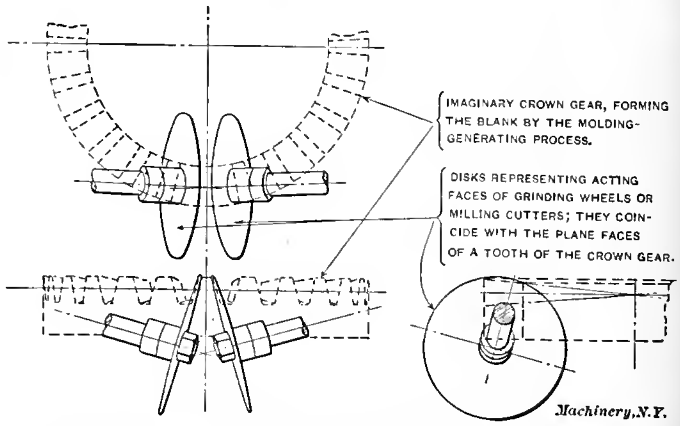

Fig. 140. Diagram suggesting the Arrangement of Milling Cutters or Grinding Wheels for Forming the Teeth of Bevel Gears by the Molding-Generating Process.

shaped to mesh with the forming gear or with any other gear of the same series. Fig. 6 has no possible counterpart in the cutting of bevel gears.

Four Methods of Operation.

By Impression: The same four methods of operation as for spur gears may be applied to the molding-generating principle, and quite generally to the other principles as well. Instead of using for illustration a rack as the generating member, we will have to use its bevel gear counterpart, the crown gear shown in Fig. 132. The impression method would simply

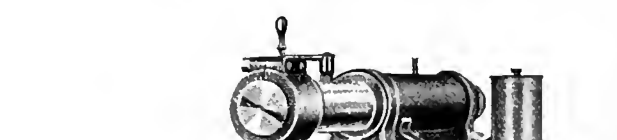

Fig. 141. Cutting Bevel Gear Teeth on a Milling Machine by the Formed Cutter Method.

consist of rolling the crown gear on axis *OA* and the pinion on axis *OB* together, when, if the latter were formed of a plastic material, the teeth of the crown gear would produce in its smaller mate corresponding tooth spaces and teeth of the proper shape.

By Shaping or Planing: There is but one form of tooth to which the planing operation of molding-generating is adapted. This is the form in which the crown gear has teeth with plane sides, which may be cut with a straight-sided tool. If

the drawing of an involute rack were wrapped around the periphery of the disk in Fig. 131, about axis AO, and the tooth outlines thus determined used in teeth vanishing at O, in the plane of the pitch line, the resulting crown gear would be of this type. In other words, it is Tredgold's approximation of the involute system. In Fig. 139 such a crown gear is shown combined with a simple mechanism for making use of the planing or shaping operation in the molding-generating process. The gear being cut is keyed on a loosely revolving spindle, to which is also keyed a master gear, formed on the same pitch cone and having, in this case, the same number of teeth. This spindle is so set in relation to the axis about which the crown gear revolves, that the master gear and

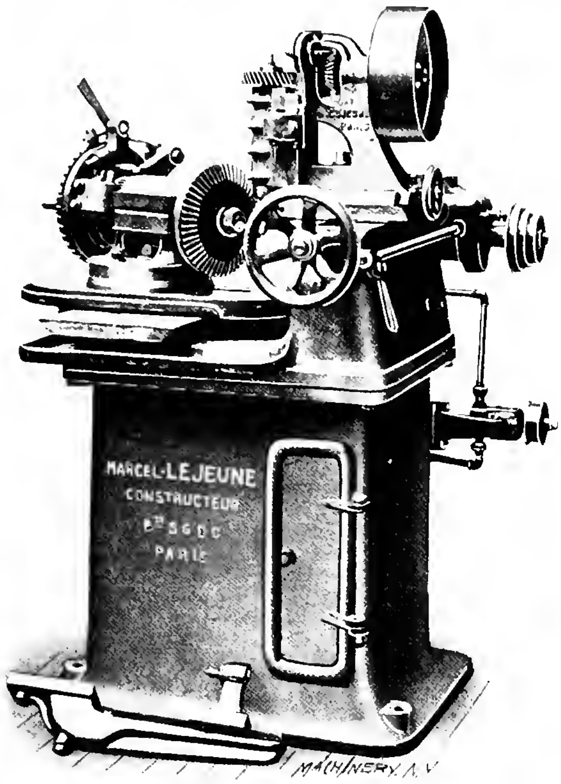

Fig 142. A Special Milling Machine for Cutting Bevel Gear Teeth.

the crown gear mesh together properly, the crown gear being of the required pitch, and having the proper number and shape of teeth for this action. If now the crown gear be rocked about its axis, the master gear will also rock with it, carrying the gear being cut.

The blade is set, as shown in the view at the right, so that its cutting edge coincides with the plane of one of the teeth of the crown gear, and being held in a slide which guides it in such a way that it moves in this plane, and so that its point follows the line OX, radiating from the apex O of the pitch cones. The tool will evidently represent the side of the tooth of an imaginary crown gear, which is adapted to mesh properly with any bevel gear such as that shown being cut, keyed to the master gear and having the same pitch cone shape and number of teeth.

If, with the mechanism so arranged, the crown gear be rotated so as to start the cut at one side of a tooth of the work (which should be first roughly cut to size) the continued rotation of the crown gear will roll the master gear in such a way that the reciprocating blade (representing the side of an imaginary crown tooth meshing with the work) will shape the side of the tooth being cut to the proper form, by the molding-generating process, on the same principle as shown in Fig. 138.

This arrangement, of course, is not a practical working machine as shown, since there is no provision for making it universal for cutting bevel gears of other pitch cone angles and numbers of teeth, or for indexing the work with relation to the master gear to cut the remaining teeth of the work shown in place. Arranged as shown, however, the machine will cut any gear within its range, of the same pitch cone angle and number of teeth as the master gear. To cut a different number of teeth it would only be necessary to alter angle XOY, as required, setting the slide at a greater angle for fewer and larger teeth, or at a less angle for more and smaller teeth.

This principle will be found applied in this and in modified forms in machines we will describe later. One of the modifications which will be seen is equivalent to making the crown gear in Fig. 139 stationary, and swinging the frame around it about axis OA, thus rolling the master gear and the work in the same relation to the tool as when the frame is stationary and the crown gear is revolved, in the way we have just described. Still another possible modification would consist in holding the master gear and work still, while the frame is swung about axis OB. In this case the crown gear would roll on the master gear, rocking the tool slide in such a way as to give the required movement. It is not possible to form a tooth space complete with a single tool, as shown for spur gears, at T_1 in Fig. 8, without cutting the tooth space too deep at the outside end. A separate blade has to be used for each side of the space or of the tooth.

By Milling, and by Grinding or Abrasion: Milling cutters or grinding wheels may be used to represent the space of the tooth, as they represent the rack tooth for spur gears in Figs 9 and 10. In Fig. 140 is shown diagrammatically an arrangement by which two cutters or grinding wheels may be made to represent the two sides of a tooth in such a way that by them a tooth space may be finished complete in the gear to be cut in a mechanism similar to that in Fig. 139, but without requiring the reciprocating movement. The same difficulty arises as in spur gears, of the center of the tooth being cut in deeper than the ends, owing to the circular form of the cutter. This, however, makes no change in the action of the finished gear.

The variety of applications for these various principles and methods of operation is fully as great in bevel gears as in

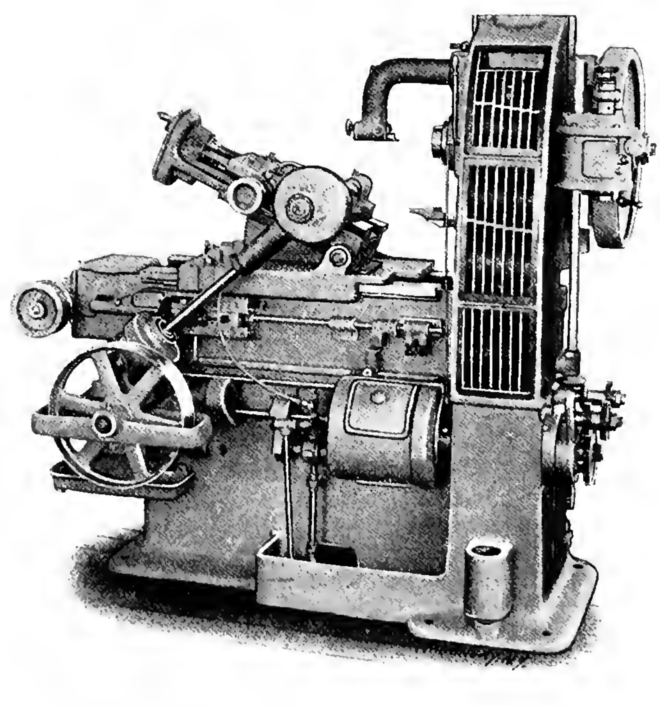

Fig. 143. Brown & Sharpe Automatic Spur and Bevel Gear Cutter, as set up for Cutting Teeth of the latter Form.

spur gears, and the machines in which they are incorporated apply these principles and methods in an even more ingenious fashion.

Machines using Formed Milling Cutters for Shaping the the Teeth of Bevel Gears.

One of the most commonly used machines employing the formed tool process is the ordinary milling machine. An example of the use of the Cincinnati miller for this purpose is shown in Fig. 141. The work is held on an arbor carried by the spindle of the universal head, by which the blank is indexed for the required number of teeth. The head is set to the proper angle to make the bottom of the tooth space horizontal. As explained in the paragraph describing Fig. 135, it

is possible to cut but one side of a tooth space at a time, if teeth of even approximate accuracy are desired. For this reason, and to obtain as nearly a correct form of tooth as possible, the side of the tooth to be cut is moved away from the cutter horizontally and then the work spindle is revolved to bring it up to it again, the amount of "set-over" and "rolling" being adjusted by judgment and by "cut-and-try," to give the best results. Instructions for doing this have recently been published in MACHINERY.*

The automatic attachment built by Ludwig, Loewe & Co., and shown in Fig. 14, is also adapted to the cutting of bevel gears in the milling machine, which it renders automatic, doing the work under the same conditions as the orthodox machine shown in Figs. 143 and 144.

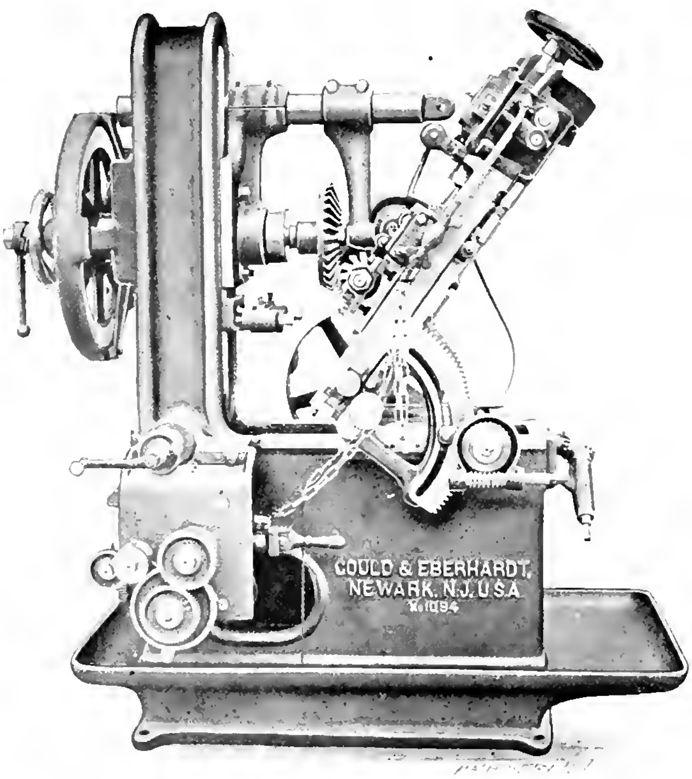

Fig. 144. Cutting a Bevel Gear on the Gould & Eberhardt Automatic Machine of the Orthodox Type.

The dividing head of the milling machine may also be used on the shaper table, for indexing the work and setting it to the proper angle when cutting the teeth with a shaper tool having a blade formed to the proper outline. The necessary set-over and rolling movements required to reproduce an approximation to the correct form are exactly identical with those necessary for the milling machine. The shaping process may be used for odd jobs where no formed cutter is available.

In Fig. 142 is shown a special machine which is identical in operation with the milling machine when used as shown in Fig. 141. Being built, however, especially for the work of cutting bevel gears, it is of simpler construction and less expensive. The bed of the machine carries sliding ways at the right, on which is mounted a knee on the face of which the cutter spindle is vertically adjustable. The latter is driven, through the twisted and bevel gearing shown, from a wide-faced pulley of large diameter. The knee is not mounted directly on the slide but is carried by an intermediate saddle along which it is adjustable in and out for the depth of cut. The feed is provided with an automatic stop, but is returned by hand. The work is mounted on a spindle set in a head, which may be clamped at the proper cutting angle on the base by which it is supported. This base may be adjusted toward or away from the cutter as well as parallel with the movement of the latter, to approximately the position required. The work is indexed by a notched plate operated by hand. The index locking pin is itself carried by an arm which may be swung about the axis of the work by a worm and worm-wheel adjustment to give the required rolling movement, independently of the indexing for correcting the shape of the teeth. What corresponds to the cross movement given the blank in the milling machine is effected here by the vertical adjustment of the cutter spindle on the face of the knee. Provision is made for making both of these adjustments positively and quickly. This machine is built by Etablissements Marcel Lejeune, 93 Rue D'Angouleme, Paris.

Another favorite way of using the formed cutter principle for cutting the teeth of gears employs a modification of the orthodox automatic gear-cutting machine, such as previously shown in Figs. 21 to 28 inclusive. When this is done, one side of the tooth can be finished clear around without attention from the operator, the cutter slide feeding up, returning, and the work indexing, as for spur gears. The cutter has to be set out of center with the blank and the latter rotated, to approximate the correct form, as with the machines previously described. After going around one side of the tooth, this adjustment has to be reversed to complete the other side, so that two operations are necessary. Fig. 143 shows the Brown & Sharpe gear-cutting machine as provided with the angular cutter slide adjustment for bevel gears, and Fig. 144 shows a Gould & Eberhardt machine arranged for the same work. Probably a greater proportion of the bevel gears made are cut on machines of this kind than in any other way. For slow running gears, the approximation, especially if the teeth are afterward filed, may be made close enough to be correct for all practical purposes. For large, high-speed gears to transmit power, one of the planing processes to be described later should be used.

In Fig. 145 is shown still another method of adapting the orthodox gear-cutting machine to the work of cutting bevel gears. The machine shown in this case is that built by the E. J. Flather Mfg. Co., of Nashua, N. H., and illustrated in Fig. 23.* The attachment consists of a supplementary work spindle connected with the main work spindle by bevel gearing in such a way that it may be adjusted to any angle, thus making it unnecessary to complicate the cutter slide and feeding mechanism. The attachment is suitable for work of small diameter, and may be applied to machines not originally designed for cutting bevel gears.

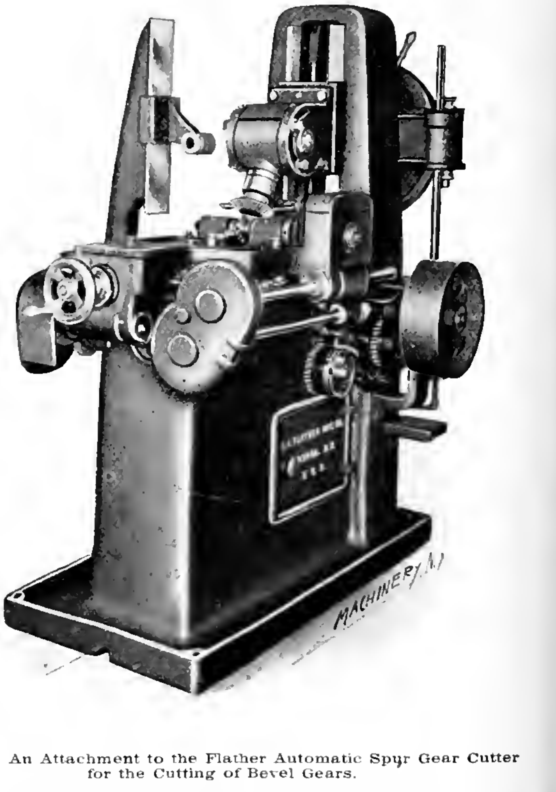

Fig. 145. An Attachment to the Flather Automatic Spur Gear Cutter for the Cutting of Bevel Gears.

The automatic idea has been carried still further in a machine developed a few years ago by the Brown & Sharpe Mfg. Co., of Providence, R. I., for cutting bevel gears for chainless bicycles. These gears were to be made in enormous quantities,

* See article "Cutting Bevel Gears with a Rotary Cutter," in the October, 1907, issue of MACHINERY.

* See "New Machinery and Tools" in the December, 1907, issue of MACHINERY.

so that the time lost in the side adjustment and the rolling of the work to bring the blank and cutter into position for cutting the other side of the teeth, after one side had been completed, consumed sufficient time to make the elimination of the operation profitable. The machine shown in Fig. 146 was therefore devised to first feed the cutter through, with the cutter and work set properly for finishing one side of the tooth;

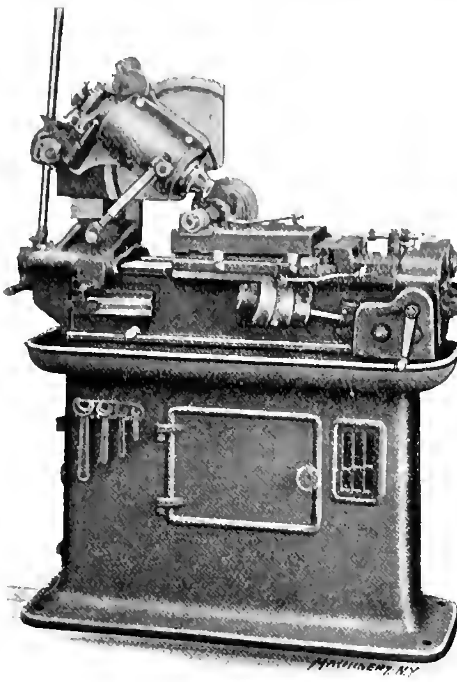

Fig. 146. A Special Bevel Gear Cutting Machine in which provision is made for Shifting the Line of Travel of the Cutter; both Sides of the Teeth are finished automatically.

when the cutter had passed through the work, the slide on which it was mounted was shifted to a different angular location, so that when it was fed backward to its starting position, the return cut operated on the opposite side of the tooth space, under conditions which finished it to the desired form. This change in angular position of the tool slide was so adjusted as to be equivalent to the rolling of the blank and the sidewise movement of the cutter or work, required in cutting bevel gears in the milling machine or automatic gear-cutter.

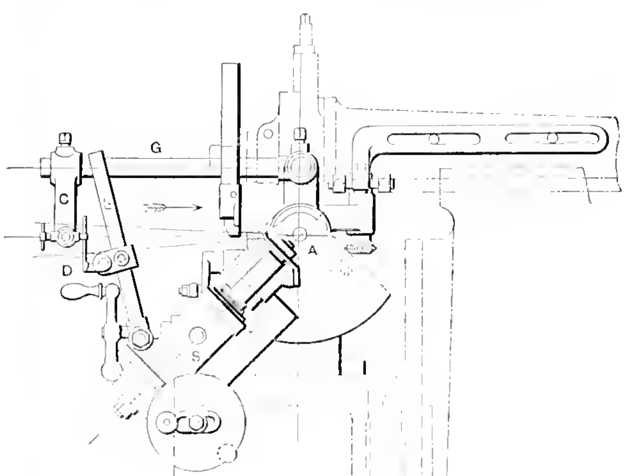

Fig. 147. A German Shaper Attachment for Forming the Teeth of Bevel Gears on the Templet Principle.

This machine indexes the work by a notched plate, stops the feed when the last tooth has been cut, and is in other ways adapted to the rapid manufacturing of gears in large quantities. The gears are afterwards finished by molding-generating process to be described later, in which the inaccuracies inherent in the formed tool principle are smoothed out. Of course, its usefulness is not limited to the bicycle field for which it was first designed.

Attachments for Forming the Teeth of Bevel Gears by the Templet Principle.

The templet principle has found a much wider commercial application for cutting bevel gears than for cutting spur gears. This is due to the fact that the formed tool method, as we have seen, is not suited to producing theoretically accurate teeth in the bevel type of gear as it does in the case of the spur, since it does not give to the teeth an outline at the small end similar to that at the large end. Since the templet process is the least complicated way of forming a tooth similar in outline from one end to the other (in other words, one whose elements vanish at the apex of the pitch cone), a number of very successful commercial machines have been built involving this principle. The first cases we will consider, however, are not complete machines, but attachments to the shaper.

In Fig. 147 is shown an attachment built by the Act.-Ges. für Schmirgel-u. Maschinen-Fabrikation, Bockenheim-Frankfurt am Main.* This is mounted on the shaper table so that the angularly adjustable head which carries the work spindle overhangs the side. The work spindle is indexed with worm and worm-wheel and index plate as in the case of the milling machine dividing head. This indexing mechanism is attached to a quill which is journaled in the work spindle head. It has adjustably mounted on its outer end a bar *B*, to which a holder is attached for supporting the templet *D*. An outer arm *C*, supported from the frame of the attachment by a

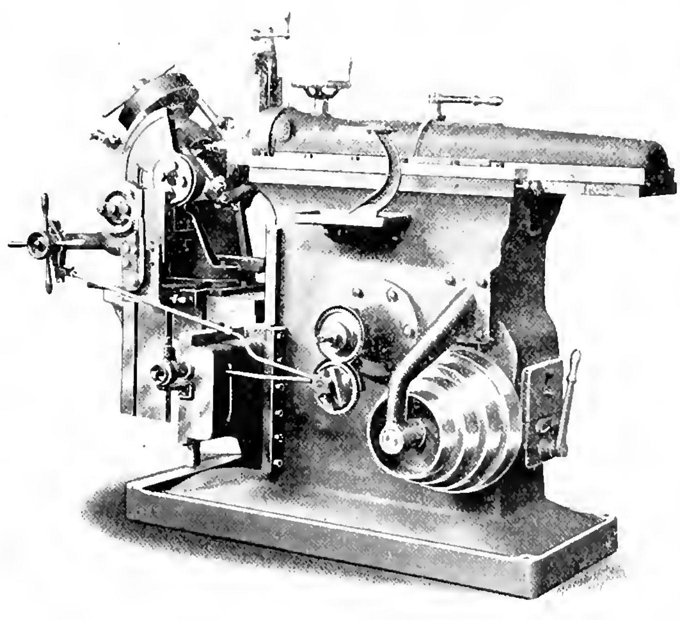

Fig. 148. An American Shaper Attachment employing a Templet for Controlling the Shape of the Bevel Gear Tooth produced.

bar *G*, carries a roll which is adapted to engage with the edges of templet *D*. The blank, in feeding, is swung up into the tool about center *A*. This swinging movement is operated by a worm and worm-wheel sector controlled by a ratchet feed. As the work is thus gradually fed up into the tool, the action of the roll on the templet will rock bar *B*, and the quill and index motion attached to it, thus swinging the work in such a way as to reproduce the outline of the templet on the outside of the tooth. The action is thus identical in its effects with that in Fig. 136, though the templet is used to control the work instead of controlling the tool.

The attachment shown clamped to the shaper table in Fig. 148 is the invention of Mr. Fred Mill, 704 Prytania Ave., Hamilton, Ohio. The design of the attachment will best be understood from the line elevations in Fig. 149. The work spindle is carried in a head *B*, which is swung on horizontal trunnions *A* in housing *C*. This housing is held by semi-circular gibs to the circular base-plate *D*, so that it may be swung about a vertical axis. The feed rod *E*, operated by the regular feed movement of the shaper, is connected through a ratchet and hand-wheel with a worm and worm gear *F*, connected by spur gear segments with the spindle head *B* in

* See article "Two German Bevel Gear Shaping Attachments" in the May, 1907, issue of MACHINERY.

such a way as to swing it about its horizontal trunnions A, and thus feed the blank up into the tool.

On the base-plate D to which the housing is gibbed, is attached a holder G to which the former or templet is fastened. The roll which bears on this templet is held in a roller slide J, which is connected with the segment gears which swing the head in such a way that, as the blank is fed upward into the work, the roller slide is fed downward, carrying the roller along the face of the templet. Since the roll and roller slide are supported by the housing C, the templet moves the housing about its vertical axis, in conjunction with the swinging of the head about its horizontal axis, so as to produce the proper shape of tooth. The roll is held in contact with the head rocks. It is possible, by providing suitable change gears between cam M and worm shaft C in place of the fixed gears shown, to use the same cam or templet M for cutting a large range of gears, it not being necessary in that case to have one for each tooth used. The principle which makes this possible was explained in a description of this attachment, previously published in MACHINERY.*

Machines for Shaping or Planing the Teeth of Bevel Gears by the Templet Principle.

In this country the templet principle is represented commercially by a single machine, that built in various sizes and designs by the Gleason Works, of Rochester, N. Y. This machine is illustrated in Fig. 151. The tool is carried by a

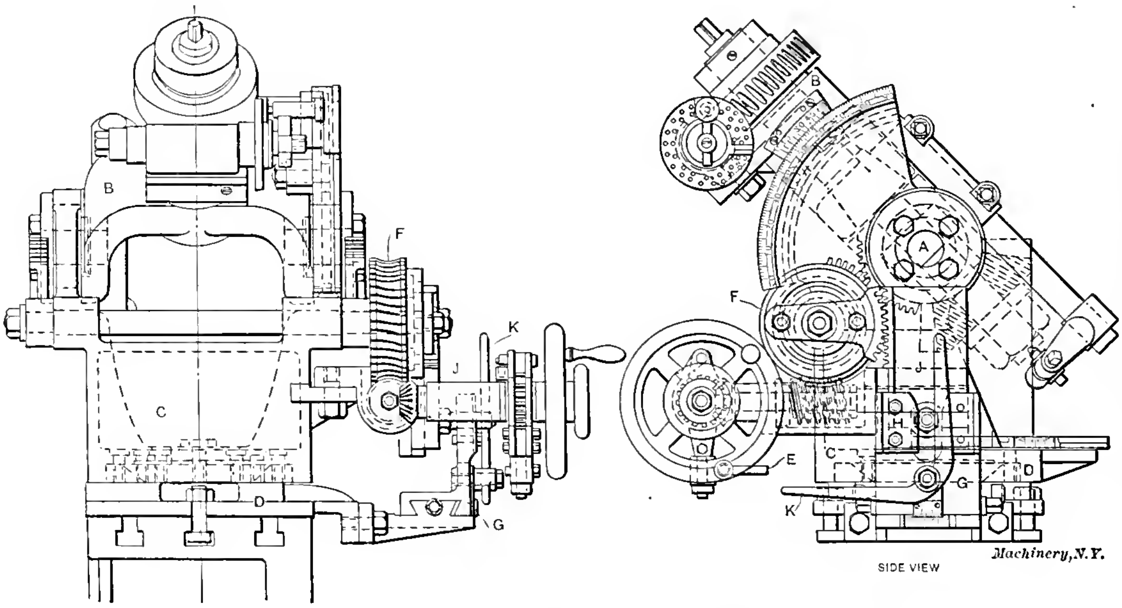

Fig. 149. Rear and Side Elevations of the Bevel Gear Shaper Attachment shown in Fig. 148.

templet by lever K, one end of which carries a weight, while the other bears on the roll stud. For shaping the other sides of the teeth, the templet is fastened on the other side of holder G, and the bent lever K is reversed so as to press the roll against the templet in its new position. A stop is provided which releases the automatic feed and quickly returns the head, so that the tool clears the work, as soon as the cut has been made to the proper depth. We understand that Mr. Mill is designing an automatic machine, operating on the same principle.

In Fig. 150 is shown a German bevel gear shaping attachment, the invention of Prof. Moritz Kroll of the Government Trade School of Pilsen. This device is also designed to be mounted on the shaper table. It has a base-plate to which are attached two standards, F and F_2, having bearings for the trunnions on head B, which may be adjusted about these trunnions to the desired cutting angle, by means of a worm, and worm sector E, fast to F_2. The work is divided by the index plate and adjustable crank shown, operating a worm meshing with the index worm-wheel on the rear end of the work spindle A. This index mechanism is supported on an arm, whose lower forked end is seen at I. The contact points on either side of this arm, as desired, may be made to bear under spring pressure on cam M, which is pinned to gear Q, in mesh with gear D, which is in turn keyed to the shaft C, carrying the worm engaging with sector E. All this mechanism is mounted on swinging head B, excepting E, which is pinned to standard F_2. From this it will be seen that the work may be swung up into the shaper tool about the trunnions on head B by operating shaft C.

As the work is thus swung upward, gear Q is revolved, and with it cam or templet M, which rocks the lower end of lever I, and with it, the work. Templet M is so shaped that this rocking movement, in conjunction with the upward swinging of the blank, causes the point of the tool in the shaper to produce the required outline of tooth. In this, as in the previous cases, the point of the tool is set to travel along a line which, if produced, would meet the intersection of the axis of the work spindle and the axis of the trunnions, about which the holder reciprocated by an adjustable, quick-return crank motion. The slide which carries this tool-holder may be swung in a vertical plane about the horizontal axis on which it is pivoted to the head, which carries the whole mechanism of tool-holder, slide, crank, driving gearing, etc. This head, in turn, may be swung in a vertical axis about a pivot in the bed. The circular ways which guide this movement are easily seen in the illustration. The intersection of the ver-

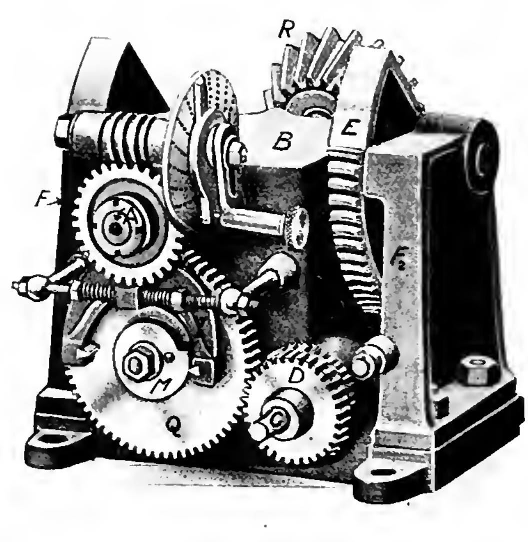

Fig. 150. Shaper Attachment devised by Professor Kroll, in which a Circular Templet is used for Forming the Teeth of Bevel Gears.

tical and horizontal axes of adjustment (which takes place in mid air in front of the tool slide) is the point O in Fig. 136, where the templet principle is shown in diagrammatic form. The apex of the pitch cone of the bevel gear must be brought to this point O. The blank is mounted on a spindle carried by a head which is adjustable in and out on the top of the

* See article "Two German Bevel Gear Shaping Attachments" in the May, 1907, issue of MACHINERY.

bed of the machine so that the apex of the cone of the gear may be brought to this point by means of the gages which are a part of the equipment of the machine. The work spindle is provided with an indexing mechanism, which operates automatically, as do all the other functions of the machine.

Three templets are used, mounted in a holder attached to the front of the bed, on the opposite side from that shown. The first of these templets is for "stocking" or roughing out the tooth spaces. It is simply a horizontal straight-edge on which rests a roller, attached to the outer end of the slide on which the tool-holder reciprocates. With the work and tool set properly, the whole tool-carrying head is swiveled about the vertical axis, feeding in at each stroke of the blade deeper and deeper, until the space has been properly roughed out. After each tooth space has been gashed in this fashion, the templet holder is revolved to bring one of the formed templets into position, and a tool is set in the holder so that its point bears the same relation to the shape of the tooth desired as the cam roll does to the templet. The head is again fed in by swinging it around its vertical axis, during which movement the roll runs up on the stationary templet, swinging the tool about its horizontal axis in such a way as to duplicate the desired form on the tooth of the gear. One side of each tooth being thus shaped entirely around, the holder is again revolved to bring the third templet into position. This has a reverse form from the preceding one adapted to cutting the other side of the tooth. A tool with a cutting point facing the other way being inserted in the holder, each tooth of the gear has its second side formed automatically, as before, completing the gear.

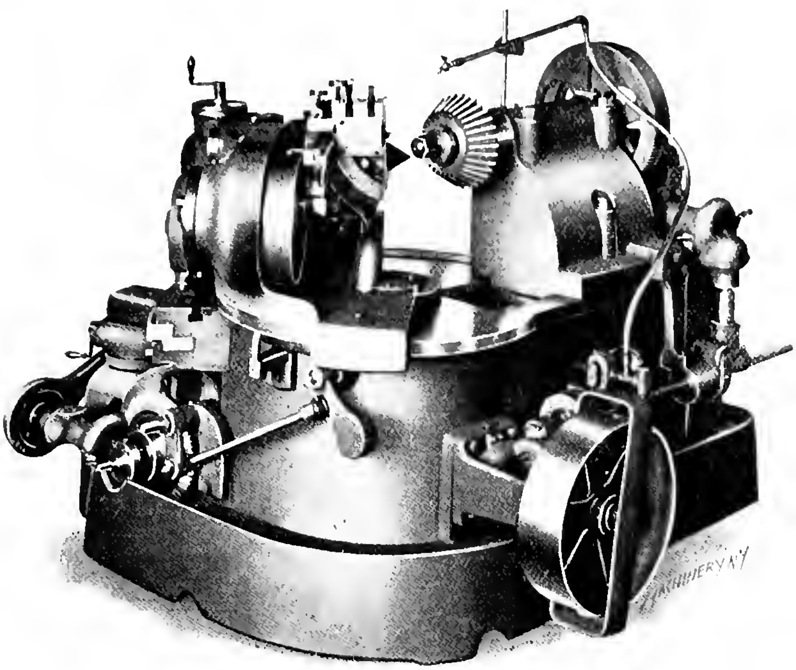

Fig. 151. Gleason Templet-controlled Bevel Gear Planing Machine.

The swinging movement for feeding the tool and the indexing of the work are taken care of by the mechanism of the machine without attention on the part of the operator. The swinging feeding movement about the vertical axis is effected by a cam and slotted link motion which may be adjusted to any degree of angular movement required. The head may be angularly adjusted with respect to its feed to agree with the pitch angle of the gear being cut. This is a more recent design than the last machine of this kind that was illustrated in MACHINERY,* differing from it particularly in the feeding arrangement. That previously shown was fed in to depth by a segment of a worm-wheel operated by a feed motion which could be given a forward movement for any required depth of cut, and a quick return, which was again reversed as soon as the indexing took place.

A French machine, built by Usines Bouhey, 43 Avenue Daumesnil, Paris, is shown in Fig. 152. While it operates on the templet principle, the movement for producing the desired outline is somewhat different from that employed in the Gleason machine, previously described. Instead of applying the movement derived from the templet to the tool, it is applied to the work, in a manner which will be evident from the illustration and the following description:

The cutting tool is carried by an overhanging arm, at the top of the frame, operated by the slotted crank shown. The work spindle carrying the wheel to be cut, the indexing worm-wheel, automatic dividing apparatus, etc., are carried on brackets attached to a swinging sector. The work spindle is so arranged that it may be adjusted longitudinally, to bring it into coincidence with the axis about which the sector is adjusted. The indexing mechanism is attached to a frame which is free to swing under the influence of the templet, which is attached to the upper end of an adjustable arm carried by this frame, and is located in a position to bear on a fixed guiding plate supported by the bed of the machine. It is held in contact with it by a weight and cord.

The action is as follows: The wheel, properly mounted on its arbor, is swung upward toward the reciprocating tool by a worm feed movement, applied to worm-wheel teeth cut in the periphery of the sector. While this angular feeding movement is in progress, a variable rocking is imparted to the entire indexing mechanism, work spindle and work, through the action of the templet on the stationary guide plate. It is this variable motion, controlled by the templet, which produces the desired outline on the tooth. When the correct depth of tooth has been reached, the feed is automatically tripped and the sector returned to its original position. The work is then indexed, the forward feed automatically re-engaged, and the cycle of operations continued until all the teeth are finished on that side, and the machine is stopped by the operator, and reversed for completing the teeth.

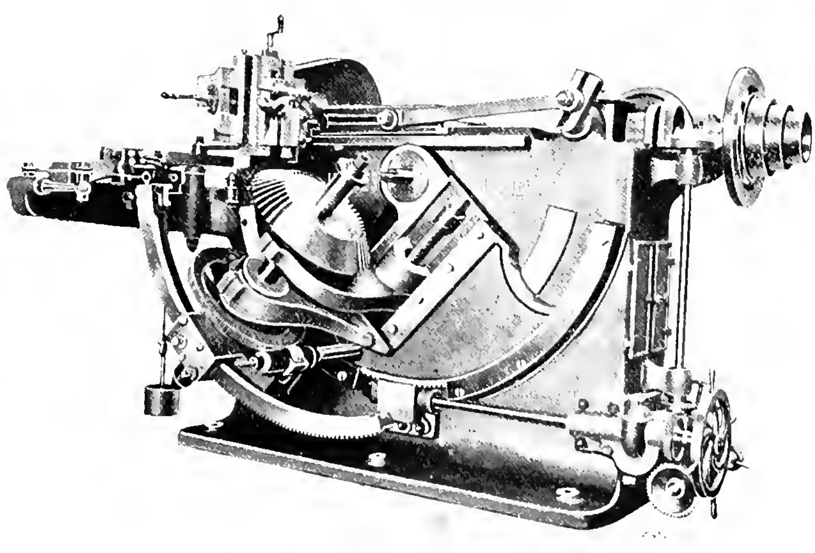

Fig. 152. The Bouhey Templet Planing Machine, in which Provision is made for the Cutting of Twisted Teeth.

A unique provision of this machine is that made for cutting bevel gears with twisted teeth, as shown in Fig. 152. It consists simply in providing for a positive connection between the indexing mechanism and the crank-shaft driving the tool slide, through the medium of change gears, so that the work and crank rotate in unison at the proper ratio to give the

* See article "Cutting Bevel Gears with Correct Teeth" in the June, 1898, issue of MACHINERY.

number of teeth desired in the work. Since the stroke then takes place while the work is rotating, a twisted form of tooth is produced. This tooth has the same shape (when seen at the ends) as when a straight tooth is being cut by the usual method. For cutting another gear of any angle to mesh with a gear cut this way—such, for instance, as the one shown in the engraving—it is only necessary to reverse the connection between the crank and the work so that rotation takes places in the opposite direction, and to set the slide and the templet for the new angle and the new tooth. This being done and the length of the stroke being the same, the teeth cut will exactly correspond in curvature with those previously cut in the mating gear.

Twisted tooth bevel gears are almost unknown in America, but have found considerable favor in Europe, where twisted tooth gearing of various kinds is in much greater favor than here. The teeth of gears thus made are not made to a true conical helix, since the motion is modified by the crank movement. All that is required, however, is that the curves of the gear and pinion should be such that the teeth of each will bear evenly on the other. This requirement is met in this machine.

An English machine, built by Greenwood & Batley, Ltd., Albion Works, Leeds, is shown in Fig. 153. The action and general arrangement of the machine are almost identical with that of the previous machine, excepting that no provision is here made for cutting twisted teeth. A comparison of the two tools serves well to show the wide variation in details resulting when two designers, independently work out the same idea. Aside from the difference in details, there are two salient changes in the mechanism. One of these relates to the feed, which is of the ratchet type, driven from a slotted disk. The other change relates to the mounting of the head, which is carried on two superimposed swiveling sectors, which pivot on a common center whose axis meets the line of travel

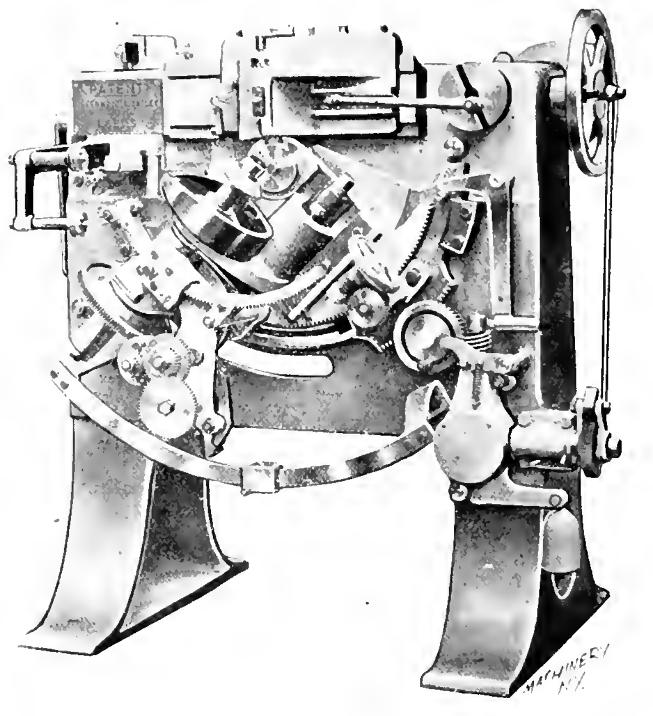

Fig 153 The Greenwood & Batley Templet Bevel Gear Shaping Machine.

of the cutting tool. The outer sector is adjustable on the face of the inner one to suit the angle of the wheel being cut, while the feed movement is applied to the latter. Except for the particulars enumerated, the action is identical with that of the Bouhey machine.

In Fig. 154 is shown still another machine with the same relations between the tool, the work and the templet. As may be seen, however, the design is so different that there is no resemblance between it and those shown in Figs. 152 and 153. The tool is carried by a ram reciprocated by a mechanism similar to that used in a crank-driven shaper; the whole arrangement of the machine, in fact, resembles that of a shaper and is structurally derived from it. The work is carried on a spindle mounted in a frame hung about a horizontal axis from pivots seated in the arms shown projecting from either side of the head of the machine. The work is adjusted on the arbor to bring the apex of the pitch cone into the horizontal axis through the trunnions. A rigid outboard support for the work arbor is furnished, as shown.

The frame carrying the work is swung upward for feeding about the horizontal trunnions by a feed movement operated by the tooth sectors shown on each side, which are engaged by pinions on a horizontal shaft, connected, in turn, by gearing with a ratchet disk seen at the side of the head. From this

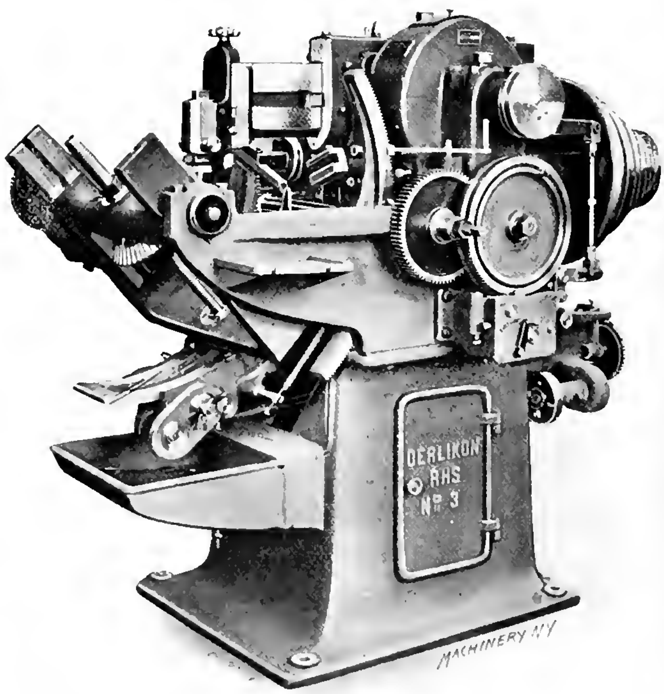

Fig. 154. The Oerlikon Single-tool Templet Bevel Gear Shaper.

the feed movement is obtained. Stops are provided on the face of the disk which limit the swinging feed movement, and actuate mechanism for returning the work rapidly when the cut has been completed, so that the tool is clear for indexing the blank. When the indexing has taken place, the upward feed is again automatically thrown in. As in the Greenwood & Batley machine, the entire dividing mechanism is attached to a bracket carrying an adjustable arm to the upper end of which the templet is attached. By means of springs this templet may be caused to bear on adjustable contact surfaces at either side, depending on which side of the tooth is being cut. The templet, bearing on the guide attached to the head of the machine on the side farthest from the observer, is somewhat imperfectly shown in the engraving.

We think it will be agreed that this tool gives evidences of careful design and construction. It has a decidedly rugged and business-like look. It is built by the Societe Suisse pour la Construction de Machines-Outils Oerlikon, Oerlikon près Zurich, Switzerland.

* * *

The United States Navy Department has decided to install oil-burning apparatus on two of the five torpedo-boat destroyers which are now being constructed by Cramp & Sons, the Bath Iron Works, and the New York Ship Building Company. Some weeks ago, Secretary Metcalf decided that it would be advantageous to have these boats equipped for burning oil instead of coal. The practicability of extending this system to torpedo-boat destroyers already in service has been talked of, and such a change carefully considered by experts, who have come to the conclusion that it would be impracticable to convert into oil-burning craft torpedo-boat destroyers already completed. Aside from the expense which such a change would entail, it was found that the installation of such apparatus would involve much work in the way of alterations, and this could only be done under great difficulty.

SPECIAL MACHINES AND TOOLS USED IN UPRIGHT DRILL MANUFACTURE.

One of the thriving cities of the Middle West—Rockford, Ill. —has acquired considerable distinction within the past few years as a machine tool manufacturing town. Six concerns building lathes, planers, drilling machines, milling machines and shapers are now located there; but machine tool building is by no means a new development in Rockford. One of the oldest concerns in the United States is the W. F. & John Barnes Co., builder of foot-power lathes, foot-power wood-working machinery and upright drilling machines. From this concern three other machine tool companies in Rockford have developed, these being the Rockford Drilling Machine Co. (formerly B. F. Barnes Co.), the Barnes Drill Co, and the Mechanics Machine Co.

The lively competition existing in the manufacture of upright drilling machines has led to the development of many interesting time- and labor-saving devices in the Rockford shops, which are largely used on drill presses. The following article relates to the shop practice of the Rockford Drilling Machine Co., and the special tools illustrated and described are to a large extent the result of the ingenuity and resourcefulness of Mr. R. Milne, the superintendent. The devices which are adapted to the drill press make good object lessons to the intending purchasers, showing them to what extent this humble machine can be used for manufacturing parts that are commonly done on much more costly tools.

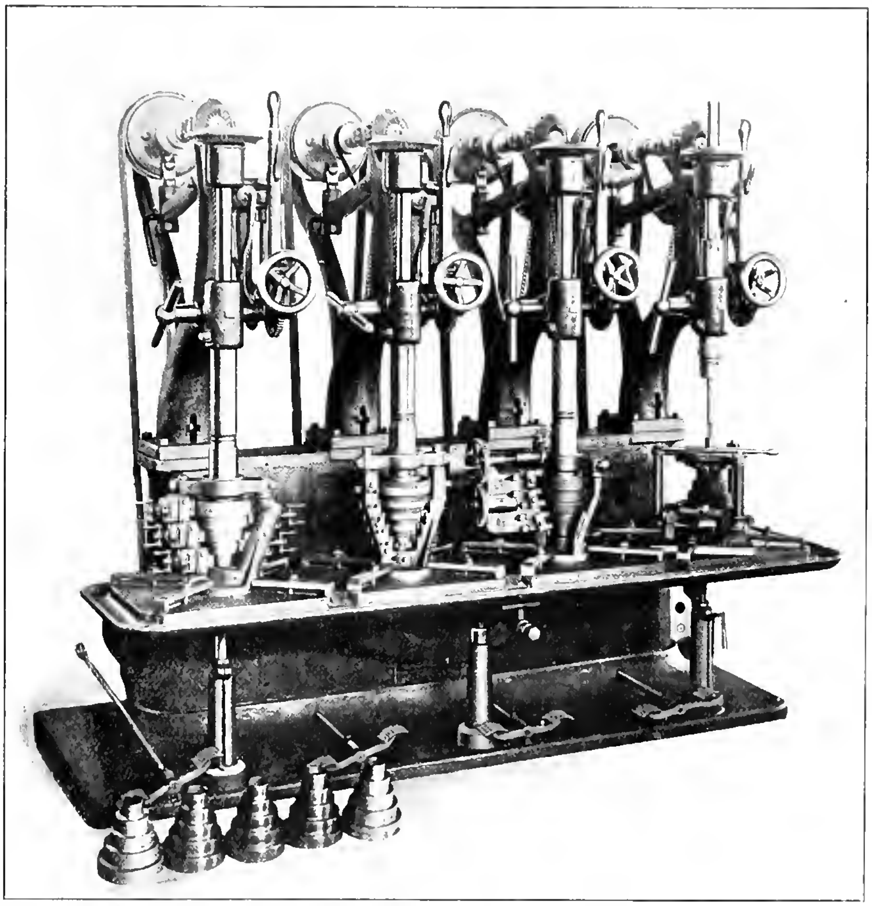

Fig. 1. Set of Tools used on Gang Drill for Boring and Turning Cone Pulleys.

Figs. 1, 2, 3, 4, and 5 are examples in point. Fig. 2 illustrates a cam-cutting attachment for cutting a special cam used in a certain style of drill press. This cam operates the feed motion of the drill spindle through ratchets. The construction of the rig for cutting the cam A is quite plainly shown in the engraving. A small gear is mounted on the lower part of the drill spindle, which drives a train of gears and worm-wheels. The first worm B and worm-wheel gives the rotary motion to the mandrel on which the cam is mounted, and the second worm-wheel driven by gear C operates the crank-shaft D, to which the slide mounted on the base E is attached by the connecting-rod shown in front. This slide reciprocates the cam underneath the end mill mounted in the drill spindle, and thus generates the required curve. The machine operates automatically, the regular feed of the drill press moving the end mill downward until the required depth is reached, when an automatic throw-out stops the feed.

Fig. 1 is another illustration of unusual drilling machine work, a set of special tools being provided for finishing small cone pulleys. The rough casting is mounted in a jig, as shown at the right, and the spindle hole is bored out, the boring tool being supported by a bushing in the top of the jig. The casting is then reversed and placed in the next jig at the left, on which is mounted a set of turning tools. As the casting is revolved, these tools face the edges of the cone steps, the feed being automatically effected by the mechanism. The next step is turning the faces of the pulleys. This jig is simpler in construction. The casting is fed downward past the turning tools held in the sides of the yoke. When this operation is finished, the steps have been turned straight. The jig at the extreme left is for coning the steps, the tools being forming tools, which are fed by hand.

Fig. 3 illustrates a drill press jig for boring pulleys. It consists of a base in which are vertically mounted three square-thread screws which act as the supports for the top plate carrying the guide bushing. The movable part of the jig is operated by three hand-wheels connected by a bicycle chain running on sprockets and held closely in contact with the sprocket by adjustable idlers. A novel feature of the jig is the jaws clamping the edges of the pulley rim. These jaws are notched in vee shape, and grasp the pulley rim internally at the top and externally at the bottom in the example shown, but a larger or smaller size would be grasped in reverse manner by the upper and lower jaws. The jig is adapted to pulleys of all sizes within its capacity, the notched jaws holding any size pulley within these limits concentric with the central hole.

Fig. 5 is a simple rig applied to a 26-inch drill for boring drill spindles. The drill is held stationary, being mounted on the table, and is of the oil tube variety. The lips are ground to cut left-handed in order to accommodate the drill to the left-hand rotation of the work. A gear is mounted on the lower end of the drill spindle, which drives a gear mounted on a sleeve in which the spindle to be bored is chucked. Lubricant is forced to the point of the drill and chips and oil are forced downward onto the table. The rig is very cheap and effective in operation. It consists essentially of only two castings, and the rotary sleeve, together with the chuck, clamping screws and driving gears.

Fig. 4 shows a set of tools used on a gang drill for boring and finishing collars. The rough casting is first caught in the three-jawed chuck at the right, and reamed and faced. It is then removed to the center fixture, which has an expanding arbor worked by the nut beneath. The arbor is expanded inside the bore and holds the casting firmly for the rough turning operation performed by the tool shown above it. The finishing operation is conducted in the same way, the bushing being held in the same manner and turned by a finishing tool of the same style as the roughing tool.

Figs. 7 and 8 show two views of a novel machine for cutting oil grooves in loose pulleys and cone pulleys. A loose pulley A is shown in place in the chuck B in Fig. 7, and the end of the cutting bar is shown projecting through the bore in the hub. The chuck used for holding loose pulleys consists of two sectors B B turned with concentric grooves to suit the various diameters of pulley rims. The handle H, shown in front in Fig. 8, loosens and tightens the frame holding these sectors.

The pulley is placed in position in the sectors, and by tightening the handle they are made to grip the pulley rim firmly. For small work, a three-jawed chuck G mounted on a plate, shown leaning against the base in Fig. 7, is employed. For

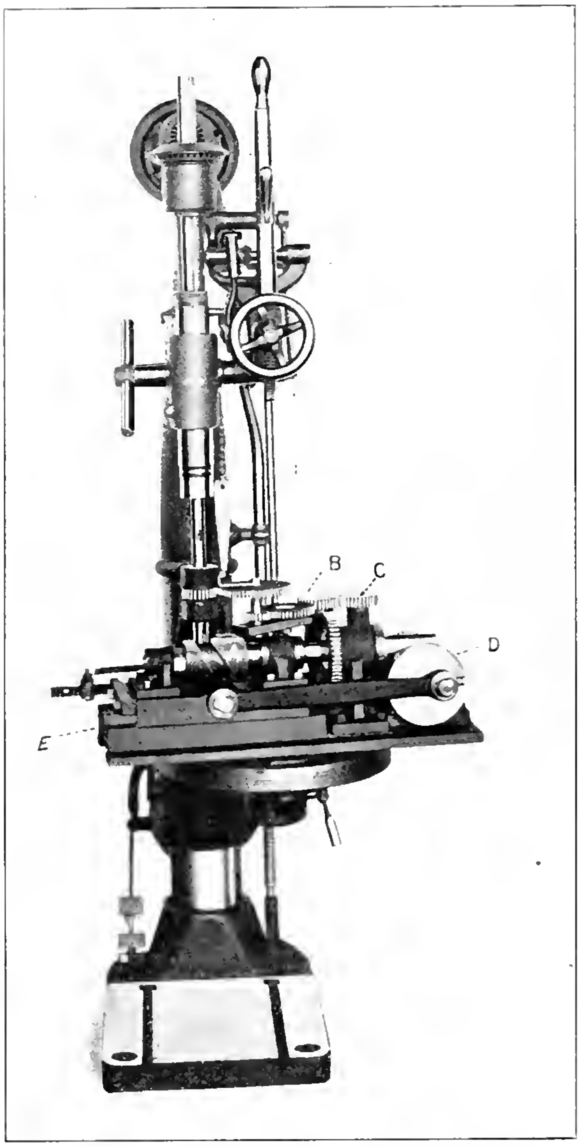

Fig 2. Cam-cutting Machine used on Upright Drill

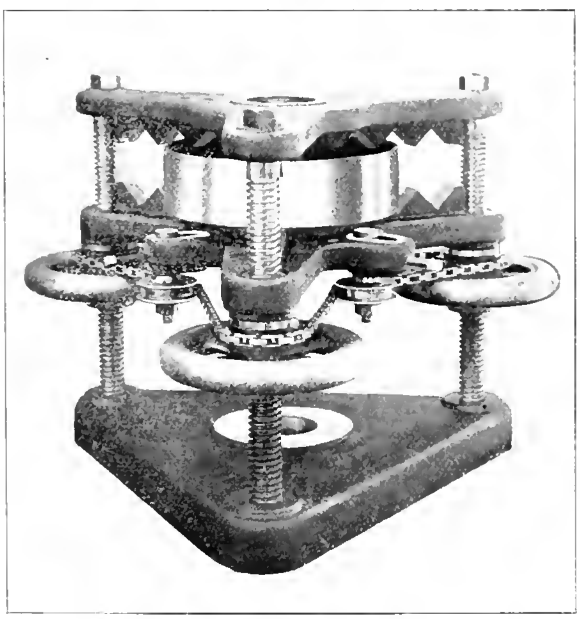

Fig. 3. Jig for Boring Pulleys.

cone pulleys the rig used for cutting loose pulleys is employed, and the adjustable support E, shown underneath, is used to support the outer end of the cone. The action of the cutting tool is a combination of reciprocating and up-and-down movements, as is required for cutting a key-seat deepest in the center. The cutter bar F is mounted on trunnions on a slide, and the rear end C is pivoted to the end of a connecting-rod D, also mounted on trunnions in a second slide. This connect-

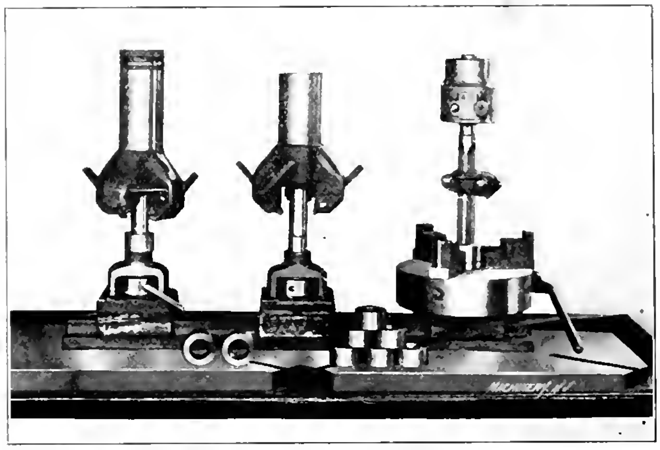

Fig. 4. Jigs for Boring and Turning Collars.

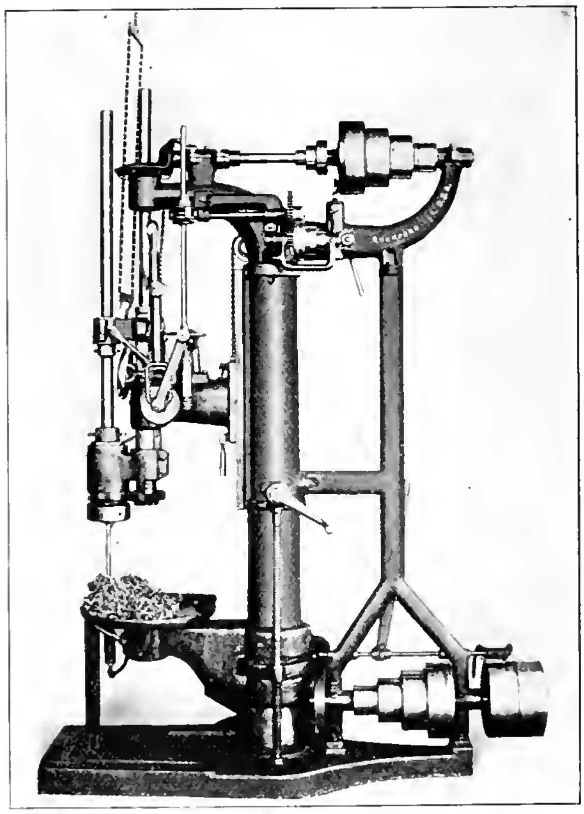

Fig. 5. Attachment for Boring Drill Spindles.

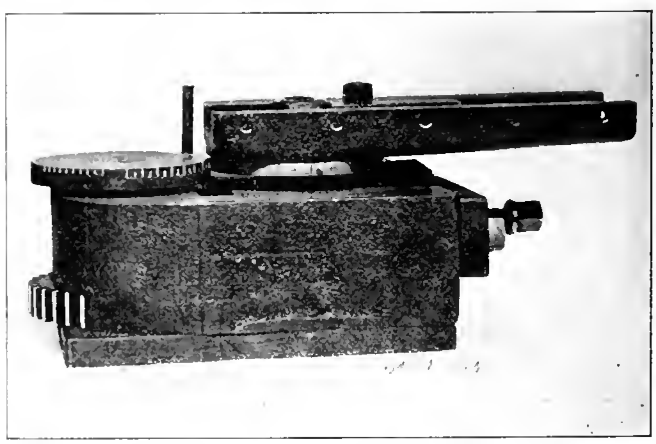

Fig. 6. Jig for Graduating Compound Rests, with Hob.

ing-rod is driven by a slotted crank disk, the stroke thus being made adjustable. The point of connection of the cutter bar to the end of the connecting-rod may be varied by changing the position of the cutter-bar pivot in the connecting-rod

T-slot. Thus the length of the stroke may be adjusted by changing the position of the crank-pin in the slotted crank disk, and the up-and-down movement of the cutter bar is adjusted by changing the location of the pin connecting it to the end of the connecting-rod. The depth of an oil groove is not necessarily a widely varying dimension, but the fact that the depth produced by the mechanism depends on the length of stroke, makes it necessary to change the up-and-down motion whenever the position of the crank-pin is changed on the crank disk. This machine is rapid in operation.

The graduations on the drill sleeves or quills are rolled in by a special device. The lines are raised on the barrel of a hardened rotary die, and this die is geared to a reciprocating table in which the quill is firmly fixed. One pass of the quill underneath the die imprints the graduations. The quill is then transferred to a simple hand jig, and located therein so that ordinary figure dies mounted in square slots will be in position corresponding to the inch graduations. These numbers are successively struck with a hammer, thus sinking the numbers into the quill. A hardened die or hob is also employed for rolling the graduations into the edge of lathe com-

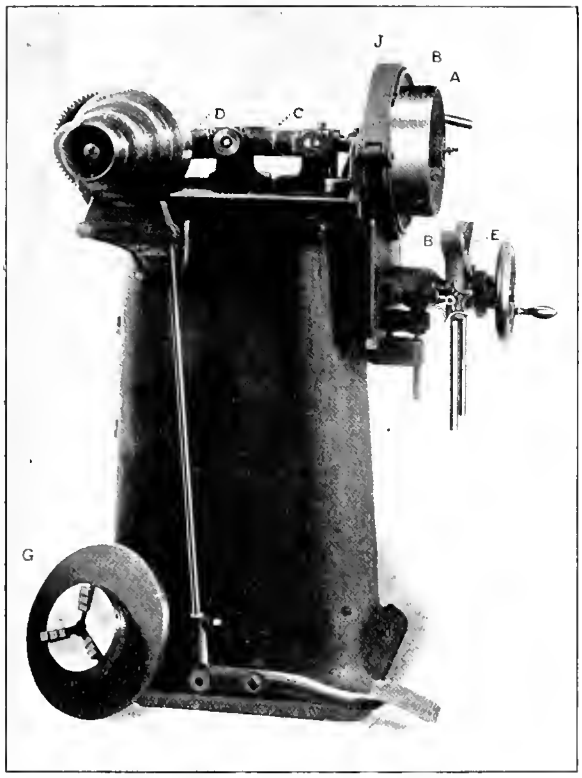

Fig. 7. Keyway-cutting Machine.

pound rests. One rotation does the work. The hob or die is mounted on a spindle which is geared to the face-plate on which the compound rest is mounted, the two thus being made to rotate together positively. See Fig. 6. A variation in diameter of 1/32 inch does not affect the accuracy of the graduations produced, as the gears force the compound rest and the hob to rotate in unison with the rotation of the gears driving them. In other words, the turning of the compound rest is not effected by the hob, but by the gear mounted on the face-plate spindle.

Fig. 9 shows a keyseater which was made from a drilling machine frame, with a few changes in the pattern. The vertical ram which takes the place of the drill spindle in a drilling machine, is operated by a walking-beam having slotted joint connections for the ram and the connecting-rod slide. The crank-shaft is driven by a pinion belted to the cone pulley at the top of the machine. It will be observed that the changes required to convert a drilling machine into a vertical slotter were comparatively small. The machine works very effectively and rapidly. It is employed for keyseating the gears and pulleys, the work being mounted on a table having hand-fed adjustment. The machine works so rapidly that the greater part of the operator's time is taken up in clamping the work in place and removing it from the machine.

The machine shop and foundry buildings are built parallel, along the side of a low bank, the foundry being placed next to the bank and a railroad switch on the bank enables pig iron, sand, coal, coke, etc., to be delivered to the foundry by gravity. The space between the foundry building and the ma-

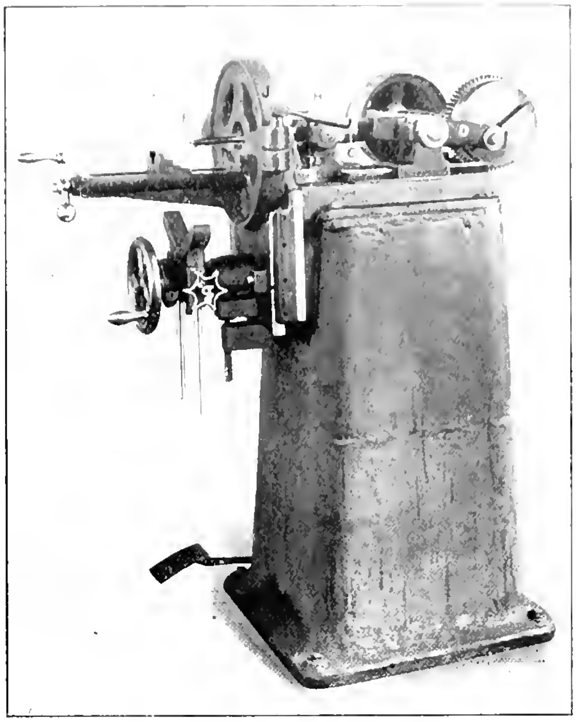

Fig. 8 Keyway-cutting Machine.

chine shop building was lately covered over, converting the space into an ideal castings court. This is illustrated in Fig. 10. A feature of interest is the crane provision made for transferring the castings from the foundry to the castings court. The foundry is provided with a hand traveling crane of the same type as that indicated in Fig. 10, having an I-beam girder for supporting the trolley. At various points in

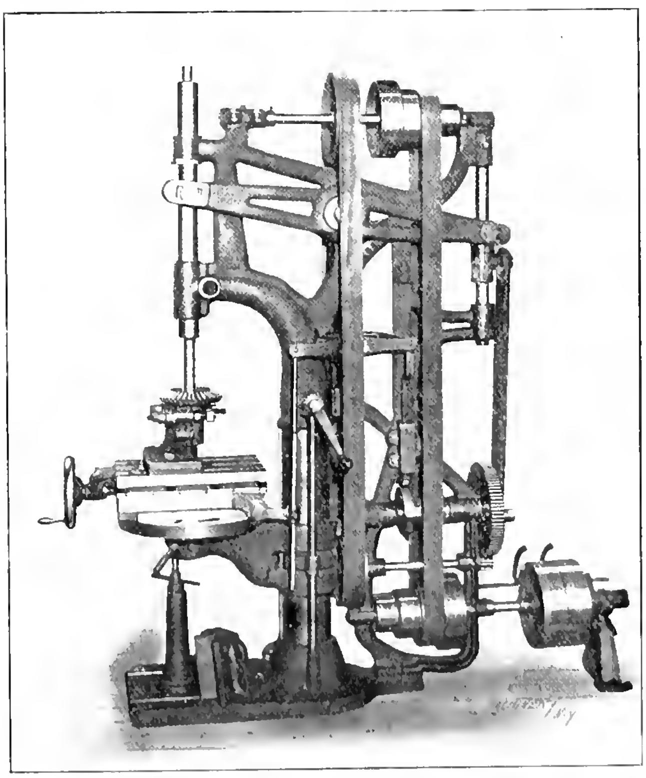

Fig. 9. Keyseater built on Drill Press Frame.

the foundry the I-beam girders are erected at right angles to the crane runway so as to be directly in line with the crane girder. With this arrangement the crane trolley can be run from the traveling crane to the stationary girder tracks and the load deposited or picked up at almost all points in the

foundry. The same arrangement provides connection with the castings court. A casting can be picked up in a far corner of the foundry, transferred to the foundry crane and carried along until opposite the opening leading to the castings court, where it is transferred to the castings court crane and then deposited in the castings court. Automatic safety devices are provided which prevent the trolley running off the end of the crane girder, except when opposite the girder runways, and when the transfer is taking place the crane is locked in position.

The system of keeping stock parts in the erecting shop is a radical departure from the systems in common use in most manufacturing plants. Instead of keeping machine parts in

Fig. 10. Castings Court between Machine Shop and Foundry.

a storeroom under the charge of a storekeeper, they are stored in metallic bins made by the Lyon Metallic Mfg. Co., located under the work benches. These bins extend nearly the whole length of the shop, and are about 1,100 in number. The stock is freely accessible to the men, no requisitions being necessary. The storekeeper takes an inventory of a certain number every day, and in six months has inventoried the whole stock. The loss of parts that cannot be accounted for is stated to be so small as to be practically negligible. Jigs and fixtures are also stored in the machine shop bay, where they are in charge of the sub-foremen. The jigs are kept in metallic lockers having wire screen doors of large mesh. The contents of each locker are plainly visible, and ordinarily the machine men are free to get any jigs that they require. The system of manufacture is such that the men act as their own inspectors of jigs and fixtures, and defects are promptly reported to the toolmaking department for correction.

* * *

The following statements by Mr. Marconi, made at the general meeting of the Marconi Wireless Telegraph Co., in London, this spring are of interest as indicating the progress of wireless transatlantic telegraphy. The seven and one-half months' experience since the transatlantic service was inaugurated, has shown that obstacles which many regarded as insurmountable, such as the interference with other stations, and the difficulty of transmitting messages for long distances during the day-time, have been overcome. For some months past the majority of the messages have been carried across the ocean during the day-time, and no interference whatever has been caused by the operation of the powerful long distance transatlantic stations with the working of the ship-to-shore communications. A speed of as high as 24 words per minute has been achieved. Mr. Marconi also states that with slight modifications of the details of the apparatus, at a very small cost, a speed of at least 30 words per minute can be obtained. Recent developments also make it possible to effect duplex working between wireless stations; that is, each station will be able to send and receive messages simultaneously.

SPECIAL TOOLS IN THE ROCKFORD MACHINE TOOL CO.'S SHOP.

The following illustrations show some special machines designed and built by the Rockford Machine Tool Co., Rockford, Ill., to facilitate the manufacture of shapers and planers, which are its product.

Feeling the need for an efficient and low-priced vertical milling machine, two were improvised from the regular shaping machines built by the company, by making the changes partially shown in Fig. 1. The tool slide on the end of the ram is replaced by the cutter spindle and its driving gear. The ram is adjusted in and out by the crank on the ram stud. This, it will be noted, is the regular arrangement for changing the relative position of the ram in its stroke when used as a shaper. The feed mechanism is belted to the counter-shaft by a separate belt, and thus works independently of the drive. Four changes of feed are provided, with reverse. The sliding pinion on the cross feed screw can be slipped onto the elevating shaft and the table fed up or down, if desired. The machine is driven by two counter-shafts and cone pulleys, giving five spindle speeds. As stated at the beginning, two of these machines are in use, and they have proved to be very satisfactory. They are used for milling T-slots and doing much other milling required in the manufacture of shaper parts. One of the uses that has been profitable is milling dovetail slides, suitable fixtures being provided for chucking the work quickly and accurately so as to preserve the standard angle. The machine will carry a 5-inch face mill and drive it efficiently.

Figs. 2, 3 and 4 show a home-made graduating machine that does good work at a high rate of speed. Fig. 2 shows the

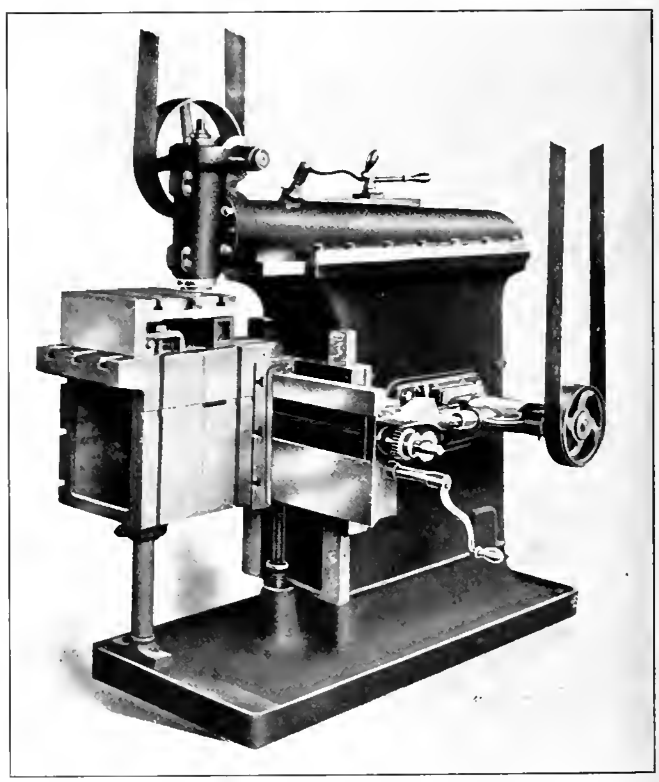

Fig. 1. Shaper converted into a Vertical Milling Machine.

machine set up for graduating the bases of the company's regular swivel base shaper vise, while Fig. 3 shows it in use graduating the saddle of a 28-inch Rockford planer. Figs. 5 and 6 indicate the character of the work done on vise base and planer saddle. It will be understood, of course, that in one case the graduations are made on the cylindrical surface of the swivel base, and in the other case the graduations are radial, being made on the face of the saddle. The machine will graduate along the edge of work ranging from ¾ to 36 inches diameter. The planer saddle shown on the machine in Fig. 4, is graduated all around the circle, and it requires only about 1½ minute's time to complete the work. An automatic trip is provided which stops the work from turning further when the exact number of graduations have been

made for which the machine is set. This feature takes care of such work as shaper vise bases and swivel plates for the head which are graduated from 90 to 180 degrees. The construction of the machine is simple, and as plainly shown, it is operated by hand. The hand-wheel shaft carries a bevel gear driving a bevel pinion operating the ratchet feed. On the end of the hand-wheel shaft is a cam having five projections. This cam operates a plunger, retracted by a coil spring. One of the cam projections is longer than the others,

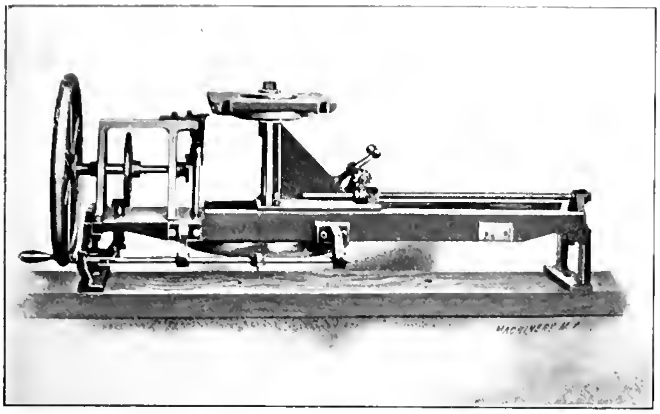

Fig. 2. Home-made Graduating Machine graduating Base of Swivel Vise.

thus making the long graduation mark required to distinguish every fifth degree position. The graduating tool is a sharp pointed piece of steel mounted on top of the plunger, as indicated in Fig. 2, for graduating along the edge of work. The bevel gears operating the indexing mechanism are in the ratio of 5 to 1, and the crank working the indexing lever is adjustable, thus permitting one or more notches to be engaged by the ratchet. This makes it possible to cut graduated collars to suit various pitches of screws, with the same index plate.

When cutting graduations on a flat surface, as indicated in Fig. 3, a different arrangement of the cutting tools is obviously required. In this case it is necessary to provide release for the tool in order to clear the work as it indexes. In the illustration the cutting tool is shown clear of the work,

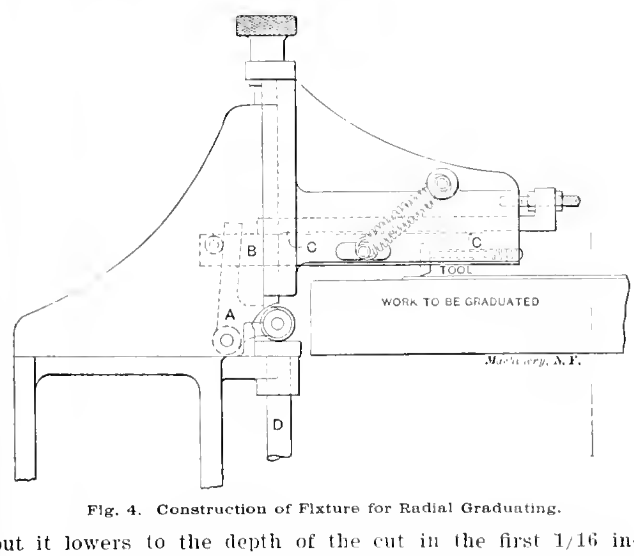

Fig. 4. Construction of Fixture for Radial Graduating.

but it lowers to the depth of the cut in the first 1/16 inch of the movement, and then moves in a parallel line to the end of the cut, when it automatically raises clear of the work and is brought back to the starting point by two springs, one of which is shown in an inclined position on the horizontal part. This release motion is effected by a simple mechanism under the slide.

The construction of the release motion is shown in the line illustration, Fig. 4. The vertical plunger D operates a bell-crank lever A, and this in turn operates a cutter slide B by working against a small roller mounted in the slide. This construction permits the tool to be adjusted vertically to the work by a screw and knurled knob on top of the fixture, and vertical adjustment of about 1 inch is thus provided. The engraving also shows the relief motion for the cutter slide, this being effected by a raised portion C about 1/32 inch high at each end of the slide. The illustration shows the cutter slide at the end of the stroke, with the tool clearing the work. On the first 1/16 inch movement of the cutter slide it moves up onto the incline, forcing the tool into the cut, then travels along to the end of the cut, and then is carried back to its starting point by the springs. The springs thus serve to hold the cutter slide up as well as to bring it back to the starting position.

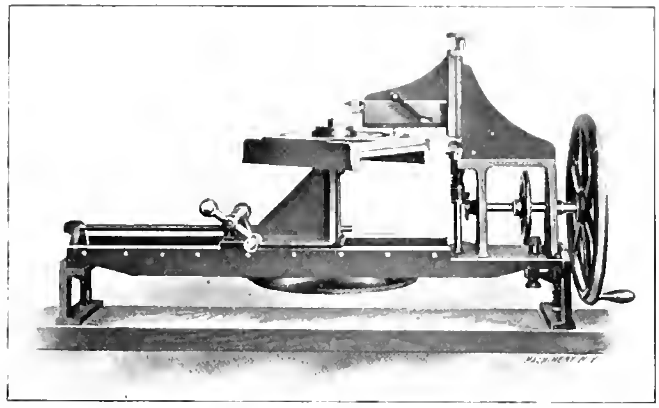

Fig. 3. Machine graduating Planer Saddle.

The index plates have been made accurate, and are 20 inches in diameter. A number have been provided to suit the various divisions required. The adjustment of the machine for circles of varying diameters is simply effected by means of the horizontal slide and screw which is worked by a revolving nut operated by a handle, through spiral gears. The machine, of course, could be arranged to be power driven, but the short time required for graduating a full circle and the small amount of power required to operate it make power unnecessary.

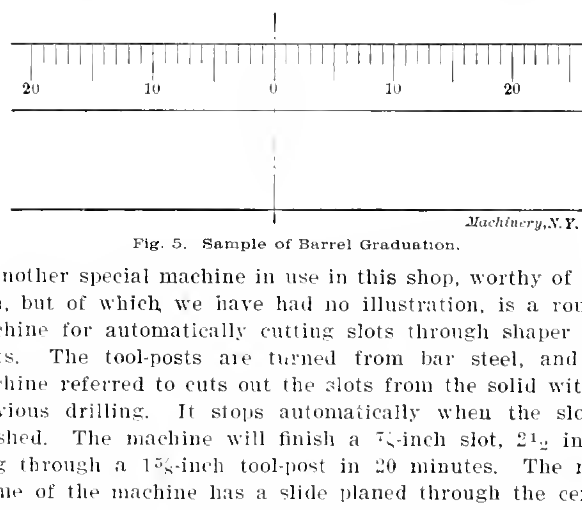

Fig. 5. Sample of Barrel Graduation.

Another special machine in use in this shop, worthy of mention, but of which we have had no illustration, is a routing machine for automatically cutting slots through shaper tool-posts. The tool-posts are turned from bar steel, and the machine referred to cuts out the slots from the solid without previous drilling. It stops automatically when the slot is finished. The machine will finish a 7/8-inch slot, 2 1/2 inches long through a 1 5/8-inch tool-post in 20 minutes. The main frame of the machine has a slide planed through the center, to which a T-slotted work table is gibbed, carrying the fixture

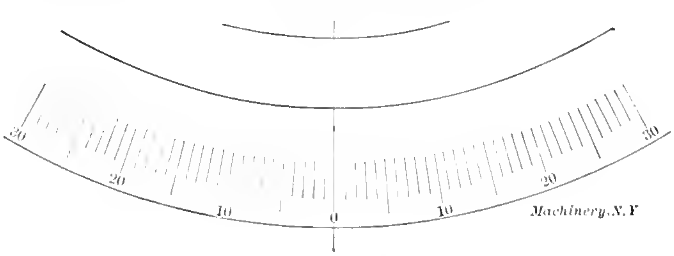

Fig 6. Sample of Radial Graduation.

for holding the work. Two heads carrying the spindles are mounted in right angle slides, one on each side of the table. Cutters are mounted in each spindle and enter the work from opposite sides. The table is moved back and forth by an adjustable crank motion, and the cutters are fed in at each end of the stroke. It stops automatically when the cutters are within 1/32 inch of the center. At this point one cutter is withdrawn and the other cutter is fed through to remove the remaining stock.

The simple boring jigs used for boring the shaft holes in planer beds and shaper frames are worthy of mention because of their simplicity and effectiveness. A jig consists of two cast iron plates, planed on both sides and held together by bolts and distance pieces. It is used on a Detrick & Harvey horizontal boring machine and supports the boring-bars, which are held in bushings in the side plates. The bars are driven by universal joints so that the jig supports the bar entirely independently of the work spindle. The planer casting is mounted on the table between the jig plates, the jig and the casting being located by certain gage points and clamped in position. When the various sizes of jigs were bored, an extra plate was bored simultaneously for each jig, and this is employed as a testing jig for the driving gears, studs being mounted in the holes on which the spur gears are set for testing. Obviously, these studs must have the same center distance for each size machine as the holes bored in the beds.

All these machines and special appliances were designed by Mr. E. D. Westrip, the general manager.

* * *

Some figures which are interesting in view of the present agitation for laws relating to employers' liability for accidents, are quoted by the *Mechanical Engineer*. It is usually considered that with advancing age the liability to accident increases. The figures quoted, which have been compiled by Sir John Brunner, and were first published in the *Times*, London, cover an investigation extending over fifteen years, and tend to disprove the previously mentioned assumption. In fact, these figures indicate that young men, under thirty years of age, are most liable to accidents, as will be seen from the table below.

Age.	Number Employed.	Percentage of Accidents Per Year.
18 to 25	633	8.5
26 to 30	533	6.8
31 to 35	616	4.2
36 to 40	656	3.6
41 to 45	531	2.8
46 to 50	382	3.7
51 to 55	251	2.4
56 and over	246	2.4

It may, of course, be assumed that the marked reduction in the percentage of accidents after the age of fifty is, to a slight extent, due to the fact of putting elderly men on less dangerous work, but it is also indicative of the fact that experience and care will increase with advancing years, and Sir John Brunner draws the conclusion that no employer is justified, not even in his own interest, in refusing to take elderly men in his service, or in dismissing them for the reason that they are more liable to accidents than younger men.

If a man is careful to avoid accidents happening to himself, he is, as a rule, also careful in preventing accidents happening to the machinery on which he is employed, and the figures quoted may therefore be considered as an indication that young men are not necessarily the best investment in a shop, but that men of more advanced years are likely to fill their places equally well, when all factors are considered.

* * *

A maddening and humiliating experience for a manufacturer to undergo is to develop a mechanical feature in an unobtrusive way and wake up some fine morning to find that another fellow had received the credit. It is not an unknown happening for a machine tool builder to work out some little kink or attachment which is good in its place but is of scarcely sufficient importance to pay the cost of taking out a patent to protect his rights. Another concern may adopt the same idea, and it is not an unknown occurrence for the copyist to be awarded credit for its origin. Still worse cases have happened, the copyist having the hardihood to actually patent an idea worked out by another. Of course, it is more charitable to believe that such cases are the result of an independent development, but whether so or not, it does not much help the feelings of the originator. What is his remedy? Show these minor developments in MACHINERY and get the credit that is your due. It helps the trade and it will help you.

MILLING SQUARE THREADS AND TURNING PULLEYS ON A DRILL PRESS.

To cut nicely finished square-thread screws on an ordinary drilling machine seems a most extraordinary operation, quite out of the range of practicability, but a simple attachment designed and used by the Mechanics Machine Co. of Rockford, Ill., does the work satisfactorily, and with a minimum of attention. The attachment, shown in Fig. 1, consists of a plate on which is mounted a master screw (shown in front) and the blank to be threaded. The master screw is splined and is driven with a worm and worm-wheel by a round belt leading to a grooved belt mounted on the regular vertical feed shaft. The master screw is directly connected with the blank shaft work spindle by spur gears without an intermediate gear; consequently the master screw is of opposite lead to the screw produced. In the illustration, a right-hand square-thread screw is being cut, the master screw being a left-hand square-thread screw. In operation, the master screw and the blank travel together to the right, the master screw reacting against a simple nut engagement shown in the front. The threading is a milling operation, as is plainly evident, the cutter being a plain, flat

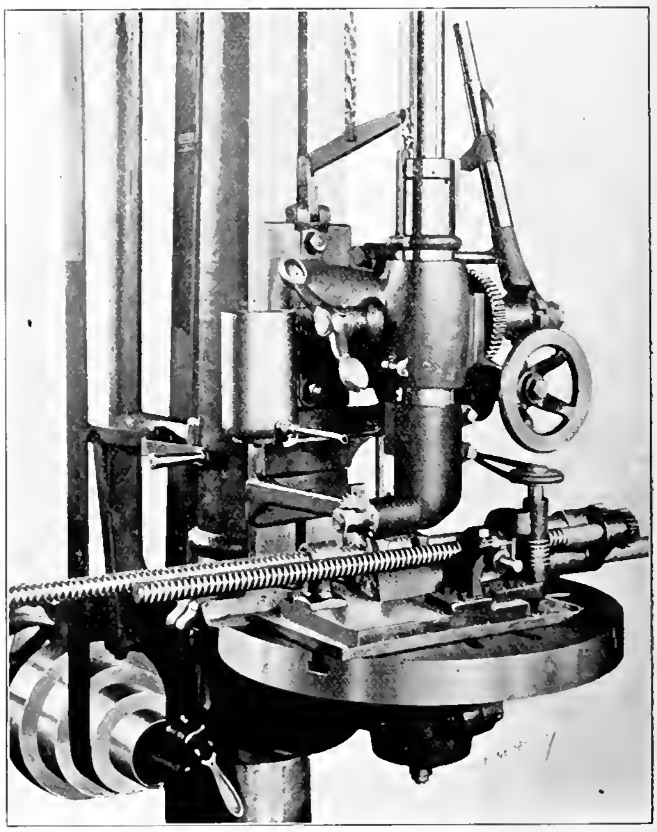

Fig. 1. Milling Square Threads on a Drill Press.

milling cutter on a horizontal shaft mounted in a casting attached to the lower end of the quill. It is driven by the drill spindle through bevel gears.

The screw milling attachment was designed on account of scarcity of help and machinery in the rush of business last year, and it has proved to be a wonderful time and labor saver. It is used for milling the table elevating screws used on upright drill presses manufactured by the company. A screw 27 inches long, 1 inch diameter, can be cut in 1½ hour, the screws produced being smooth and perfect copies of the master screw except in the change of hand or direction of spiral. An intermediate gear would correct this, but for the sake of simplicity it is omitted. The attachment works automatically, the principal attendance required being to put in a new shaft when the previous one is completed. The screw being cut is held by an ordinary spring collet on the work spindle. The attachment is extremely simple in construction, and being capable of producing threaded work of high accuracy because of directly reproducing the master screw, it would seem to have many possible uses.

Another drill press attachment used in the same shop, of almost equally surprising use, is that shown in Fig. 2 for

turning crowned pulleys. The principle of this attachment is not new, pulley milling machines having been used by other machine tool builders for several years, but the development of a drill press attachment for such work, we believe, is new. The attachment is simple, consisting of a base carrying a horizontal spindle, on one end of which the pulley is mounted and on the other end a worm-wheel, engaging a worm. This combination is driven by a second worm and worm-wheel in order to get the required reduction of motion. On the upper end of the second worm shaft is a pulley belted to another pulley mounted on the cutter-head. This cutter-head is fixed in the spindle with a Morse taper shank, fitting the drill socket. Of course the pulleys are bored and keyseated previous to the milling operation.

The milling attachment is located on the drill press table, so that a vertical plane through the work or pulley shaft and coinciding with its axis, stands a short distance to one side of the spindle center line. In the other plane at right angles to the pulley shaft the center line of the spindle coincides with the center plane of the pulley being milled. This position of a milling cutter of sufficient diameter to sweep the entire

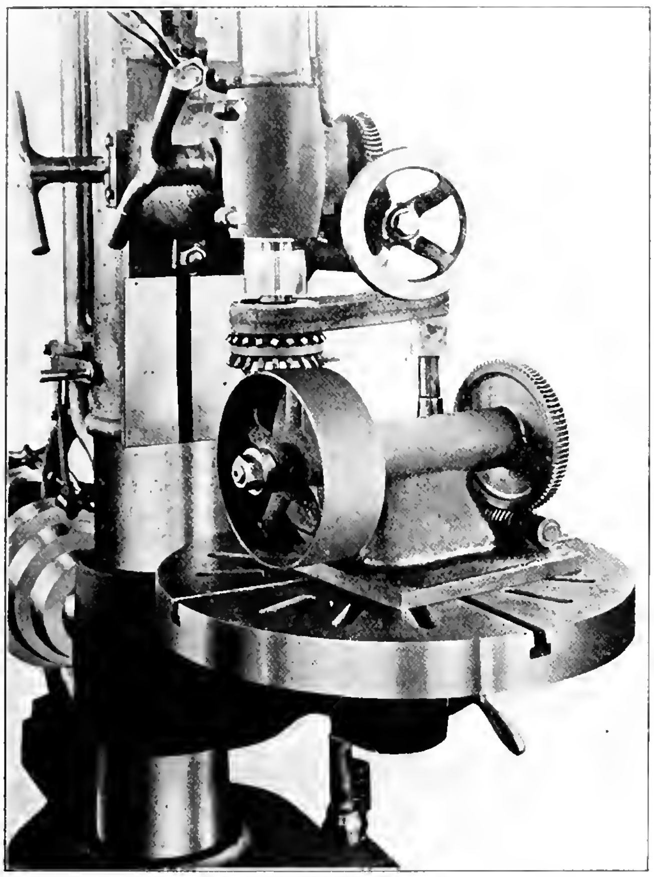

Fig. 2. Milling Crowned Pulley Faces on a Drill Press.

face of the pulley, generates a curved surface that answers the requirements of crowning. The attachment is automatic and requires but one hour to face and crown a 12 x 4-inch pulley. High-speed steel cutters are used, which require regrinding very seldom, so the labor cost of machining the faces of pulleys is reduced to but little more than that of putting the work on the attachment and removing it when finished.

* * *

The importance of well lubricated bearings, as well as the importance of an oil suitable for lubrication purposes, is given in a paper before an English society of engineers, by Mr. T. C. Thomson, some weeks ago. He stated that in a certain machine shop driven by an electric motor, the power needed to drive the shafting and the machine running idle amounted to 37 K. W. when one kind of oil was used, and 25 K. W. when a better quality of oil was substituted. The total rated capacity of the motor was only 65 K. W., so that even with the best oil, it is seen that the frictional losses remain a very substantial fraction of the total energy expended.

JIGS AND FIXTURES—4.

EINAR MORIN.*

CLAMPING DEVICES.

In order to hold the work rigidly in the jig, so that it may be held up against the locating points, while the cutting tools operate upon the work, jigs and fixtures are provided with clamping devices. Sometimes a clamping device serves the purpose of holding the jig to the work, in a case where the

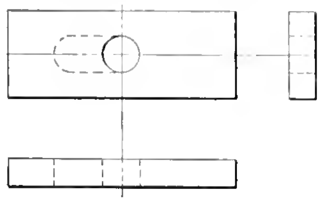

Fig. 37. Form of Clamps used in Jigs and Fixtures.

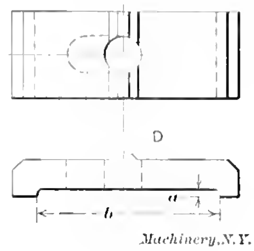

Fig. 38. Improved Form of Clamp.

work is a very large piece and the jig is attached to the work in some suitable way. The purpose of the clamping device, however, remains the same, namely, that of preventing any shifting of the guiding bushings while the operation on the work is being performed. As has been previously mentioned, at the time when the general principles of jig and fixture design were treated in the first installment of this series

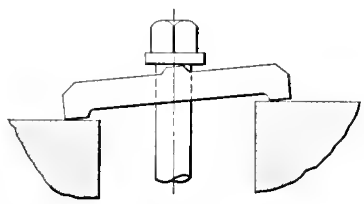

Fig. 39. Action of Clamp shown in Fig. 38 when used to clamp Work which is not Level with the Clamping Surface.

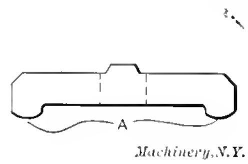

Fig. 40. Clamp shown in Fig. 38, Further Improved.

(April issue), the clamping device should always be an integral part of the jig body in order to prevent its getting lost.

The clamping device may either directly clamp the work to the jig or *vice versa*, but very frequently the clamps simply hold in place a loose or movable part in the jig, which can be swung out of the way to facilitate the removing and the inserting of the work in the jig. The work itself is in

TABLE V. DIMENSIONS OF COLLAR-HEAD SCREWS.

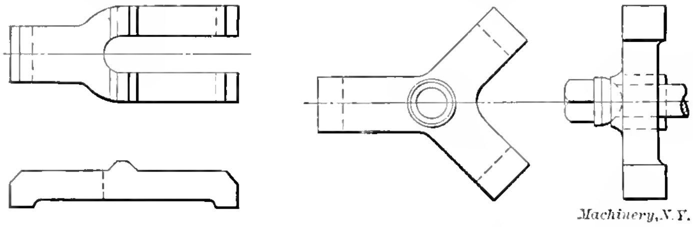
turn clamped by a set-screw or other means passing through the loose part, commonly called leaf. The simplest form of clamping device is the so-called clamp, of which a number of different forms are commonly used. Perhaps the most common and most reliable of all clamps is the one shown in Fig. 37. This kind of clamp is also commonly termed a strap. It is simple, cheap to make, and for most purposes it gives satisfactory service. The clamp shown in Fig. 38 is practically made on the same principle as the one shown in Fig. 37,

* Address: 833 W. Sixth St., Plainfield, N. J.

but several improvements have been introduced. The clamp is recessed at the bottom for a distance *b*, to a depth equal to *a*, so as to give a bearing only on the two extreme ends of the clamp. Even if the strap should bend somewhat, on account of the pressure of the screw, it will be certain to bear at the

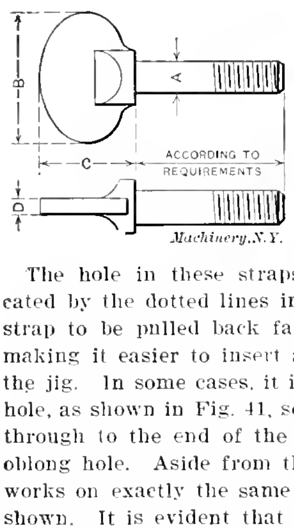


Figs. 41 and 42. Special Forms of Clamps.

ends, and exert the required pressure on the object being clamped. This strap is also provided with a ridge at *D*, located central with the hole for the screw, as shown in Fig. 38. This insures an even bearing of the screw head on the clamp, even if the two bearing points at each end of the clamp should vary in height, as illustrated in Fig. 39. The clamp in Fig. 37 would not bind very securely, under such circumstances, and the collar of the screw would be liable to break off, as the whole strain, when tightening the screw, would be put on one side.

A still further improvement in the construction of this clamp may be had by rounding the under side of the clamping points *A*, as shown in Fig. 40. When a clamp with such rounded clamping points is placed in a position like that indicated in Fig. 39, it will practically bind the object to be held fully as firmly as if the two clamping surfaces were in the same plane.

TABLE VI. DIMENSIONS OF SHOULDER THUMB SCREWS.



A	B	C	D
3/16	9/16	1/2	3/32
1/4	1	11/16	1/8
5/16	1 1/8	3/4	5/32
3/8	1 1/4	13/16	5/32
7/16	1 1/2	15/16	3/16
1/2	1 5/8	1 1/8	3/16

The hole in these straps is very often elongated, as indicated by the dotted lines in Figs. 37 and 38. This allows the strap to be pulled back far enough so as to clear the work, making it easier to insert and remove the piece to be held in the jig. In some cases, it is necessary to extend the elongated hole, as shown in Fig. 41, so that it becomes a slot, going clear through to the end of the clamp, instead of being simply an oblong hole. Aside from this difference, the clamp in Fig. 41 works on exactly the same principle as the clamps previously shown. It is evident that the clamps described may be given a number of different shapes to suit different conditions. The screws used for clamping these straps are either standard hexagonal screws or standard collar head screws, dimensions

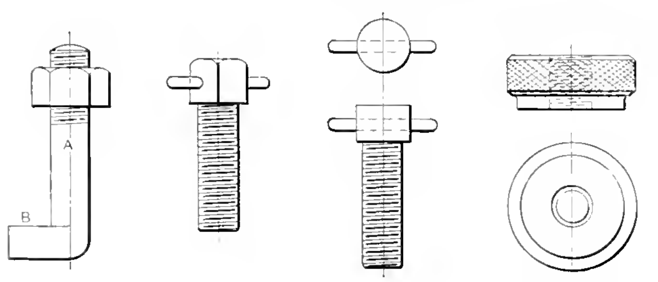


Fig. 43 Fig. 44. Fig. 45. Fig. 46.

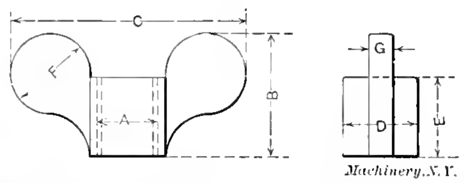
of which latter are given in Table V. In a case where it is not necessary to tighten the clamps very much, shoulder thumb screws, as shown in Table VI, may be employed.

Instead of having the strap or clamp bear on only two points, it is sometimes necessary to have it bear on three points, in which case it may be designed similar to the strap shown in Fig. 42. In order to get an equal pressure on all the three points, a special screw, with a half-spherical head like the one shown, may be used to advantage. The half-spherical head of this screw fits into a concave recess of the same shape in the strap. When the bearing for the screw head is made in this manner, the hole through the clamp must have plenty of clearance for the body part of the bolt.

When designing clamps or straps of the types shown, one of the most important things to take into consideration is to provide enough metal around the holes, so that the strap will stand the pressure of the screw without breaking at the weakest place, which naturally is in a line through the center of

TABLE VII. DIMENSIONS OF WING OR THUMB NUTS.



A	B	C	D	E	F	G
3/16	5/8	1 1/8	5/16	3/8	7/16	1/8

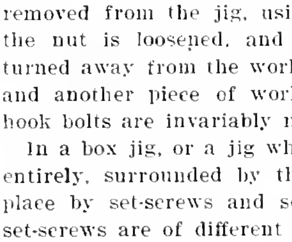
7/16	7/8	2	21/32	5/8	11/16	3/16
1/2	1 1/16	2 1/4	3/4	13/16	7/8	3/16

the hole. As a rule, these straps are made of machine steel, although large clamps may sometimes be made from cast iron.

The hook bolt shown in Fig. 43 is better adapted for some classes of work than any other clamping device. At the same time, it is very easy and cheap to make and easily applied. The bolt *A* passes through a hole in the jig, having a good sliding fit in this hole, and is pushed up until the hook or head *B* bears against the work, after which the nut is tightened. When great pressure is not required, the thumb or wing nut, such as shown, together with its dimensions, in Table VII, permits the hook bolt to be applied more readily. The thumb or wing nut is preferable to the knurled nut, shown in Fig. 46, which sometimes is used. It is possible to get a better grip, and to tighten the bolt more firmly by a

TABLE VIII DIMENSIONS OF REGULAR THUMB SCREWS.



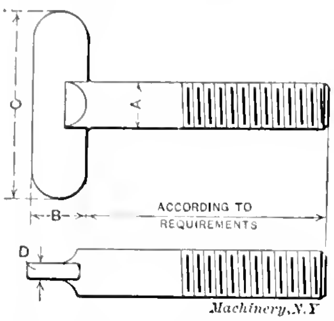
A	B	C	D
3/16	3/4	5/8	3/32
1/4	15/16	3/4	1/8
5/16	1 1/8	7/8	5/32
3/8	1 1/4	15/16	5/32
7/16	1 1/2	1 1/16	3/16
1/2	1 5/8	1 3/16	3/16

wing nut than it is with a knurled nut. When the work is removed from the jig, using the hook bolt clamping device, the nut is loosened, and the head or hook of the bolt is turned away from the work, thus allowing it to be taken out, and another piece of work to be placed in position. The hook bolts are invariably made of machine steel.

In a box jig, or a jig where the work is entirely, or almost entirely, surrounded by the jig, the work is easily held in place by set-screws and sometimes by screw-bushings. The set-screws are of different kinds, the most common being the standard square head set-screw, which is used whenever great clamping pressure is required, the square head allowing the use of the wrench. Sometimes screws of this kind may be tightened enough for the purpose by hand if a pin is put through the head of the screw, as shown in Figs. 44 and 45. This means is used not only when great pressure is not necessary, but also when the work is liable to spring if the screws are tightened too hard. In such a case, if a pin is inserted, it would be obvious that the screw head is not intended for a wrench, but that the pin is intended for getting a good grip by the hand for tightening the screw without

resorting to any additional means. Usually it is not possible to use an ordinary machine wrench on such a screw, as it generally is rather thin, so that if applied to the top of the screw, it would not permit a very good grip. Of course, a monkey-wrench could be applied, but it ought to be stated in this connection that a monkey-wrench ought not to be employed in ordinary manufacturing shop work, as it is intended

TABLE IX. DIMENSIONS OF THUMB SCREWS WITH WIDE GRIP



A	B	C	D
3/16	1/4	7/8	3/32

1/2	9/16	2	3/16
9/16	5/8	2 1/4	3/16
5/8	11/16	2 1/2	7/32

primarily for jobbing work. More screws probably have been tightened too hard and twisted off by the injudicious use of a monkey-wrench than in any other way. When a monkey-wrench is used, it should be used with discretion. This, of course, does not mean to imply that the monkey-wrench is not one of the handiest tools that a machinist ever had in his possession, but it is intended to impress the idea that unless the monkey-wrench is used in such a manner that, when it is applied to a small screw head, the power applied at the end of the handle is in proportion to the screw, it is a risky tool to have around.

While a screw with a round head, as shown in Fig. 45, and with a pin put through the head, is undoubtedly better and

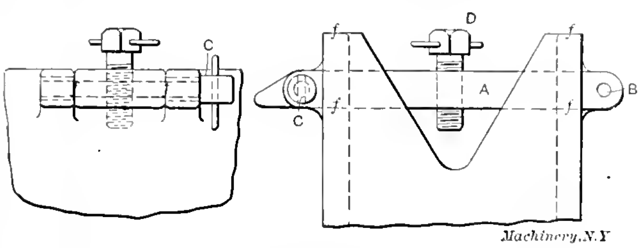

Fig. 47. Common Design of Leaf in Drill Jigs. Screw D Clamps the Work.

more convenient to use than the one shown in Fig. 44, the latter is cheaper to make, because standard screws can be taken right from stock, and a pin hole put through them, after the heads have been annealed. If thumb screws like the ones shown in Tables VIII and IX are available, they are preferable, as they give a good hold to the hand when they are tightened, and, besides, there is very little work required in finishing them. The use of a screw-bushing for clamping work has already been referred to. The clamping screws mentioned so far are generally applied directly onto the work, after having passed through the wall of the jig, or some projecting part serving as a seat for the screw.

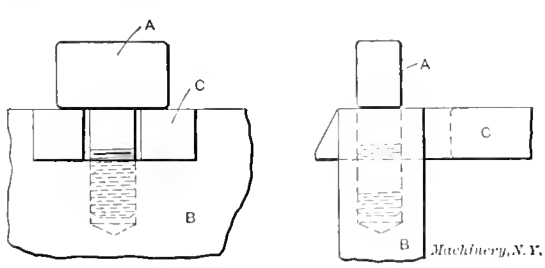

Fig. 48. Clamping Device for Leaf in Drill Jig.

Loose leaves which spring out, in order to permit the work to be inserted and removed, are usually constructed in some manner similar to that shown in Fig. 47, in which *A* represents the leaf, being pivoted at *B* and held by a pin at *C*, which goes through the two lugs on the jig wall and passes through the leaf, thus binding the leaf and allowing the tightening of the set-screw *D*, which bears against the work. The holes in the lugs of the castings are lined with steel bushings in order to prevent the cast iron holes from being worn out too soon by the constant pulling out and putting in of the pin. This kind of leaf, when fitted in nicely, is rather expensive, and is not only used for binding purposes, but also for guiding purposes, making a fitting seat for the bushings. If the leaves are fitted well in place, the bushing will guide the cutting tools firmly.

Another way of holding down the leaf is shown in Fig. 48, in which *A* is a thumb screw, screwed directly into the wall *B* of the jig, and holding the leaf *C* down, as indicated. To swing the leaf out, the thumb screw is turned back about a quarter of the turn, so that the head of the thumb screw stands in line with the slot in the leaf, this slot being made wide and long enough to permit the leaf to clear the head of the thumb screw. This is a very rapid way of clamping,

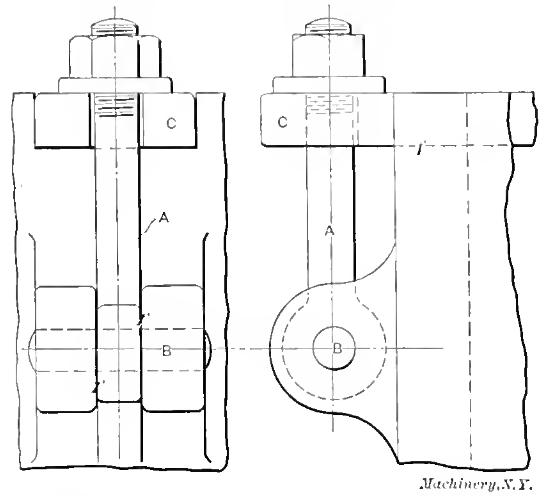

Fig. 49. Eye-bolt used for Clamping Drill Jig Leaf

and is frequently used. The lower side of the head of the screw will wear a long time before the head finally comes in line with the slot when binding. It can then easily be fixed for binding the leaf again when standing in a position where the head of the thumb screw is at right angles to the slot, by turning off a portion of the head on the under side. The size of these thumb screws is made according to the strain on

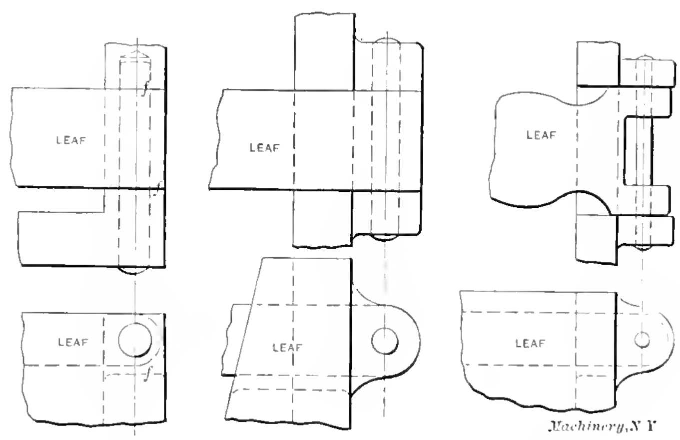

Fig. 50. Detail Designs of Joints between Leaf and Jig.

the leaf and the size and design of the jig. No standard dimensions could be given for this kind of screw.

The hinged bolt, shown in Fig. 49, is also commonly used. Here *A* represents an eye-bolt, which is connected with the jig body by the pin *B*. The leaf or movable part *C* of the jig is provided with a slot in the end for the eye-bolt, this slot being a trifle wider than the diameter of the bolt. The threaded end of the eye-bolt is provided with a standard hexagon nut, a knurled head nut or a wing nut, according to how firmly it is necessary that the nut be tightened.

When the leaf is to be disengaged, the nut is loosened up enough to clear the point at the end of the leaf, and the bolt is swung out around the pin *B*, which is driven directly into lugs projecting out from the jig wall, a slot being pro-

vided between the two lugs, as shown, so that the eye-bolt can swing out with perfect freedom. At the opposite end, the leaves or loose parts of the jig swing around a pin the same as in Fig. 47, the detailed construction of this end being, most commonly, one of the three types shown in Fig. 50. It must be understood that to provide jigs with leaves of this character involves a great deal of work and expense, and they are used almost exclusively when one or more guide bushings can be held in the leaf.

* * *

ADJUSTABLE LEVELING BLOCKS FOR PLANERS.

The adjustable leveling blocks shown in Figs. 1 and 2 are used in the shops of the Pratt & Whitney Co., Hartford, Conn., and the style shown in Fig. 1 is intended, in particular, for the planers made by the company. The design and action of these adjusting blocks are plainly shown in the engravings. The frame *A* is bolted to the concrete foundation by four anchor bolts *B* surrounded by pipes *C*, which prevent the concrete from coming in direct contact with the bolts, and permit a slight adjustment in longitudinal and sideways direction. At each end of the frame *A* are finished surfaces, planed to an angle of 15 degrees. On these surfaces slide the adjusting blocks *D*, also planed on the under side to a 15-degree angle, the upper side being level. These adjusting blocks or wedges are made of cast iron and provided with a long slot *E* permitting a lengthwise as well as a sidewise adjustment, the slot being two inches long and one inch wide, while the bolt, passing through it, is only ⅝ inch in diameter. The blocks are adjusted by set-screws *G*, provided with lock nuts. When properly adjusted, so that the planer table is level, the bolts *F* are tightened down, holding the planer firmly to the frame *A*, which itself is firmly embedded in the concrete foundation, and, as mentioned before, held down by the anchor bolts.

When the lower portion of the planer is of the construction shown in Fig. 1, so that it is possible to place the adjusting screws *G* on the inside, the frame and wedges are made so that the upper surface of the adjusting block will lift the planer table when pushed outward. On many planers, particularly those of larger sizes, it is not possible to have the adjusting screws on the inside, as they would be almost inaccessible. In such cases, the adjusting screw is placed as shown in Fig. 2, the frame and the adjusting block being reversed in their construction. The adjusting block is then pushed inward when it is desired to raise the leg resting upon it. With this exception, the principle of the adjusting block shown in Fig. 2 is exactly the same as that shown in Fig. 1.

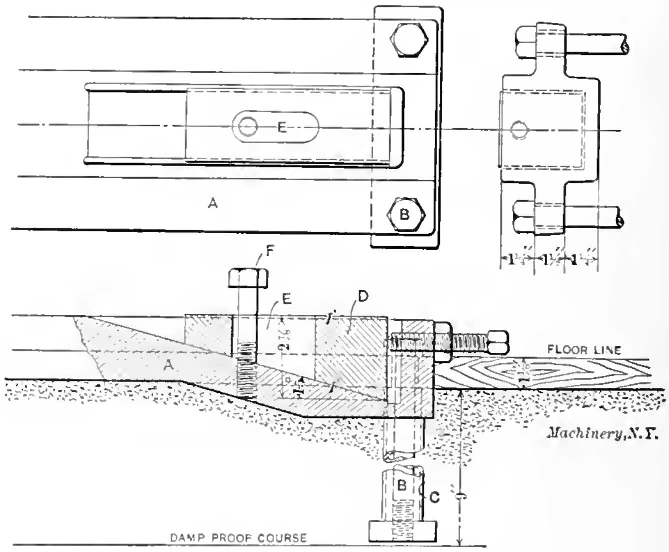

Fig. 2. Leveling Block with the Adjusting Screws on the Outside, instead of on the Inside, as in Fig. 1.

The frame *A* can be made in any length required by the length of the planer, the same pattern being used for all sizes, with the exception of lengthening pieces which are put in to make up for the required length over all. These leveling blocks have been found very convenient and suitable for the purpose for which they are used, and as there is allowance for adjustment in practically all directions, it is comparatively easy to get the desired results with this adjustable arrangement.

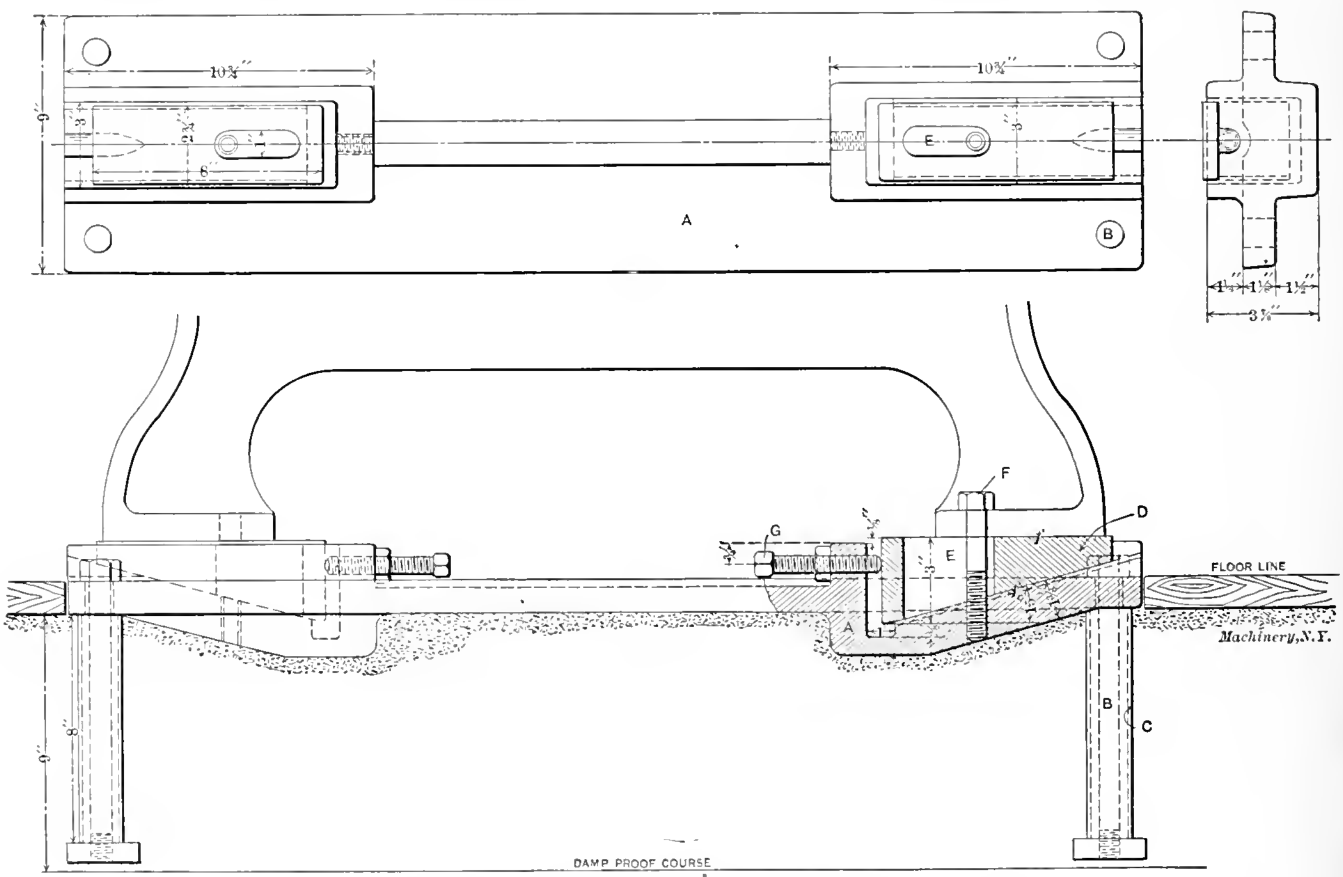

Fig. 1. Leveling Block for Planers, applied to a Pratt & Whitney Co. Planer.

* * *

It is of the utmost importance that plants and machinery be maintained in a high state of efficiency. General recognition, however, is not given to another thing, which is of equal importance, namely, the maintenance of the operatives themselves in a high state of efficiency.—*Practical Engineer.*

SPECIAL AND ADJUSTABLE TAPS.

ERIK OBERG *

STAYBOLT TAPS.

Staybolt taps are extensively used in locomotive boiler work. The ordinary or the radial staybolt tap is shown in Fig. 1; in Fig. 2 is shown the spindle staybolt tap, which has derived its name from the guiding spindle upon which the tap proper revolves.

Radial Staybolt Taps.

If we first give our attention to the radial staybolt tap, as shown in Fig. 1, the length *C* represents the threaded portion. Of this part, the portion *F* is straight or parallel, and the part *G* is chamfered. The part *E* is a taper reamer which reams the hole previous to tapping. The taper of this reamer is usually 3/32 inch per foot. The diameter at *H* is equal to the root diameter of the thread. The diameter of the shank is about 0.005 inch below the root diameter. Staybolt taps are usually made with 12 threads per inch, of the sharp

V-form. Although practice has almost universally favored the employment of the sharp V-thread, the main advantage (and perhaps the only real advantage) of a thread of this kind is that it can be made tight in the boiler sheets and kept tight without any great difficulty. On the other hand, the use of the V-thread violates one of the fundamental principles of machine design—the principle, namely, of avoiding all sharp angles, and of filleting every place where such angles tend to occur. This must have occurred many times to engineers and designers, and yet no general movement has been made to discard the V-thread and substitute for it a form that shall not be open to the same objection. The Whitworth thread is receiving considerable attention at the present time, however, for use upon staybolts, and it is regarded with favor by certain builders of large experience, notably by the Baldwin Locomotive Works, which is now using this thread upon locomotive staybolts. If experience shows that staybolts can be made tight and kept so when fitted with this thread, it is probable that its adoption will extend to other builders.

Staybolt taps receive very rough treatment, and are exposed to hard usage, and should therefore be made of an extra good quality of steel. The thread should be relieved both on top and in the angle of the thread on the chamfered portion. The parallel portion of the thread is not relieved. In order to prevent having cutting edges which are too wide toward the smaller end of the chamfered portion, the tap is threaded taper about one-half of the chamfered part. This prevents the tap from reaming instead of cutting. In order to gain the same end, it is advisable never to make the chamfer any longer than, at most, 6 inches. The interrupted thread shown in Fig. 6 in the article on Taper Taps in the April issue, is particularly of value in the case of staybolt taps, and is probably used more on this class of taps than on any other.

In Table I the dimensions for standard radial staybolt taps, as made by a prominent tap manufacturing firm, are given. However, staybolt taps are made in a variety of sizes and designs for special requirements; but the two kinds given in the table are the most commonly used. All staybolt taps, of the

* Associate Editor of MACHINERY.

sizes given in the table, should have five flutes. The oversize limit of difference in diameter from the correct size of staybolt taps is commonly assumed to be 0.002 inch for taps smaller than 1 inch in diameter, and 0.003 inch for larger sizes. It is evident that it is not permissible for the tap to be *under* the correct size; consequently the diameter is required, after hardening, to be between the standard diameter and a diameter of 0.002 or 0.003 inch, respectively, above the standard.

Sometimes staybolt taps are provided with a threaded guide at the upper end of the thread. This guide is not fluted and should be made slightly smaller in diameter than the cutting size of the tap. The amount which the diameter is smaller is usually about 0.010 inch, and should apply to the angle diameter as well as to the top of the thread. While not fluted, this threaded guide ought still to be grooved by a small convex cutter for oil passages to the flutes.

Spindle Staybolt Taps.

The spindle staybolt tap, as shown in Fig. 2, is not provided with a reamer, and with but a short chamfer. It is fluted about half the way of the threaded part. The remaining part of the thread acts as a guide, and should be made in the same way as threaded guides for radial staybolt taps. The guide E on the end of the spindle holds the tap in place in relation to the inner tube sheet, while the outer one is threaded. The standard dimensions for these taps are given in Fig. 2 and in Table II.

Straight Boiler Taps.

Straight boiler taps are, strictly speaking, only a special class of hand taps. They have a long chamfer, and a straight guide at the point. The chamfered portion is relieved on the top of the thread. These taps are fluted in the same way as hand taps. In Table III the dimensions for these taps are given. The most important of these dimensions are determined from the formulas:

$A = 3D + 2\frac{3}{4}$ inches,
$E = 2\frac{1}{4}D + \frac{7}{8}$ inch,
$F = D$,
$H = \frac{3}{8}D + 3/16$ inch,

in which formulas

A = total length of tap,
D = diameter of tap,
E = length of threaded portion,
F = length of full or parallel thread, and
H = length of guide.

In making these taps the same limits in regard to oversize diameters as employed for regular hand taps should be adopted. (See MACHINERY, July, 1907: Remarks on the Making of Hand Taps.)

Straight Pipe Taps.

Straight pipe taps are only a variation of hand taps, but have the same number of threads per inch as the corresponding sizes of taper pipe taps, and a diameter arbitrarily adopted by the manufacturers of these taps. Table IV gives the dimensions for taps up to and including ¾ nominal diameter. The larger sizes are given in Table V. It will be noticed that the difference in appearance between the larger and smaller sizes is simply that the latter is provided with a short neck, turned down below the root diameter, while on the larger sizes the whole shank is turned down below the root of the thread.

These taps are chamfered the same as plug hand taps, and relieved only on the top of the thread on the chamfered part.

The number of flutes may be made the same as for corresponding sizes of Briggs' standard pipe taps (see MACHINERY, March, 1908: Taper Taps); if it is considered that less flutes would be more advisable, approximately the same number of flutes as is given to regular hand taps will be satisfactory. In cases like this the number of flutes, within reasonable limits, is largely a matter of judgment. The straight pipe tap, being actually a hand tap, should evidently be fluted like a hand tap. But inasmuch as the tap has a greater number of threads per inch than corresponding sizes of ordinary hand

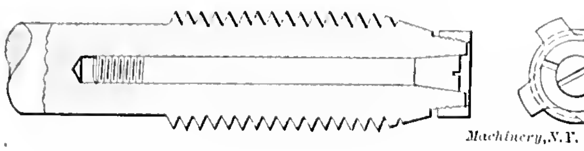

Fig. 6. Adjustable Tap made from Solid Stock.

taps, there is a reason for providing it with a greater number of flutes. English pipe taps, having Whitworth form of thread, and made according to Whitworth's thread system for gas and water piping, are given in Tables VI and VII.

Adjustable Taps.

Adjustable taps are made for the purpose of permitting adjustment to a correct standard size. As the solid tap, on account of changes in hardening, cannot be depended upon to measure exactly the diameter for which it was intended, and because of the impossibility of preventing a tap from decreasing in diameter through wear, the adjustable tap has a wide field of usefulness where correct size nuts must be produced. The adjustable tap may either be made from a solid piece,

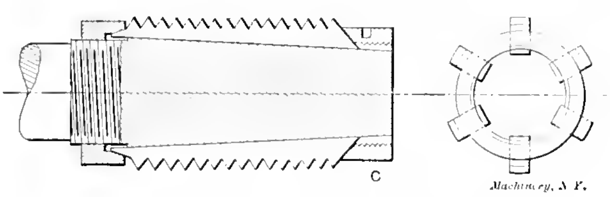

Fig. 7. Adjustable Tap with Inserted Blades.

split in a suitable manner to permit adjustment, or may be provided with inserted blades or cutters, which are so held in the tap body that a slight movement of these blades in the longitudinal direction of the tap moves the cutting points of the thread nearer or farther from the axis of the tap, thus decreasing or increasing the diameter, as the case may be.

Another cause for inserted blade taps other than adjustability may also be mentioned. The efforts constantly made by progressive manufacturers to decrease the cost of tools without impairing their efficiency, have resulted in the design of a number of taps of this type, which permit a cheaper grade of material to be used in the tap body, while the best quality steel may be used for the inserted blades, the total

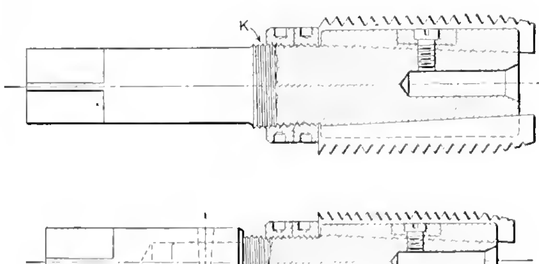

Fig. 8. Improved Design of Adjustable Tap.

cost, especially in the case of large taps, being smaller than if the tap were made solid of ordinary tool steel throughout. Incidentally another advantage is also gained. Inasmuch as the cutting portion of the tap is the only one which, in general, when worn, has caused the tap to be discarded, the inserted blade design makes it possible to retain the body proper and replace the cutters only.

In the case of large taps and coarse pitches, the adjustable tap does not give very good satisfaction if a thread is cut by one passage of the tap, because the strain on the tap is so great as to spring it to a certain extent. It is evident that an adjustable tap cannot possibly be made fully as rigid as a solid tap. But in such cases the tap still retains its superiority as a "sizing" tap, used to finish the thread after it has been roughed out by means of an ordinary tap somewhat under size.

Examples of Adjustable Taps.

The form of adjustable tap, previously referred to, which is cut from a solid piece and split, is shown in Fig. 6. The body is split straight through, a nut with a taper thread serves to hold the tap together at the end, and a screw with a taper head is used to expand the tap, as shown. As the expansion is effected by bending the cutting lands when the tapered head of the screw travels inward, the thread form is not accurately retained, and the tap is not to be recommended. When accurate work is required, the inserted blade form of adjustable taps is the preferable form. The requirements for a good inserted blade tap are that the blades when bound in place shall be practically solid with the body, that the design shall permit a liberal adjustment in regard to size, that this adjustment shall be easily accomplished, and that the means employed for binding and adjusting the blades shall not be of such a kind as to prevent the use of the tap in any case where the solid tap could be used. This latter requirement involves the possibility of tapping clear through a hole as well as the tapping down to the bottom of a hole.

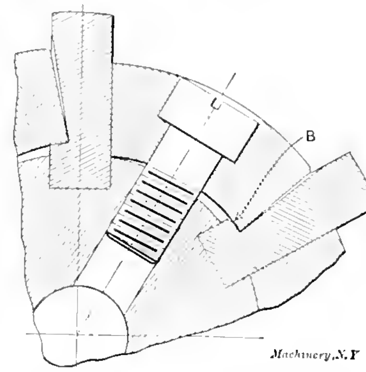

Fig. 9. Method of Binding the Blades in Tap, Fig. 8.

A tap which fills fairly well all these requirements, with the exception of the one mentioned last, is shown in Fig. 7. The blades are held in place by nuts, beveled on the inside to fit the tapered ends of the blades. In this manner the blades are prevented from longitudinal motion as well as from moving out or in in relation to the center line of the tap. The blades fit into slots in the tap body and are thus prevented from moving sideways. The adjustment is provided for by the tapered bottom of the slots in the body, by means of which the cutting size of the tap increases when the blades

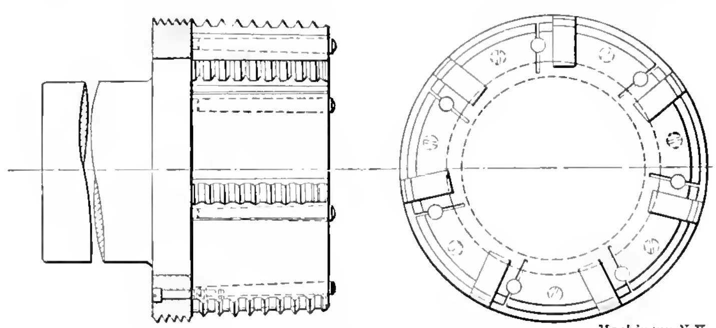

Fig. 10. Inserted Blade Pipe Tap

are moved upward toward the shank end of the tap. The adjustment is easily accomplished, it only being required to loosen the upper nut and push up the blades, and then tighten the lower as well as the upper nut solidly upon the blades. It is, however, not possible with the design shown to tap down clear to the bottom of a hole, nor is it possible to tap straight through a hole. This latter requirement could, of course, easily be obtained by making the slots deeper and the blades wider, thus making it possible to decrease the outside diameter of the upper binding nut so that it would be less than the root diameter of the thread. This would permit the tap to pass through a threaded hole. There is, however, a more serious objection to this design. The backing of the blade by means of a tapered surface in the nut is not very positive, and the blades are liable to be a trifle incorrect in their relative posi-

tiou in regard to lead. It is evident that if that is the case the thread cut will be incorrect in its shape, the space cut in the nut being wider than the thread itself. A tap which overcomes the objections raised in regard to the tap in Fig. 7 is shown in Fig. 8. The construction of this tap was described in the July, 1907, issue of MACHINERY, in an article entitled Adjustable Reamers and Taps with Inserted Blades. In this article the reasons for the superiority of the design of taps and reamers made as indicated in Fig. 8 were stated, and it is unnecessary to repeat this discussion here. Those who may not have read the article in question can easily see the principle of the design from the sectional view of the tap, Fig. 9, which shows the principle employed for binding the blades very clearly.

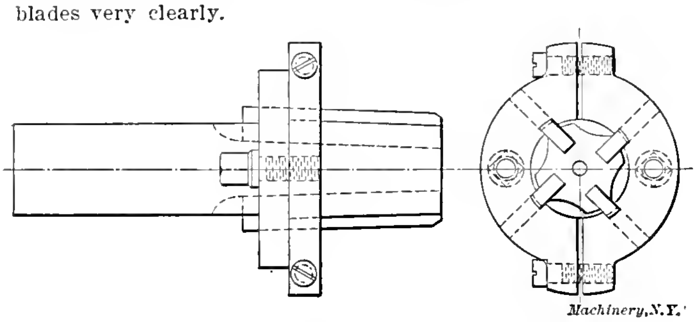

Fig. 11. Another Design of Inserted Blade Pipe Tap.

Inserted blade taps are not adapted to very small sizes. As a rule, it should not be attempted to make such taps in sizes smaller than 1½ inch, or, at least, not below 1¼ inch in diameter.

Other Examples of Inserted Blade Taps.

In Fig. 10 an inserted blade tap, of a design common for pipe taps, is shown. Here the chasers are held in place by means of taper pins, which wedge the metal of the body firmly against the blade. The correct location of the blades in a longitudinal direction is obtained by means of a ring, held to the body by screws. It is plainly seen from the construction that this tap is not intended to be adjustable, but is simply made with inserted blades from an economical point of view. This design which is most commonly used for large taps, affords a considerable saving in material. The tap shown in the engraving is provided with interrupted thread, as frequently used on pipe taps, and taper taps in general.

Another form of inserted blade tap is shown in Fig. 11. The blades are here held in place by means of a ring threaded on the inside to fit the thread of the blades or chasers, and split and provided with binding screws so as to make possible a positive grip over the blades. The advantage of this design is that the threads of the various chasers must necessarily be so located as to form a continuous helix all around the tap, inasmuch as the threaded ring fits upon the thread in the chasers. But the design is open to the objection that the ring prevents threading as far down in a hole as may sometimes be required, and the ring may interfere with lugs or projections on the piece to be threaded. In this respect the former of the two taps last described is superior, as it is free from any outside incumbrance, and takes up no more room than a solid tap.

* * *

THE TOOL ROOM VERSUS THE MACHINE SHOP SHAPER.

WILLIAM ECKER.*

A shaper for tool-room use can never answer its purpose with economy if used for regular machine shop work, as it cannot retain its accuracy when subjected to the strains and hard knocks common in machine shop practice. A tool-room shaper should not be expected to rush out work with heavy cuts, as this leads to distortion of the working parts, and constitutes an abuse of the machine. A reasonable cut indicates judgment.

The tool-room shaper should be well graduated on all screws used for adjustment in practical tool work; such graduations, if reliable, are more convenient for use than measurements made by scale or caliper. A first-class mechanic will have a great respect for a tool that is graduated and reliable, because this eliminates all guess work, and relieves the worker of anxiety, as he depends on the machine to produce the work correctly. "The smile that won't come off" is on both the tool-maker's and the apprentice's face when he takes a piece of work out of the shaper vise and finds it square and parallel; that smile, however, is never seen on the face of the man using the machine shop shaper, but only a look of anxiety, for he works by "guess." He knows his shaper is not true; consequently more cuts and calipering, with final filing and scraping, all of which is not economical. Filing and scraping in a first-class tool-room, after machining a piece of work, is only a indication that the work has been done on a poor machine, or in a hurry and not deliberately, and causes loss of time amounting to, perhaps, four times the time required for machining the work over again, and still not producing so good looking a job when inspected by a capable judge. To sum up, while graduations are desirable on the adjusting screws, if they are out of true, they are only confusing; for this reason few machanics use them even when they exist, because they have lost confidence in the machine.

The feed on a tool-room shaper is usually one, two, or three teeth. Rather than to use a heavier feed, the tool-maker, when cutting tool steel, may adjust the machine to take a deeper or shallower cut. The tool-room shaper does not require so large a range as is required by the machine shop shaper, and can, therefore, be designed along lines leading towards rapid and convenient manipulation, and more compact and rigid construction. The class of people the best tool-makers come from are generally thin, nervous and very sensitive, and a heavy and clumsy design does not appeal to them at all, but produces a feeling of antagonism. As they are the ones who have to use the machine, they are in general, the best judges of the machine. The standard of a tool-room is always greatly influenced by the standard of tools used, for even a good, first-class workman will grow indifferent, if indifferent tools are to be used.

The machine shop shaper, as considered apart from the tool-room shaper, is generally called upon to do a great variety of work, and must be designed with more liberal proportions, and is not so well adapted to perform small, reliable, exact operations; "snagging" and "hogging" is considered quite the proper thing with this tool. This always produces the same result. The machine will not long remain reliable, and consequently there is a great deal of measuring, calipering, squaring and swearing, all multiplied four times by waste of time. In the machine shop practice, the work to be done calls for a greater variety of feeds than a tool-maker usually demands. The machine shop shaper is also often in the care of workmen of inferior training. This fact always influences the design of the machine and leads toward clumsiness, which is the opposite of the tool-room shaper.

On account of these differences between the tool-room shaper and the machine shop shaper, it is reasonable to assume that the design fitted for tool-room purposes is not suitable for the machine shop. Therefore, we should have a tool-room shaper built for the purpose of tool making, and a machine shop shaper for machine shop purposes. This difference cannot be denied, or all claims for specializing machinery must be renounced. "Happy mediums" are sometimes good, but should be called so, and there are very few of them at present.

A suggestion in the designing of shapers which may not be out of place is that on account of the fact that in any make of shaper the ram has considerable weight, and travels at a comparatively high speed, it would only be reasonable to make an attempt at counterbalancing, having the same kind of springs or shock absorbers as usual in some other kinds of machinery, to take up the shock at the end of the stroke.

* * *

Steel wool is a by-product much used by wood finishers, painters, etc., in preference to sandpaper, especially on molded work. It is the long, hair-like chips produced in drilling rifle barrels. A curious commercial fact about this product is that it sells for several times the cost of the steel composing the barrels, the retail price being about 50 cents per pound.

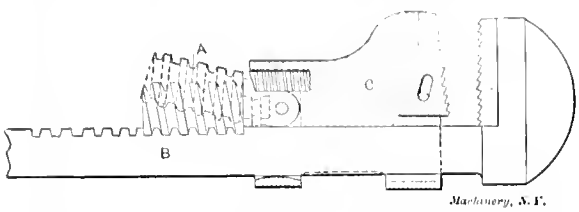
ITEMS OF MECHANICAL INTEREST.

QUICK-ADJUSTMENT PIPE WRENCH.

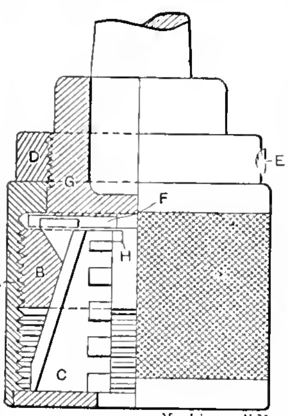
The accompanying engraving shows an interesting pipe wrench made on the monkey-wrench principle and patented by Mr. M. G. Ewer, of Detroit, Mich. The principal feature of this wrench is its quick adjustment to various sizes of pipe. It will be seen that the binding or adjusting screw A, which engages with the thread cut in the handle B of the wrench, is pivoted to the movable jaw C, and when it is required to move this jaw a long distance out or in, the adjusting screw is simply lifted out of engagement with the thread on the shank as shown by the dotted lines, and the jaw is slid along the shank until it has approximately reached the location required. Then the screw is pushed into engagement with the thread on the shank, and the final adjustment and clamping are made as usual.



Pipe Wrench which is adjusted quickly by disengaging Adjusting Screw, as shown by the Dotted Lines.

A NEW DRILL CHUCK.

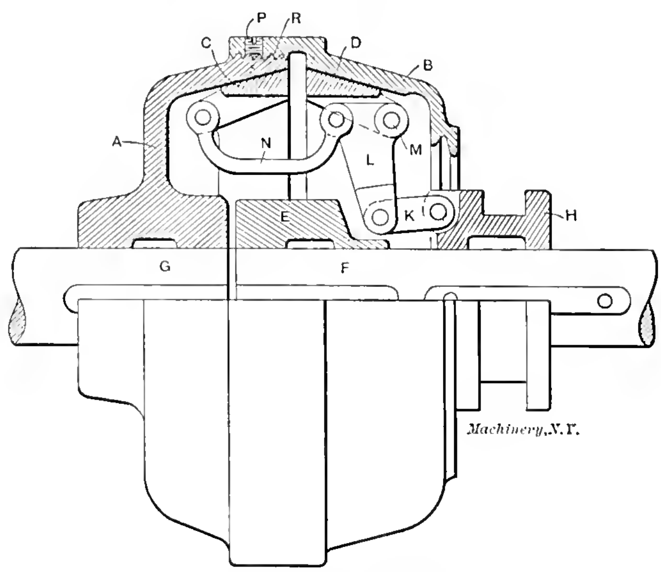
A drill chuck, embodying an interesting feature, whereby the drill is clamped more firmly in the chuck as the pressure on the cutting tool increases, has been designed by Mr. P. G. Lagerbäck, of Aktiebolaget Nordiska Artilleriverkstäderna, Finspong, Sweden. The following description of this drill chuck is abstracted from *Industritidningen Norden*. The sleeve A is threaded on the inside and engages with the chuck ring B, provided with grooves for receiving the chuck jaws C. The sleeve A is prevented from lateral motion by the nut D, provided with binding screw E for holding it in place. The jaws are provided with a projection F, which enters in a groove in the chuck holder G. When the sleeve A is turned in relation to the holder G, the jaws C and consequently the chuck ring B, are thus prevented from taking part in this rotary motion, and consequently the chuck ring B will move in a lateral direction, thereby closing the chuck jaws on, or releasing them from the tool shank. A small projection H is provided on each of the jaws, and the end of the tool shank rests against this projection. The length of the jaws is slightly less than the place within the chuck provided for them, so that after having been clamped upon the tool shank, when the pressure is applied on the tool, the end of the tool shank will press on the projections H, thereby having a tendency to force the jaws upward, and this, in turn, will clamp the tool more firmly in the chuck, inasmuch as the jaws, in order to move upward, will also be forced inward by the taper on their back surface.



Drill Chuck which clamps Tool more firmly as Pressure Increases.

FRICTION COUPLING OF SIMPLE DESIGN.

Judging by the great number of different designs of friction couplings placed on the market during the last year, it seems as if special energy had been devoted to the design of simple and efficient friction couplings in Germany. We have illustrated several of these designs in the columns of MACHINERY during the past year. The accompanying engraving shows another design which, in regard to simplicity, probably excels most of the others. This coupling is manufactured by the Sächsische Maschinenfabrik, Chemnitz, Germany. As seen in the engraving, this coupling consists of a housing made in two sections A and B. The inside of this housing is made tapered from the center, and friction rings C and D transmit the motion from this housing to a central hub E, which in turn is keyed to the shaft F. The housing itself is keyed to the shaft G, power being thus transmitted from the shaft G to the shaft F. The friction rings C and D are operated through a lever mechanism from the sleeve H, which in turn is operated by a fork bolted to the shifting lever. The sleeve is connected through link K with the lever L which is pivoted at M. The link N connects the two friction rings C and D, and according to the position of the lever L, the rings will be pressed against the housing or released from it. On account of the shape of the link N a certain spring action is possible in this member. It will be noted that the two sections A and B of the housing are connected with each other through the threaded portion at R, a set-screw P being used for binding the part B to the part A after being adjusted. This threaded joint permits of a very close adjustment of the two halves of the housing so that the tapered surfaces on the inside can be placed in such positions as to insure a binding action at exactly the place required by the position of the levers. It



German Friction Coupling.

also makes it possible to adjust the two sections of the housing when worn on the gripping faces. It is evident that a coupling of this character can be made of comparatively small diameter. The friction rings C and D are running in oil, and on account of the spring action of the lever N and this oiling arrangement, a very gradual gripping is insured and breakages and wear are reduced to the minimum. The objectional pressure in one direction, which is common with many friction clutches of the usual design, is obviated by the use of two conical friction surfaces inclining in different directions. It is claimed that under normal conditions couplings of this type can be used to advantage for shafts up to about 5 inches diameter. Upon examination of the lever arrangement it will be found that the coupling cannot accidentally release inasmuch as the levers are arranged to give a kind of toggle action so that when lever L once comes into position where it clamps the friction rings to the housing it cannot again release, unless considerable force is applied at its lower end from sleeve H through the link K. In a design of this kind there are, of course, normally two or four sets of links of the same kind as the one set shown in the sectional part of the engraving.

A FEAT OF HALF-TONE ILLUSTRATION IN JOURNALISM.

Here is the record of the latest feat of half-tone illustration in journalism. A New York daily newspaper photographed the finish of the Brooklyn handicap at Gravesend, L. I., race track, June 1, at 4 o'clock, carried the negative in an automobile to Herald Square, developed it, made a half-tone plate, electrotyped it and placed printed papers containing the illustration on the street at 6 o'clock that night.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,

NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JULY, 1908.

PAID CIRCULATION FOR JUNE, 1908, 21,397 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

SELF-OILING MACHINERY.

We believe that if there is one great improvement in modern machinery and machine tools that should be extolled beyond all others, it is the self-oiling feature that is being used on high-grade high-speed steam engines and certain machine tools. It seems, when one reflects on it, that many manufacturers must have been asleep to be content to go along year after year building and using machines that require the continual attention of the operator's oil-can. The common attitude of indifference among machinists and machine builders to self-oiling machines doubtless is largely because of early education. About the first thing that an apprentice or machine tender is taught is to keep his machine well oiled. Oiling his machine regularly becomes part of his mental make-up and it is something of a shock to his ideas of the fitness of things to see and use highly developed machinery that requires no attention whatever from the oil-can. We must get away from the antiquated idea that each and every bearing requires individual inspection and oiling two or three times a day, for there is no good reason why a machine should not oil itself. To be sure, the first cost of such machinery is more, but the difference is negligible when the advantages are considered. The mechanical efficiency may be increased so much as to save in power the extra cost of the improved oiling facilities in the first six months. Bearings carrying comparatively light loads will run indefinitely with no perceptible wear if they are continually oiled. Then there is the item of cleanliness which alone makes the self-oiling feature worth adoption in shops that require all machines to be kept in a cleanly condition.

* * *

OBSOLETE TOOLS IN MACHINE TOOL SHOPS.

Machine tool builders are interested directly and indirectly, more than any other manufacturers, in promoting the general use of up-to-date labor-saving machinery; yet the experience of one who has visited a large number of works indicates that the best equipped machine shops are sometimes *not* those engaged in the building of machine tools. The demand for nearly all new machine tools depends largely on the ability of the seller to demonstrate their economy in production over preceding types; yet we have noticed in some machine tool shops obsolete machines that occupy valuable space and waste a large part of the operator's time because of their inefficient productive capacity. Think of the effect of such examples on a possible purchaser who is being taken through a shop containing such tools—not to speak of the result of this policy on ultimate profits as well as on the progress of the shop and the development of its product.

This is a good time for each machine tool builder to take stock of his own equipment and decide what machines are unprofitable or can be replaced by others that will yield a good return on the investment and perhaps raise the standard of the product by their superior work. Although no manufacturers can live by "cutting each other's hair," the machine tool builders can help one another considerably just now by installing some of the valuable machines built by their contemporaries. Such purchases will greatly increase the general efficiency of American machine tool shops and prove a welcome addition to the order books of most manufacturers. Both buyers and manufacturers can take the time now to ensure the right tools being installed for the work required, which may not be the case three months from now.

* * *

BACK TO FIRST PRINCIPLES IN STOCK-KEEPING.

Years ago when the building of machines was conducted in a primitive manner, stock-rooms under the charge of responsible persons were practically unknown, and the small parts needed in construction work were commonly produced as they were needed. This applied to castings, bolts, screws, nuts, shafts, pulleys and all other parts that are now commonly made up into stock and used as required. Then followed the period when small parts were manufactured and kept in a stock-room to be issued only upon requisitions made by the foremen or other responsible employes. This system naturally followed the discovery that it was cheaper to manufacture parts than to make them one by one when needed. The requirements of bookkeeping and economical administration apparently made the store-room system a necessity to avoid the losses that would follow where employes were free to help themselves to finished parts. So obvious is this proposition that to keep stock parts worth thousands of dollars in open bins in the shop, freely accessible to workmen, seems a rank heresy, but that is exactly the present practice of a number of western machine tool builders who have followed it for some time with much success. In the manufacture of drill presses, lathes, etc., it is possible to make large quantities of small gears, pulleys, handles, knobs, spindles, pinions, clutches, tool-posts, worms, worm-wheels, etc., at low cost per piece, but if they are stored in a stock-room and given out only on requisitions, there is a chance that a considerable part of the saving made possible by the system of manufacture will be lost because of time wasted by men waiting for these parts and the time consumed by foremen and store-keepers in attending to these wants.

Where the parts are freely accessible, each man helps himself, under the supervision of the sub-foreman, of course, who sees that no parts are wantonly wasted. It saves time and promotes rapid work. There is little incentive to purloin these parts as they are of practically no value to individuals, being made of iron and steel. Of course, in the case of parts made of brass or other intrinsically valuable metal the system would hardly be practicable, nor would it be feasible, perhaps, for such parts as might be applied to mechanical uses outside of the designed use.

A saving of considerable importance in shops where space is at a premium is the abolition of the large store-room. The parts to be readily accessible should be in the erecting shop, and it is usually possible to utilize space under benches or by the walls, that is of little value for other purposes. This factor alone might sometimes be a deciding one in the adoption of the "open shop" store-room plan.

* * *

Imitation indicates limitation.—*The Silent Partner.*

THE PERSONNEL OF WORKMEN.

The "Confidences of a Manufacturer" (see November, 1907, issue) enunciated one principle that has been applied, by at least a few manufacturers, with great profit to themselves and their employes. It is a principle that foremen should understand and foster, as it will tend to make the management of their departments easy and successful.

The principle is simply to hire new help, so far as possible, only upon the recommendation of old employes. Of course, good judgment must be exercised to prevent the formation of parties or cliques, and that is exactly what the system will discourage if rightly directed. If a new man is hired upon an employe's recommendation, that employe feels a certain responsibility in his success, and will help the stranger to make good, instead of discouraging him at the outset, as he might do under different circumstances.

A man of good habits and a master of his trade is not likely to recommend a man of bad habits or one who is incompetent, and while trade union influences may change all this in certain cases, in general it will apply. The plan has proved successful in the employment of girls in manufacturing.

* * *

LIMITATION OF AUTOMATIC MACHINERY.

Notwithstanding the great development of automatic machinery, there yet remains a large number of mechanical operations for doing which no automatic machinery has been developed that can compete successfully with hand-operated machines, especially in the machine tool field. The manufacturers of brass valves and other brass goods use hand-operated lathes almost exclusively for turning, boring and threading spindles, caps, stuffing-boxes, bodies, collars, studs, etc. These manufacturers, of course, are keenly anxious to displace manually-operated machines wherever they can do it profitably, but little automatic machinery has been developed, so far, that is as efficient in operation and that does not cost far more for up-keep. The operators of brass lathes become so expert that the time required for some operations is but little more than that required for picking up the piece, chucking it and removing it from the machine. Unless the competing automatic machine is so highly developed that it will feed itself from castings thrown into a hopper, the saving in wages is more than eaten up by the interest and depreciation on the larger investment, and by the cost of the tool-maker's attention. The hand-operated lathe is a simple machine costing only \$300 or \$400 with a full equipment of tools. The automatic machine for doing the same work would cost, perhaps, five or six times as much, and the tool-maker's annual charge against it is likely to be heavy.

In another line—the manufacture of twist drills—we find automatic machinery used to a very small extent. In the making of small twist drills there is a large amount of hand work. Twist drills are fluted, relieved, hardened, tempered, straightened, polished and pointed by hand. No automatic machinery has been devised, so far as we know, that does not cost more for attendance and repairs than the present human and simple machinery equipment. The difficulty seems to lie in the necessity of many handlings of pieces by operators who must feed the machines. Automatic machines there are that display almost human dexterity in handling and selective qualities, but they are costly and complicated in construction and very likely to fail in operation. There is little or no profit in an automatic machine that requires an attendant constantly. An attendant can soon acquire the skill that will enable him to run the much simpler and cheaper hand-operated machines. The success of automatic machinery in the machine tool field is most noticeable in the case of screw machines wherein the parts are practically finished complete on the end of a bar and when once cut off require little further work, of consequence. In this way the difficulty of handling parts of irregular shape is avoided. The practicability of automatic machinery for manufacturing twist drills apparently lies in the application of the same idea, that is, avoiding the handling of parts by doing all operations, including *hardening, tempering* and *straightening* while yet attached to the stock bar. This perhaps means a machine of the multiple-spindle type with spindles mounted in a revolving cylinder or the equivalent. So far as we know the scheme has never been tried, but it may be found to be the most feasible way of manufacturing twist drills by automatic machinery.

In the very nature of the proposition, an automatic machine can be successful only when it requires the operator's attention a small part of the working time; by this we mean machines built automatic to save labor cost, and not those made to perform certain functions automatically because of the impossibility of doing them by hand. The conclusion then is that automatic machinery is most successful in manufacturing when it is of essentially simple construction in both the operative and feeding parts. We do not think that such will always be the condition, but it appears to be so in the present state of the art of designing and building machinery.

* * *

INTERLOCKING FORMED MILLING CUTTERS.

When concave milling cutters, provided with eccentric relief, have part of the cutting edge lines perpendicular to the axis of the cutter, it is often a perplexing problem to know whether it is best to relieve those perpendicular parts or not. If the cutting edges are not relieved at those points, it is evident that they will not cut in the ordinary meaning of the word, but will simply scrape the work on the sides. If, on the other hand, these edges are relieved, then when the formed cutter is subsequently ground in the usual manner, that is, by grinding on the face of the tooth, the outline of the teeth will be changed, the perpendicular parts of the cutting edges becoming further apart as the faces of the teeth are ground down more and more. In general, of course, cutting edges perpendicular to the axis are avoided as much as possible on eccentrically-relieved cutters, but sometimes it is necessary to have them. If the exact width of the work is not of particular importance, it may be advisable to relieve the perpendicular edges, but otherwise it should never be done. One of the common fallacies in the making of eccentrically-relieved formed cutters having perpendicular edges, and one that we, in particular, want to call attention to, is that those cutters can be interlocked in such a manner as to provide for adjustment when the faces of the teeth are ground off, even though the teeth be relieved on the perpendicular faces. When the cutter has been ground so that the distance between these perpendicular faces is enlarged, it is supposed that the interlocking faces can be ground off an amount corresponding to the increase between the perpendicular faces, and that the shape of the cutter is thus retained. A little thought, however, will convince anybody that there are very few cases of formed milling cutters where the original shape of the cutter would be retained. If the cutter be concave at the center where the two halves of the cutter are interlocked, then, if it be perfectly circular when the cutter is new, the grinding away of the faces will produce a sharp corner at the juncture, which will become more and more pronounced as the faces are ground off.

The interlocking of formed milling cutters, which are relieved on the perpendicular faces, therefore, should only be permitted when the width between these faces is the most essential dimension, and the form of the work, otherwise, can stand slight changes; but, if the work is expected to be absolutely of the same shape in all respects, perpendicular cutting edges on the formed cutters should be avoided. Whatever finish is necessary on the sides of the work should be performed in a separate operation with ordinary cutters. The belief that formed cutters, however relieved, can be ground without changing their shape, and that they can be interlocked so as to provide for any changes that would occur on account of their side relief, is so common that we consider it important to call attention to this error.

* * *

It may be that we seldom are able to achieve all that we try to achieve, but it is well to constantly have a high aim ahead of us. The man with ideals measures higher and grades better than the man without ideals and ambitions; and besides, if one measured up to one's ideals, and achieved all that one's ambition demanded, that would simply be a sign that one's ideals and ambitions were not high enough.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

It is reported by Consul-General Robert J. Wynne that the ninth tunnel under the Thames, London, will shortly be opened. Of the tunnels under the Thames, five are used exclusively by subways and railroads, and the other four used for general traffic.

Evidence of the industrial progress of Germany is given by the increase in its coal consumption which, according to the *Mechanical World*, increased nearly 40 per cent between 1902 and 1907. In 1907, the increase in the coal consumption over that of 1906 was 9 per cent.

Japan's advance in machine building is indicated by the fact that its exports during the last year were five times greater than the average for the last five years. A large proportion of the exports consists of cotton gins, textile machinery, and printing presses, for China.

It is mentioned in an item in the *Horseless Age* that the city of Milwaukee will, in a short time, use no horses for municipal purposes, except to draw fire engines. The city officials are convinced that the automobile is so far in advance of the horse in cost, maintenance, and utility, that there is hardly any room for a comparison.

Another step toward the accomplishment of aerial navigation made by Mr. Henry Farman, the winner of the Deutsch-Archdeacon prize referred to in the March issue of the engineering edition, in covering a complete circle two and a half times at Issy-les-Moulineaux, France. The total length of the flight was over a mile and a half.

A chimney, 400 feet high, is to be erected for carrying off the fumes from the assay furnaces from the new ten-story Assay office building of the United States Treasury Department in New York City. The chimney is intended to carry the poisonous fumes entirely above the surrounding high office buildings in the neighborhood.

The second largest masonry arch in the world has, according to *Engineering News*, recently been built on a new railway in Austria. This arch is the largest span of a bridge over the Isonzo River, and is 278.9 feet, having a rise of 78 feet. The arch is of cut stone founded on reinforced concrete footings, backing into solid rock. It is 6.6 feet thick at the crown. The largest masonry arch in the world is at Plauen, Germany, having a span of 295 feet, and the hitherto second largest, at Luxembourg, with a span of 277.6 feet.

England's first skyscraper will, according to the news despatches, be built in Liverpool, the city having authorized the construction of an office building which will rise to a height of 300 feet over the street level. The site of the new building is opposite the Prince's landing stage on the bank of the Mersey. It is rather surprising that conservative England is the first European country to adopt the American high building construction. On the other hand, considering the disadvantages that follow high buildings, it is not likely that continental Europe will permit itself to be deluded into allowing structures of such enormous height.

Lead, according to *Cassier's Magazine*, is said to act like steel at ordinary temperatures when reduced to a very low temperature in liquid air. It will serve as a helical spring, for example. This behavior of soft, non-elastic metals is very interesting. It shows how very important temperature is. Just as iron is soft and inelastic at a high red color, so lead is dull and soft at ordinary temperatures, for it is well on its way to be melted. Mercury is actually fluid at ordinary temperatures, but can be frozen at about 20 degrees F. into a soft metal. At lower temperatures it may, perhaps, be possible to make springs of mercury.

A correspondent to the *Times Engineering Supplement* states that a well perfected process for the construction of artificial gems has been developed by the Deutsche Edelstein Gesellschaft, at Idar, Germany. Instead of building up a stone from fragments, by which means the so-called "reconstructed rubies" are obtained, this company is said to make flawless rubies and other precious stones of perfect color and brilliance, and of great size, directly from the chemical elements. These gems possess all the chemical and physical properties of the real stones, and are indistinguishable from the genuine, even by experts. They can moreover be obtained in the most perfect tints, and of any required size.

The experimental stage of electric traction on the Swedish State Railways has now been concluded, and the Department of Railways has furnished the government with a report of all the experiments. The fact particularly accentuated is that mono-phase alternating current provides for the simplest, best, and cheapest system for electric traction on railways. The department states that, in its opinion, there is, at the present time, no reason for delaying the electrification of the main portions of the state railways. The experimental section will be left intact for carrying on experiments later on for determining some details which may be required to be investigated as the work proceeds.

An interesting phenomenon that may be of use in the ignition of explosives is creating some interest in Germany. According to a consular report, it has been discovered that an alloy of iron and cerium, lanthanium, or any other of the rare substances which are used in the manufacture of incandescent gas mantles will create luminous sparks on being struck with a metal tool, such as a knife edge, file or the like. The sparks given off at the point of impact are sufficient to ignite not only gas, but even a cotton wick saturated with alcohol, and it is possible that these alloys may be utilized for igniting all kinds of explosives. The behavior of these alloys has been found to vary according to their percentage of iron, the sparking reaching a maximum when the iron content is 30 per cent.

The substitution of a cheap and indestructible material for timber used in mines is a problem which sooner or later will come forcibly before mine owners and engineers. Experiments have been carried on in England with reinforced concrete beams, which point to the possibility of using this material largely as a substitute for wood, especially for work which is intended to be of a relatively permanent nature, and in which the increased cost of the concrete beam is justified by its indestructibility and freedom from decay. As the cost of Portland cement tends to fall, while that of timber rises, it is, says the *Times Engineering Supplement*, only a question of time when concrete will become a very effective means of construction for mining operations. In this country, at the present time, reinforced concrete beams are manufactured and sold for mining purposes in the mining districts of Colorado.

In the February and March, 1907, issues of MACHINERY the Poulsen system of wireless telegraphy was referred to. At the present time the inventor is paying more attention to the question of wireless telephony than that of telegraphy, although, of course, an advance in one direction may, in a sense, always be considered as an advance in the other. The results so far obtained by wireless telephony by the Poulsen system have been gratifying. Music has been transmitted for a distance of 290 miles, and conversation 170 miles, the reproduction of the speech being clear, and the voice easy to recognize. The question of wireless telephony is of particular importance in Europe, where many of the countries are segregated from one another by the sea, for comparatively

short distances. Telephoning through submarine cables has presented great difficulties, and for this reason it is expected that wireless telephony will fill a distinct demand.

An idea in electric heating which, however, would not be applicable to the United States, is mentioned in the *Western Electrician*. Throughout Germany and most of Continental Europe, the prevailing method of heating rooms is by means of large ornamental tile stoves, which reach nearly to the ceiling, and have a large heating surface at a rather moderate temperature. These, of course, are usually intended for wood or coal. A system of electric heating adapted to these stoves has, however, recently been brought out in Berlin. An electric radiator is mounted inside the stove, so that it will rapidly heat the walls by a circulation of the enclosed air. The heat is given off from the exterior tile surface of the stove, and is thus tempered so as to avoid the dry, high temperature effect. As the average cost of current in Germany is about 4 cents per K. W. hour, this system seems to have opened up a promising field for electric heating in that country. It is stated that an average sized room can be heated in one hour, and will then remain warm for a considerable period, as the tiles retain their heat for a long time.

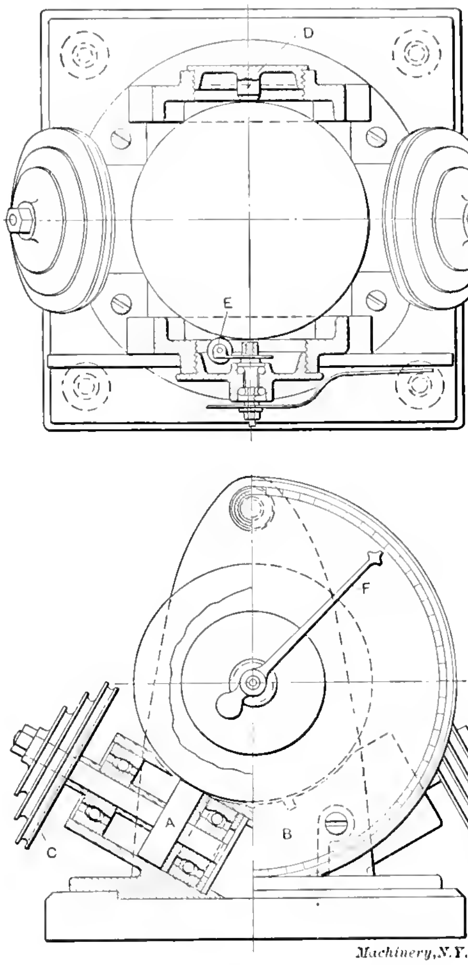
In view of the present agitation for the safeguarding of the life and limb of industrial workers, and in connection with the recent exhibit of safety appliances which took place in New York City during April and May, some figures given by Dr. Joseph A. Holmes in the Bulletin of the United States Geological Survey, although they refer in particular to the coal mining industry, should be of interest to everybody who realizes the necessity of greater vigilance in regard to safety appliances. Dr. Holmes says that the experience in deeper and more dangerous coal mines, particularly in Belgium, indicate that American mine accidents may be reduced to less than a third of their present frequency. He says that American coal mining methods are less safe than those of any other country. In 1906, 3.4 men were killed for every one thousand employed. In Belgium the corresponding figure was only 0.94 in the same year. In Great Britain the corresponding figure was 1.29, and in France 0.84 in 1905, and in Prussia 1.8 in 1904. What makes this comparison all the more significant is a further statement by Dr. Holmes that in no country in the world are the natural conditions so favorable for the safe extraction of coal as in the United States. The work done both privately and publicly for safeguarding industrial workers, both in the coal mining industry and in other fields of industrial activity, should receive increased impetus from statistics of this character.

NEW USE FOR MANGANESE STEEL.

A good example of how the development of one industry helps another is found in an order for manganese steel disks recently placed by the Cutler-Hammer Clutch Co., of Milwaukee. This company, in addition to manufacturing magnetic clutches, makes a specialty of lifting magnets for handling pig iron and scrap metal. The growth of this latter business and the natural desire of the manufacturers to perfect every detail of their product has led to the adoption of manganese steel for coil shields—the coil shields being the flat disk fastened to the under side of the lifting magnet for the double purpose of protecting the magnetizing coil and interposing between the two poles of the magnet an area of non-magnetic material. Brass, which is non-magnetic, has heretofore been used for this purpose. Ordinary steel will not do, because it is a magnetic metal and would serve to conduct the magnetic lines of force from pole to pole instead of compelling them to seek a passage through the material to be lifted. Manganese steel seems to be the ideal metal for this purpose. It is non-magnetic, like brass, and infinitely harder—so hard, in fact, that the continued hammering of the pig iron or other metal on the under surface of the magnet makes not the slightest impression on it. The 50-inch magnets recently furnished by the Cutler-Hammer Clutch Co. to a number of steel mills in the Pittsburg district are all equipped with manganese steel coil shields instead of with the brass coil shields formerly used.

DIFFERENTIAL SPEED INDICATOR.

An interesting differential speed indicator was shown at the Exhibition of the Royal Society, London, England, on May 13. The device was exhibited by Sir John Thornycroft, and the accompanying illustration is taken from *Engineering*, issue of May 15, 1908. The device consists of two cylindrical rollers, one of which is shown at *A*, and the other located at the opposite side of the device inside of the cover *B*, in a position similar to that occupied by the roller *A*, only inclined to an opposite angle. The axes of the rollers are in the same vertical plane, simply being inclined to one another, as mentioned, after the fashion of the guide rollers of a conveyor. These rollers are mounted on shafts on the ends of which are mounted pulleys *C*, which in turn are driven from the shafts the relative speeds of which are to be compared. Resting on these cylindrical rollers is a solid steel ball, 3 inches in diameter. To prevent the ball from rolling off the rollers, it is held in place at the back by a small stop *D*, and



Differential Speed Indicator.

at the front by a small wheel *E*, as shown in the plan view of the device. The wheel *E* is mounted on an arm fixed to a spindle, free to rotate, so that the wheel with its carrying arm forms a sort of caster. It is clear that if both the supporting rollers are driven at an equal speed in the same direction, the ball will rotate about a transverse horizontal axis and will carry the caster wheel either vertically up or down, as the case might be. Its direction will be indicated by the pointer *F* on the graduated scale of the device. If either of the supporting rollers runs faster than the other, the ball would rotate about some inclined axis, and the caster wheel would naturally turn so that its axis would be parallel to that of rotation of the sphere. The indications of the instrument are claimed to be very definite, and it is stated that a difference in speed of the rollers due to a nominally $2\frac{1}{2}$-inch diameter driving pulley being 0.001 inch less in diameter than the other, can be detected.

While the device itself may be as sensitive as this statement indicates, it seems, however, that to make the indications absolutely sure the motion should be transmitted from

the respective driving shafts, not by belt drives, as indicated, but by some means of positive drive, like gearing, or at least by chain drive. The slip of the belt alone, it seems, could effect a change in the speeds of the two cylindrical rollers, so that the sensitiveness of the device would be largely neutralized.

RECENT DEVELOPMENT OF THE GAS TURBINE.

Alfred Barbezat in *Cassier's Magazine*, April, 1908.

In the March, 1907, issue of MACHINERY an illustrated article was published on practical results with actual operative gas turbines in France. This article consisted of an abstract from an article on the gas turbine in *Cassier's Magazine*, for January, 1907. The same magazine has again published additional information regarding the recent developments in this field, the following abstract containing the most important points regarding these developments.

The first experiments with gas turbines were made with a small turbine of the same type as the De Laval steam turbine, capable of developing about 30 H. P., and after noting the performances of this machine when driven by compressed air alone, arrangements were made to use it in connection with a combustion chamber, delivering the products of the combustion of liquid hydro-carbon fuel at constant pressure through a nozzle upon the blades of the turbine. The combustion chamber is provided with a refractory lining, and in dealing with such high temperatures of combustion as are met with in engines of this kind, the temperature of combustion being over 3,200 degrees F., the best refractory lining has been found to be carborundum, this material being a product of the electric furnace, and thus having already sustained a higher temperature than that in the turbine combustion chamber. An elastic backing of asbestos provides for the expansion of the carborundum lining. The nozzles through which the cases are discharged are also made of carborundum. In addition to the refractory lining, the combustion chamber must be provided with a water jacket in the form of a coil of pipe imbedded in the metal of the chamber walls. When the water has circulated in the jacket tube, it is sent through small holes into the combustion gases just before they enter the nozzle, and the water is there converted into steam which acts to lower the temperature of the issuing gases to a point where they will not injure the blades of the turbine.

In order to obtain the desired result of a machine involving only rotary motion, it has been found necessary that the compressed air, by which the combustion chamber is fed, should be produced, not by a reciprocating combustion compressor, but by some form of rotary motion, preferably so arranged that it can be coupled directly to the turbine itself. This means that the complete gas turbine must also include a rotary air compressor, and that such a compressor must have a high efficiency in itself, otherwise it will produce such a large proportion of negative work as to detract materially from the efficiency of the compound machine.

After several experiments, a multiple turbine compressor was decided upon, which was found to be capable of delivering one cubic meter of air per second, at a pressure of six or seven atmospheres, with an efficiency ranging between 60 and 70 per cent. A large-sized gas turbine has been built, and in this machine the compressor is found to absorb about one-half of the power developed by the turbine. The machine when running at about 4,000 R. P. M. develops about 300 H. P. over and above the negative work absorbed by the compressor. It is stated, however, that the thermal efficiency of the machine it not as yet as high as that of a reciprocating gas engine. During the past few months a practical application of the gas turbine has been made in connection with the operation of submarine torpedoes. The turbine made for this purpose developed 120 H. P. at a speed of 1,000 R. P. M. The weight of the turbine alone is about 2.86 pounds per H. P.

While the gas turbine is, of course, still in its experimental stage, it has made a material advance during the past year, the 300 H. P. compound compressor turbine being an accomplished fact, and a number of 120 H. P. machines of special type being actually installed for service. When this rate of progress is compared with the time required to bring the reciprocating gas engine to its present state of perfection, there appears to be a reason for encouragement and interest in this form of gas engine.

PHOSPHOR-BRONZE.

Edwin S. Sperry, in the *Brass World*.

The term phosphor-bronze is used to designate an alloy of copper, tin and phosphorus, or of copper, tin, lead and phosphorus. The phosphorus is added in small quantities, with the sole object of reducing the oxide of copper, which forms during the melting. Any greater amount of phosphorus than the amount required for deoxidizing the bronze is injurious. The determination of the amount necessary to reduce the oxide of copper is quite difficult, as no two melts of copper oxidize the same. One melt may be heated longer than another, and thus absorb more oxygen. In general, however, it may be said that 0.05 per cent of phosphorus is sufficient. In making castings where scrap is used, it is often advisable to add more than enough to deoxidize the copper. From 0.10 to 0.25 per cent of phosphorus is advisable for this class of work.

Phosphor-bronze may be made in two ways: First, by introducing the phosphorus into a mixture of copper and tin; second, by first introducing the phosphorus into molten tin and making a phosphor-tin. This, in turn, is then added to the copper. The introduction of phosphorus into copper and tin while melted, as in the first process, is a dangerous operation, and accompanied by a loss of phosphorus. Sticks of phosphorus, kept under water to prevent spontaneous ignition, are placed in a bell-shaped arrangement of graphite called a phosphorizer, and the whole is pushed down under the surface of the molten copper. A violent ebullition takes place, with much loss of phosphorus, and danger to the operator. From 20 to 30 per cent of the phosphorus burns, the rest alloying with the copper.

The second process, in which the phosphorus is introduced into the molten tin, to make phosphor-tin, embodies the same processes as those outlined above, except that the phosphorus is first introduced into tin alone. As tin melts at a much lower temperature than copper, the introduction of phosphorus is attended with less danger. The copper is then melted in the usual manner, and the tin, and lastly the phosphor-tin, added.

One of the principal uses of phosphor-bronze is in the form of springs. A good mixture for phosphor-bronze springs is as follows:

Copper	95 parts by weight
Tin	4½ parts
5 per cent phosphor-tin	½ part

For phosphor-bronze of the highest possible strength, the following mixture is recommended:

Copper	90 parts
Tin	9 parts
5 per cent phosphor-tin	1 part

The mixture made according to this formula is poured into ingots, and then remelted and poured into sand castings. The remelting increases the strength. For ordinary work, when a medium strength is required, and when scrap must be used over and over again, the following mixture is recommended:

Copper	90 parts
Tin	8 parts
5 per cent phosphor-tin	2 parts

The scrap from this mixture may be used over and over again, with good results.

Phosphor-bronze, for use as bearings, which is one of the principal uses of phosphor-bronze in machine tool construction, must always contain lead. It is the lead which gives the bearing its "anti-frictional" qualities. The phosphorus prevents the separation of the lead. Lead may be present in the mixture up to 15 per cent, but the majority of makers use less. Tin must be used in the mixture as well. A good, general mixture of phosphor-bronze bearings is as follows:

Copper	80 parts
Tin	8 parts
Lead	10 parts
5 per cent phosphor-tin	2 parts

Zinc should never be present in phosphor-bronze. It causes liquidation and formation of tin-spots in a marked degree.

Tin-spots are small, hard, white masses in the interior of the casting. Frequently they are so hard that a file will not touch them. The excess of phosphorus in phosphor-bronze mixtures is also a cause of tin-spots. The secret of success in producing phosphor-bronze, in fact, is simply, in the first place, to keep the phosphor content down as low as possible in consistency with the serving of its purpose, and not to add any zinc.

NEW DEVICE FOR VARIABLE SPEED TRANSMISSION.

Abstract from pamphlet entitled *Theory and Practice of the Dieterich Universal Drive Axle.*

An interesting variable speed device has been brought out and patented by Mr. L. M. Dieterich, president of the Herma Securities Co., Kansas City, Mo. The fundamental principle of the device is best understood by reference to the diagrammatical view in Fig. 1. In this, *A* represents the shaft driven at the variable speed, while *B* and *C* are two disks receiving their motion in some suitable manner from the driving source, and running loose on the shaft *A*. The disk *D* is pivoted on the arm *B* at *O*, so that it can be inclined as shown by the dotted lines. The arm *B* is keyed to the shaft *A*. The drive to the shaft *A* is transmitted through this arm *B* from disk *D*, provided that this disk with its pivot *O* is given a rotary motion around the axis of shaft *A*.

It will be noticed that the inside of disks *B* and *C* are of spherical shape, so that when disk *D* is inclined, it will still be in contact with both of these outside disks. Now, if disk *D* is parallel to shaft *A*, and the two disks *B* and *C* are revolving in an opposite direction at the same speed, it is clear that while the rim of disk *D* will be revolving about its pivot *O* and around an axis at right angles to the axis of shaft *A*, the center of disk *D* will be stationary in relation to the axis of shaft *A*. Consequently, the arm *B* and the shaft *A* will also remain stationary. If, however, the disk *D* is placed in an angular position as indicated by the dotted line *EF*, it will be in contact with the disk *B* at the point *E* and with the disk *C* at the point *F*. The point *E* on disk *B* is revolving at a higher circumferential speed than the point *F* on disk *C*, the former point being located on a larger circle than the other. Under these conditions, it being assumed that there is no slip be-

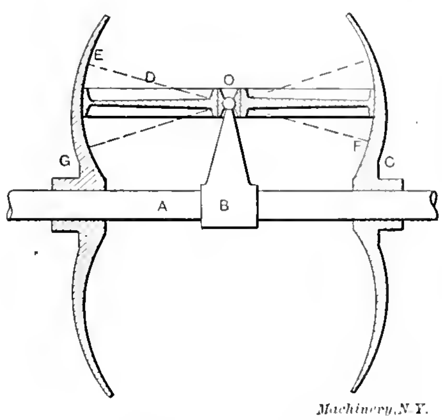


Fig. 1. Diagrammatical View Illustrating Principle of Variable Speed Device.

tween the disk *D* and the driving disks *B* and *C*, the center *O*, where the disk *D* is pivoted, must assume a rotary motion around the axis of shaft *A*, and the shaft *A* will consequently be carried around or driven at the speed determined by the angularity of the inclination of the disk *D*. The greater the angularity, the greater will be the difference in the driving diameters of the two disks *B* and *C*, and the greater also the speed of shaft *A*. It will be seen that it is possible to revolve the shaft *A* to any speed desired from zero to maximum, by giving the disk *D* different angular positions. It is also evident that by inclining the disk *D* to a position opposite to that of the line *EF*, as shown by the other dotted line in Fig. 1, the shaft *A* can be revolved in a reverse direction, although the two driving disks revolve constantly at the same speed, but, of course, in opposite directions.

This principle has been made use of in constructing the variable speed device shown in Fig. 2. A bevel gear *H*, mounted on the end of the driving shaft, gives motion to two bevel gears mounted on bearings concentric with the shaft *A*, which is the shaft to which motion is to be transmitted. These two bevel gears are provided with spherical surfaces on the inside, which form a contact path for the cork surface of the disk *D*. This disk revolves on an annular ball bearing, the inner surface of which is placed on a ring, pivoted on a stud in the head-bearing of an arm, keyed to the hollow shaft. As will be seen, the principle of the drive has been transferred almost identically to the practical working apparatus.

A lever, integral with the pivoted ring is operated by a linkage system, consisting of a stud reaching through a slot of the axle wall to a rod, the outer end of which is similarly connected with a sleeve revolving with the axle. An annular groove of this ring forms the path of the studs inserted into a forked lever, which, being pivoted in the axle housing, permits, by its operation, the oscillation of the floating disk. This device shows the simplest design of the principle ex-

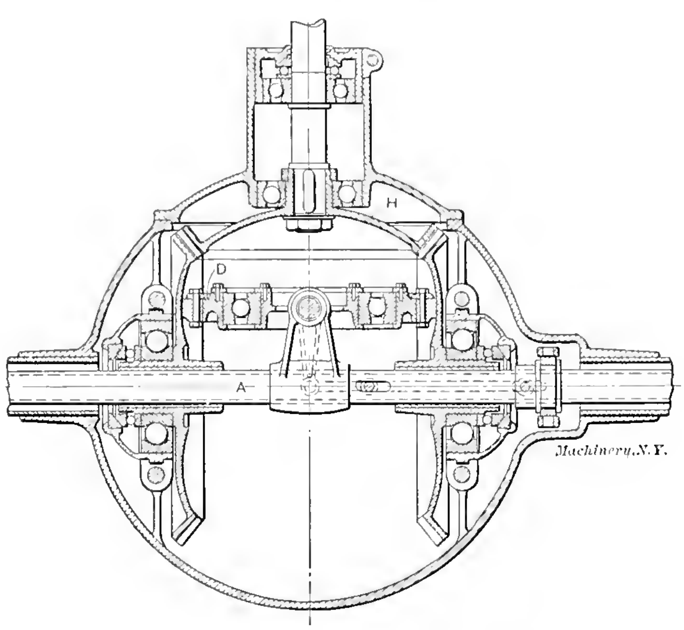

Fig. 2. Sectional View of the Variable Speed Device.

plained, applied to a variable speed mechanism intended for automobile work. Or course, the principle can be applied to more complicated devices, fulfilling their object in even a more perfect way than the one shown, and the inventor has brought out several different models.

[The one objection to drives based on this principle is that the variation of speed does not change the torque, so that even though the speed be small, the torque will not be proportionally greater, on account of the fact that the limiting factor for the torque is the frictional adherence between the driven and driving contact surfaces, and this frictional resistance is independent of the speed at which the shaft *A* is running. Consequently, while variable speed devices in general are of such construction that the torque increases when the speed decreases, in the present case the speed is variable, while the torque remains constant. As the main feature of variable speed devices is often not the variation of speed in itself as much as the increased torque obtained by a decrease in speed, the objection referred to is one of great importance —EDITOR.

* * *

The Cunard steamer *Lusitania* established a new record for a day's run June 9, when she reeled off 641 knots in 24 hours. Until the advent of the *Lusitania*, the record was held by the *Deutschland*, of the Hamburg-American line for her performance of 603 knots, July 29, 1901.

* * *

Felice Nazarro, an Italian automobile driving expert, made a world's record June 8. He drove a car on the Brooklands track, London, 23¼ miles at the rate of 120 miles per hour. This record does not include the swiftest mile, however. Demogeot, driving a car on Ormond beach, January, 1906, covered two miles in 58 1-5 seconds, or at the rate of 122.4 miles per hour. The best mile straightaway is held by Marriott, driving a Stanley steam car one mile in 28 1-5 seconds.

MAXIMUM STRESSES—3.*

JOHN S. MYERS.†

COMBINED TORSION AND BENDING.

One of the most familiar examples of combined stresses is that of torsion and bending, the torsional stresses being shearing stresses, and the bending stresses being tension and compression stresses. The maximum stress may be found by first calculating each separately, and then combining them according to formulas 26 and 27 as given in the May issue. A more direct method is to combine these equations with those for torsion and bending, thus producing formulas which give maximum stresses at once.

Let M_b = bending moment,
M_t = torsional moment,
I_r = rectangular moment of inertia,
I_p = polar moment of inertia,
Z_p = polar section modulus,
C_r = distance to extreme fiber from rectangular axis,
C_p = distance to extreme fiber from polar axis,
S = unit shearing stress due to torsion,

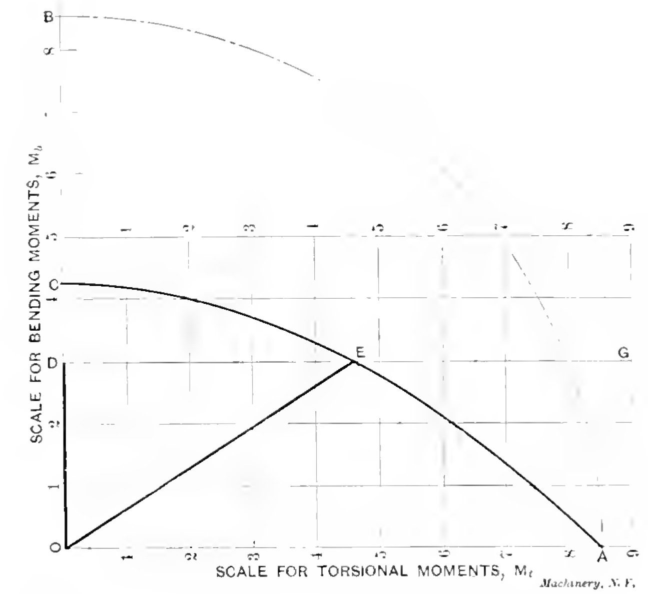

Fig 8. Method of plotting Curves for Combined Torsion and Bending.

t = unit tensile or compressive stress due to bending,
S_m = maximum or combined shearing stress,
t_m = maximum or combined tensile or compressive stress.

Then

$$S = \frac{M_t C_p}{I_p} \quad (31) \qquad t = \frac{M_b C_r}{I_r} \quad (32)$$

$$S_m = \sqrt{S^2 + \left(\frac{t}{2}\right)^2} \quad (26) \qquad t_m = \frac{t}{2} + \sqrt{S^2 + \left(\frac{t}{2}\right)^2} \quad (27)$$

Substituting the values of S and t as given by formulas (31) and (32) in equations (26) and (27), gives,

$$S_m = \sqrt{\left(\frac{M_t C_p}{I_p}\right)^2 + \left(\frac{M_b C_r}{2 I_r}\right)^2} \quad (33)$$

$$t_m = \frac{M_b C_r}{2 I_r} + \sqrt{\left(\frac{M_t C_p}{I_p}\right)^2 + \left(\frac{M_b C_r}{2 I_r}\right)^2} \quad (34)$$

Formulas (33) and (34) are general, being applicable to any case of combined torsion and bending. The most usual cases, however, are either round or square sections for which $C_p = C_r$ and $2\, I_r = I_p$. Substituting these values in equations (33) and (34) gives, for round and square sections,

$$S_m = \frac{C_p}{I_p} \sqrt{M_t^2 + M_b^2} \quad (33a)$$

$$t_m = \frac{C_p}{I_p} (M_b + \sqrt{M_t^2 + M_b^2}) \quad (34a)$$

The polar section modulus $Z_p = \frac{I_p}{C_p}$; then.

$$S_m = \frac{\sqrt{M_t^2 + M_b^2}}{Z_p} \quad (33b)$$

$$t_m = \frac{M_b + \sqrt{M_t^2 + M_b^2}}{Z_p} \quad (34b)$$

Now from equation (33*b*) we have the quantity $\sqrt{M_t^2 + M_b^2}$ which expresses the measure of the two moments to produce torsional or shearing stresses. This quantity may be called the ideal torsional moment. Equation (34*b*) gives the quantity $M_b + \sqrt{M_t^2 + M_b^2}$ as the measure of the two moments to produce bending stresses, *i. e.*, tension and compression stresses. This quantity is generally termed the ideal bending moment, although this name is rather misleading, inasmuch as it is developed in connection with the polar section modulus, which is used for torsional or shearing stresses. The ideal bending moment if used in connection with the rectangular section modulus should be taken as $\frac{1}{2}(M_b + \sqrt{M_t^2 + M_b^2})$, which could more logically be called an ideal bending moment. For

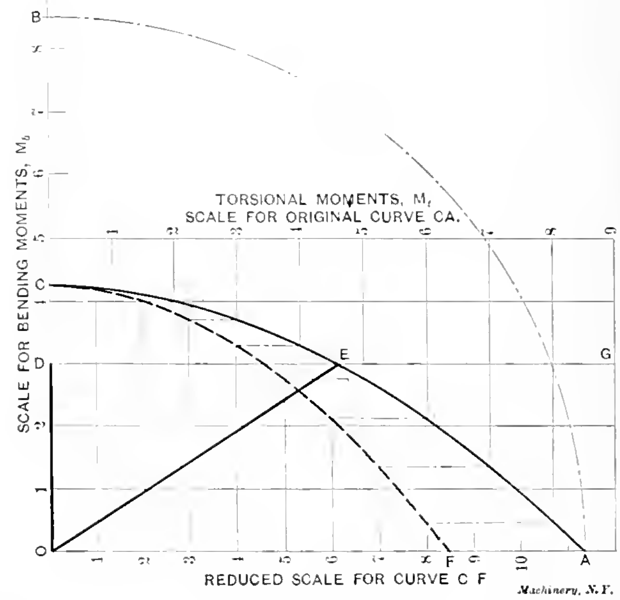

Fig 9. Method of plotting Curves for Diagrams Figs. 10, 11, 12, and 13.

the present article, it was deemed advisable to have both expressions developed for the polar section modulus, in order that they may show the relative values of the maximum combined shearing stress as compared with the maximum combined tension or compression stresses.

Tables IX and X of the Supplement give tabulated values of the ideal torsional moment T, and the ideal bending moment B, according to the formulas

$$T = \sqrt{M_t^2 + M_b^2} \quad (35)$$

$$B = M_b + \sqrt{M_t^2 + M_b^2} \quad (36)$$

both being for use with the polar section modulus as before mentioned.

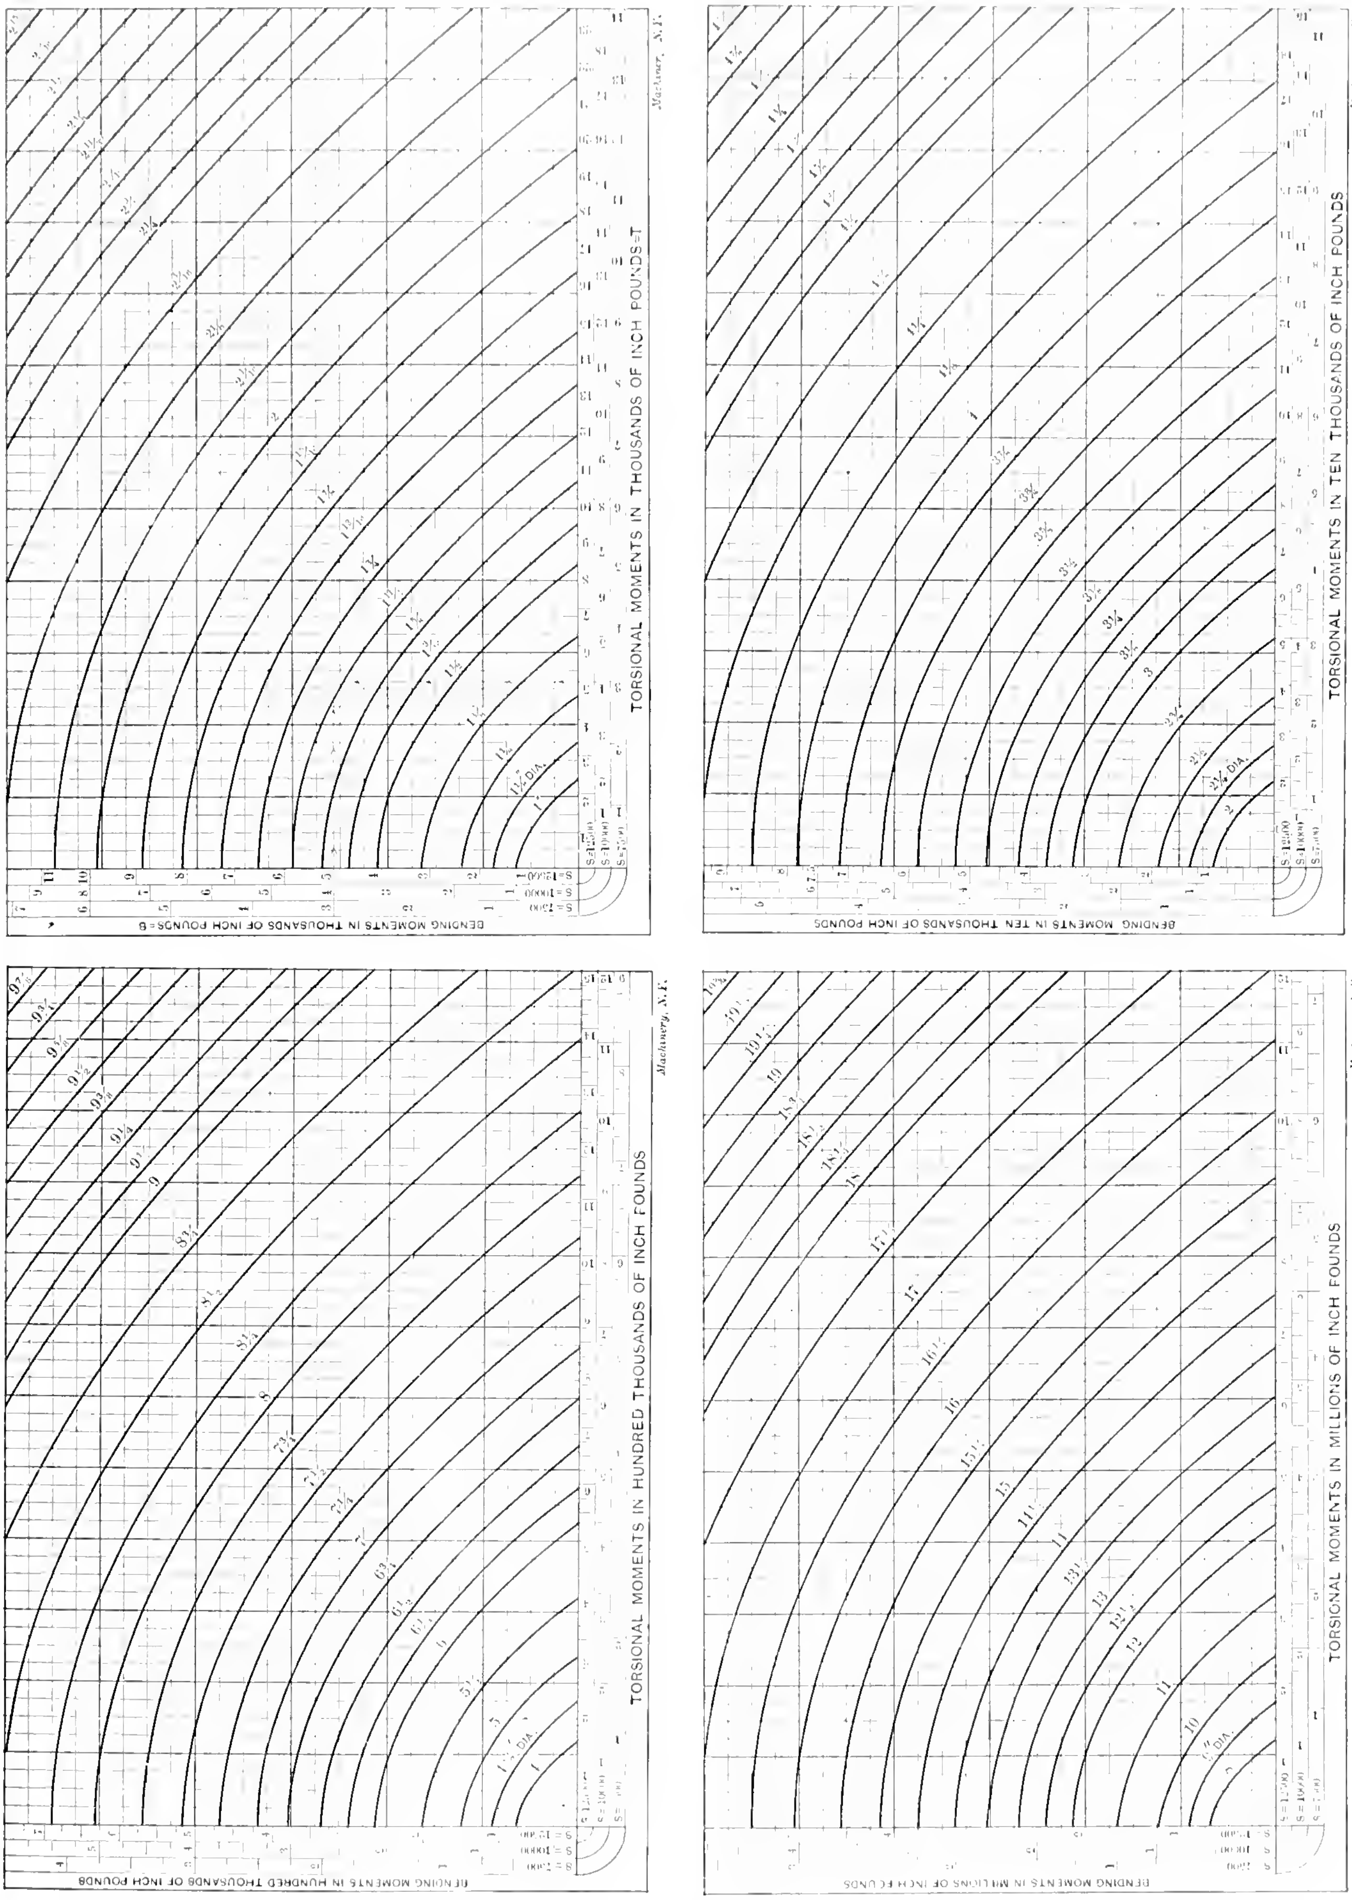
Equations (33b) and (34b) may now be written,

$$S_m = \frac{T}{Z_p} \quad (33c), \quad \text{and} \quad t_m = \frac{B}{Z_p} \quad (34c)$$

It will be noted that B is always greater than T. It is then the combined tension and compression which determines the size of section to be used, and the ideal torsional moment may be neglected entirely.

Authorities do not all agree on the subject of combined torsion and bending. The above formulas agree with Rankine's, while Grashof gives as the ideal bending moment $B = \frac{3}{8} M_b + \frac{5}{8}\sqrt{M_b^2 + M_t^2}$, or, if expressed for use with the polar section modulus as is formula (36), it becomes $B = \frac{3}{4} M_b + \frac{5}{4}\sqrt{M_b^2 + M_t^2}$. An inspection of the two formulas will show that Grashof gives greater value to the torsional moment than does Rankine, for if the bending moment be zero, then $B = \frac{5}{4} M_t$, which would agree with the usual assumption

* Continued from the May issue.
† Address: 2456 Almond St., Philadelphia, Pa.



Figs. 10, 11, 12, and 13 Diagrams giving Diameters of Shafts for Combined Torsion and Bending Stresses in Thousands, Ten Thousands, Hundred Thousands and Millions of Inch-pounds.

that the ultimate shearing strength of steel is about 4/5 of the ultimate tensile stress.

In this connection it is well to note that, in the case of shafting, the location and direction of the tooth loads or belt pulls, producing bending, remain fixed while the shaft rotates. The bending stresses are thus constantly varying in direction, and since a greater factor of safety should be used for reversible stresses than for those constant in direction, some

designers recommend that the allowable working stress vary, higher stresses being used when the torsional moment predominates than are allowed when the bending moment is the greater. One of the exponents of this idea assumes an ultimate tensile stress of 62,500 pounds per square inch, and gives as the safe value of the working stress $t_m = 11{,}350$ when $\frac{M_b}{M_t} = \frac{1}{4}$, or less, and $t_m = 8{,}750$ when $\frac{M_b}{M_t} = 2$ or more, t_m to be proportional for intermediate values of $\frac{M_b}{M_t}$.

On the other hand, the ultimate tensile stress is approximately 25 per cent greater than the ultimate shearing stress; the determining stress is always the combined tension or compression, and not the shear, and since the Rankine formula is less liberal in its recognizance of the torsional moment than is that of Grashof, the writer believes the use of the Rankine formula, with a constant allowable safe stress, makes ample provision for the fact that the bending stresses are reversible.

Example.—A shaft $3\frac{1}{2}$ inches in diameter is subjected to a torsional moment of 36,000 inch-pounds, and a bending moment of 35,000 inch-pounds. What is the combined shearing stress and the combined tension compression stress?

Solution.—Referring to table X (see Supplement of current issue), and remembering that all values may be multiplied by 10 we have for $M_t = 36{,}000$ and $M_b = 35{,}000$, $T = 50{,}210$ and $B = 85{,}210$. From table VII of the Supplement to the May issue for a $3\frac{1}{2}$-inch shaft $Z = 4.209$. The polar section modulus being twice this, we have $Z_p = 2 \times 4.209 = 8.418$.

By formulas (33c) and (34c)

$$S_m = \frac{T}{Z_p} = \frac{50{,}210}{8.418} = 5970, \text{ and}$$

$$t_m = \frac{B}{Z_p} = \frac{85{,}210}{8.418} = 10{,}130, \text{ approximately,}$$

A formula for computing the diameter of a shaft for combined torsion and bending may be derived from equation (34c) by substituting for Z_p its value $\frac{\pi D^3}{16}$, and for B its value as given by formula (36), and then solving for the diameter D, which results in the expression

$$D = 1.72 \sqrt[3]{\frac{M_b + \sqrt{M_t^2 + M_b^2}}{t_m}} \qquad (37)$$

Tables XI and XII of the Supplement give diameters of shaft for combined torsion and bending according to formula (37), the tables being arranged for fiber stresses of 7,500, 10,000, and 12,500 pounds per square inch to suit different classes of work or grades of material at the discretion of the designer.

Example.—At 10,000 pounds per square inch fiber stress, what should the diameter of a shaft be to sustain a bending moment of 80,000 inch-pounds, and a torsional moment of 100,000 inch-pounds?

Solution.—Referring to table XI, opposite 80 in the 10,000 pounds stress column, and vertically under 100 in the same stress column, the required diameter is seen to be $4\frac{3}{4}$ inches. The above problem, if solved by the application of formula (37) would be,

$$D = 1.72 \times \sqrt[3]{\frac{80{,}000 + \sqrt{100{,}000^2 + 80{,}000^2}}{10{,}000}} = 4.735 \text{ inches.}$$

which shows the labor saved by a convenient table. One trouble with tables is the interpretation for intermediate values. A diagram or chart is much better in this respect, and if drawn to a convenient scale should be preferable. In Fig. 8 is illustrated a graphical method of plotting a curve which will represent all the various combinations of torsional and bending moments that a shaft of given diameter and given fiber stress can withstand. The method is as follows:

Let D = diameter of a shaft, and t_m = fiber stress. Then the torsional moment the shaft can withstand $= t_m \frac{\pi D^3}{16}$. Calculate this value for any particular size of shaft and lay it off on the scale of torsional moments, as OA in Fig. 8. The location of the point A on the scale then represents the torsional moment the shaft can sustain. The bending moment the shaft can withstand is $t_m \frac{\pi D^3}{32}$, or one-half the torsional moment. Consequently, to find a point C on the scale of bending moments, which by its location will represent the bending moment the shaft can withstand, take O as a center and, with a radius equal to OA, describe an arc AB, intersecting the scale of bending moments at B. Bisect the line OB, thus locating the point C. The points A and C are now the two limits of the desired curve. To locate any intermediate point, as E, where the curve cuts any line, as DG, take a radius equal to DB, and with O as a center describe an arc, cutting the line DG at E. To show that E is a point in a curve which satisfies the conditions of the problem, equate the torsional resisting moment with the ideal moment as given by formula (36), which results in the expression,

$$t_m \frac{\pi D^3}{16} = M_b + \sqrt{M_b^2 + M_t^2} \qquad (38)$$

Now, in the location of this point, $OD = M_b$, and $DE = M_t$, then $OE = \sqrt{M_b^2 + M_t^2}$, and $OD + OE = M_b + \sqrt{M_b^2 + M_t^2}$. By construction, $OA = OB = t_m \frac{\pi D^3}{16}$; also, by construction, $OE = DB$; then $OD + OE = OD + DB = OB = t_m \frac{\pi L^3}{16} = M_b + \sqrt{M_b^2 + M_t^2}$, or location of point E satisfies equation (38), which shows the method of construction to be correct.

Having the method of locating points on the curve, we have only to locate a number of such points and then draw the curve. A diagram constructed in this manner will, however, make the length of sheet double its width, which is not a desirable proportion. To overcome this difficulty, the curves of diagrams, Figs. 10, 11, 12, and 13, were first plotted as illustrated by Fig 8. Then a new scale for torsional moments was constructed three-fourths the length of the original one, as illustrated by Fig. 9. Points where the curve intersected an ordinate on the original scale were then projected onto the equivalent ordinate of the new scale, resulting in the curve as shown by the dotted line CF.

* * *

A very satisfactory steam-pipe covering consists of a wrapping of asbestos, followed by a layer of excelsior and, over all, a piece of canvas fastened down with wire. The canvas may be painted to insure greater longevity.—*Valve World.*

* * *

On a trip made the latter part of May, the *Mauretania* had the misfortune to break one of her propeller blades. Upon her return to Liverpool the propeller was stripped, but lack of time prevented replacing it, and she made another crossing with three propellers. The absence of the propeller seemed, if anything, an advantage, and according to veracious (?) newspaper report, it is proposed to use only three propellers hereafter, instead of four.

* * *

Casein cement consists of casein and tannate of lime. A solution of tannin is first prepared, either by dissolving tannin in water or boiling Chinese gall-nuts in water and straining the fluid. Clear lime is gradually added to this solution till precipitation ceases and red litmus paper, dipped in the fluid, is colored blue. The fluid is then decanted and the precipitate dried. The dried product designated chemically tannate of lime, is then mixed with casein and the mixture ground and sifted. The proportion in which the ingredients are mixed depends upon the purpose to which the mixture is to be applied; as a rule, 90 parts of casein and 10 of tannate of lime are taken. When required for use, a sufficient quantity of water is added to the cement. A tenacious binding material of the requisite consistency is thus obtained. When completely dry the cement is very hard and tough, and absolutely insoluble in water, petroleum, or oil; consequently it is admirably adapted for a large variety of purposes.—*Scientific American.*

EVENING SCHOOL OF TRADES—RINDGE MANUAL TRAINING SCHOOL, CAMBRIDGE, MASS.

E. R. MARKHAM.*

When one has been engaged for some time in a certain work, and has seen many cases where those with whom he has associated in the work have been directly benefited, he naturally becomes very much interested therein. Eight years ago, while superintendent of a shop building machinery, I was asked to take charge of the machine shop in an evening school. I accepted the charge, and have been identified with such work ever since. Our school—The Rindge Manual Training School, Cambridge, Mass.—is open three evenings a week for 21 weeks each year to men who are anxious to learn certain branches of shop work which their experience has not given them an opportunity to learn. In our shop building there are classes in blacksmithing, pattern-making and machine-shop work, each under the supervision of an instructor who has worked for years at the particular trade he is teaching.

to the school by those who have been with us for a year, or a number of years, and that many who had several years shop experience ask us to start them off with preliminary work, in order that they may become thoroughly familiar with the principles that underlie a successful knowledge of the business.

We have had in our evening school a number of first-class tool makers, die-makers, and others, who ranked high in the particular branches in which they were employed. These men came to us to learn some particular thing in which they knew themselves weak. I have in mind two men who were excellent workmen, both tool-makers, who had been engaged for a number of years on punch press die work; they were anxious to learn to harden dies and punches; both men spent two terms with us, and on a number of occasions have said that the time in the school was well spent.

Scope and Nature of Instruction.

As previously stated, we intend to adapt the work to the man, and thus try to help him to improve his condition. To accomplish this, we have classes in mathematics in connection

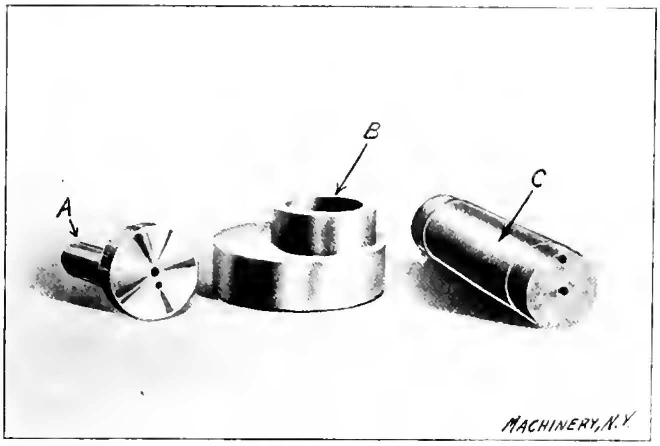


Fig. 1. Work done in Trade School—Examples of Shrink Fits and Eccentric Turning.

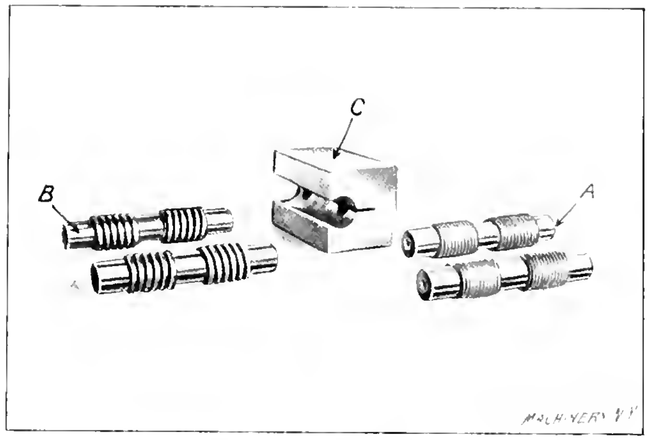

Fig. 2. First Threading Jobs.

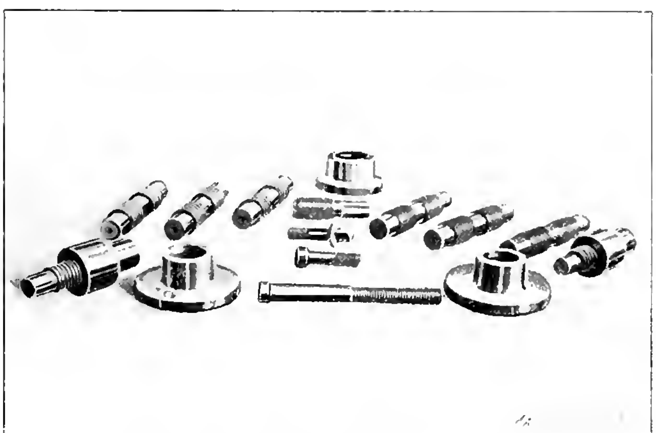

Fig. 3. Face-plates, and Additional Threading Jobs.

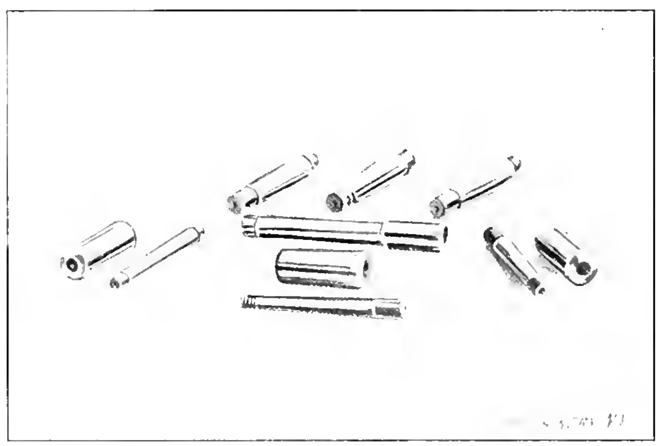

Fig. 4. Examples of Taper Turning.

As I am engaged in teaching machine-shop work, I will confine myself to the work done in that particular department. I would say, however, that the patterns for such parts of our work as are made from cast iron are made by the men in the pattern-shop, and all forgings, both of machine parts and cutting tools, are made in our forge shop.

The Purpose of the Evening Courses.

The applicants for admission to our evening courses must be engaged in the daytime in the same, or similar, lines of work. We have lathe hands who have been running lathes for years, doing straight turning, who are anxious to learn to turn tapers, to cut screw threads, or to lay off work and locate it on the face-plate of the lathe, for machining some portion or for drilling and boring. In fact, we intend making each case an individual case, and give the man just what he needs. Many times we are able to help the man in deciding just what will be for his best interest. We find, as time goes on, that new men come to us who have been induced to come

* Address: 7 Greenough St., Cambridge, Mass.

with our shop work. In the mathematical work our men are divided into three classes, the elementary, the intermediate, and the advanced class. Each class meets one evening each week in the class room, the other two evenings are spent in the shop. The instruction given is all of a practical nature. The elementary class is composed of those men who have had very little training in arithmetic, and includes the simple principles of arithmetic, common fractions, ratio and proportion, and decimal fractions. The problems are all practical shop problems. We find the men greatly interested in the work, and they make remarkable progress.

The intermediate class, after a hasty review of the things given the elementary class, commence with ratio and proportion. They are given problems in figuring change gears of lathes for screw cutting, and similar work. Then follows mensuration of surfaces, such as finding the area of circles, rectangles, triangles, hexagons, octagons, etc.; then the finding of the cubical contents of bars of various sections; then the weight of such bars, if made of wrought iron, cast iron,

steel, lead, or various alloys. This instruction is continued until the men are able to compute the weight of bars of various sizes, shapes and lengths. The student measures a bar, figures out the weight, and then weighs the bar to verify his figures. After sufficient ground has been covered, the class is given general shop problems and formulas that pertain to shop work.

The advanced class commences with weights of materials, problems in belting and gearing, and such problems and formulas as enter into ordinary shop work. The men take great interest in shop mathematics, and several have asked to be allowed to spend two evenings a week in the class room. The majority ask for extra problems to take home and work out between times. In fact, we have been very pleasantly surprised at the interest the men manifest in this branch of the work.

Instruction in Shop Work.

In the shop we have no set order of procedure. The man is given such work as seems best adapted to his particular needs. However, men who are not familiar with lathe work, or those who manifest a desire to commence at the beginning, are given the same exercise as we give the boys in our day school, as we have found by experience that greater progress is made, with a minimum waste of stock, if the elementary principles are taught by the use of exercises which involve these principles. In general, I am not an advocate of exercises, and do not use them in my day school, except to teach the elementary principles, as stated above.

The first exercise is turning a cylindrical piece of cast iron. The pupil centers it according to instructions given, squares

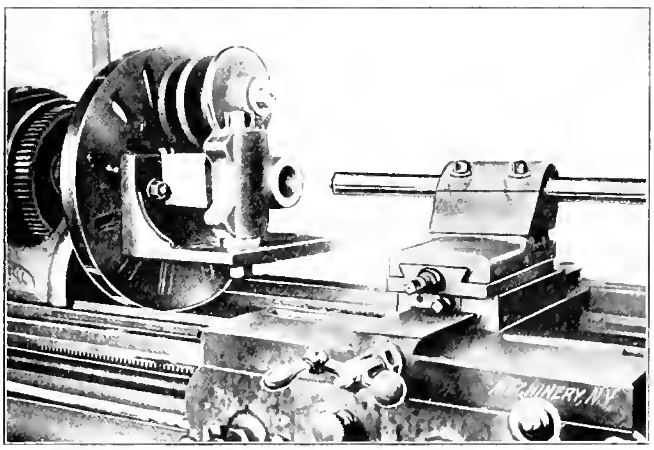

Fig. 5. Boring Job.

the ends in the usual manner, then turns it to a given size, gaging the size by means of spring calipers set to a scale. He is taught how to use the calipers to get a definite size. The lathe is then set to turn a given taper; this is done by setting over the tail-stock. No fit is attempted on this piece. The small end is turned to a specified diameter.

The second exercise is making a lathe center. The pupil is taught to compute the amount he must set over the tail-stock center to produce a taper that will fit a given lathe spindle; he measures a center that fits the spindle hole, finds how much it tapers in a given length, and then finds, by proportion, how much the tail-stock must be set over to produce the same taper on the piece he is to turn. He turns, tries, and fits it in the usual manner. When the taper is turned to a fit, and so it enters the spindle hole the proper distance, it is inserted in the hole, and the end is pointed by setting the compound rest at the proper angle, thus producing the desired angle on the point.

The third exercise is making a shrink fit. The completed piece appears as shown at *A*, Fig. 1. A disk is placed in the lathe chuck so that a center punch mark which is $\frac{3}{8}$ inch from the true center of the disk will run true. A hole is drilled and then bored from 0.003 to 0.005 inch less than $\frac{7}{8}$ inch, and then reamed with a $\frac{7}{8}$-inch hand reamer. The gaging of this hole is done with a pair of inside spring calipers set to a micrometer. After reaming, the hole is measured, and the end of the cylindrical piece is turned 0.003 inch *larger* than the hole. The disk is then heated and shrunk onto it. The sides of the disk are faced parallel, and eccentric centers ($\frac{3}{8}$ inch eccentricity) are drilled in each end. The disk is then turned on the eccentric centers. We consider this a valuable exercise, as it enables us to teach several things. At first, it is not wise to try to teach more than one step at a time, and on this piece but one step is taken at a time, but successive steps bring out several different points.

After completing the shrink-fit exercise, a threading job is taken up. A cylindrical piece of cast iron is turned and threaded as shown at *A*, Fig. 2. A right-hand thread is cut at one end, and a left-hand at the other, as shown. No at-

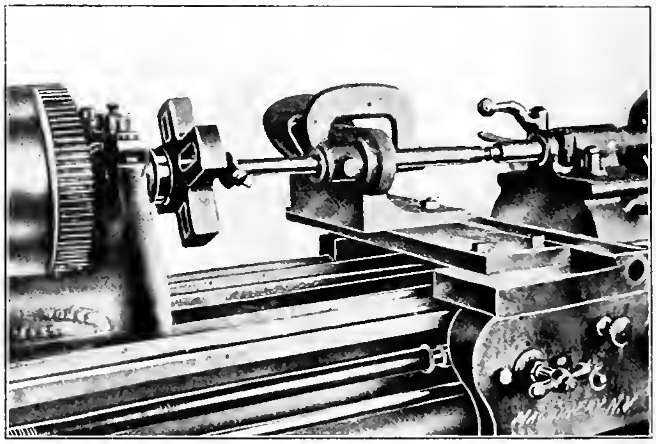

Fig. 6. Using the Boring-bar.

tempt is made to fit this to a nut, as experience has taught us that new processes are the more readily grasped when the beginner has but one thing in his mind at a time. He next cuts a right- and left-hand square thread, as shown at *B*, Fig. 2.

After these two preliminary pieces of work are completed, a face-plate is made. The face-plate is made to fit the spindle of one of the wood-turning lathes used in the pattern-shop. The hole is drilled and bored, and the thread cut with an internal threading tool until a tap of the proper size will just enter. The three end threads are recessed out. The face-plate is then taken from the chuck and the thread finished by the tap. After this operation it is placed on a threaded mandrel and turned to final dimensions. In Fig. 3 two of the face-plates are shown in the foreground, while at the back of the table is shown a chuck back. In the case of a man wanting to get an added experience in internal threading, he is allowed to make one or more chuck backs after he has completed the face-plate. Some of the men are anxious to devote considerable time to screw cutting. To these we give the job

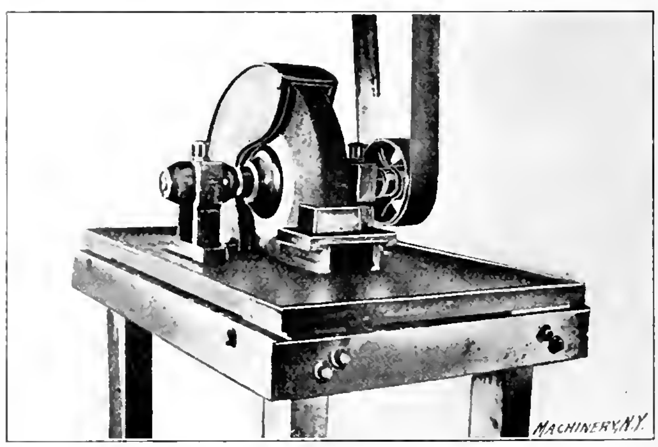

Fig. 7. Tool Grinder built in the Trade School Shops.

of making various forms of screws and threaded mandrels, as shown in Fig. 3. We are constantly reminding them of the necessity of keeping their lathe centers in proper condition, in order that the various portions of a piece shall be concentric.

Fig. 4 shows three tapered sleeves with taper holes, a drill collet, and several tapered mandrels. These mandrels have hardened ends and soft bearing portions. The ends are hardened, and the tapered portion turned afterward. After making one or more of the tapered pieces shown, the men are

given such work as will be to their advantage. We have found that it is wise for us to build machines, provided we do not "bite off more than we can chew." We do not consider it advisable to build anything that would necessitate our keeping our machines tied up for a number of weeks on one piece. It is necessary to bear in mind the fact that our men are with us but three evenings a week, and but two hours each evening.

The various parts of the different machines being built furnish a variety of work that enables us to select jobs adapted to the various men. Fig. 5 shows a job of boring, the piece being held on an angle-iron. The hole at right angles to the one being machined was bored and reamed first, the piece being held in a lathe chuck. The piece was then placed on a stud on the angle-iron as shown, and the hole bored to size.

Fig. 6 shows a boring-bar job. It was necessary to make a number of tool rests for our wood-turning lathes. The bottoms of the rests were planed. The rests were then clamped to the angle iron as shown, and the holes bored to size.

Fig. 7 shows a tool grinder built in the shop. As it was necessary to use this before the pattern for the base was completed, it was mounted on a wooden frame. We have several of these grinders under way.

Fig. 8 is a combined surface grinder and tool grinder. The knee supporting the tilting table is adjustable up and down by means of the hand-wheel shown. We have two more grinders similar to the one shown, under way. At either end of the driving pulley are hardened collars to take the end wear. One of these is threaded into the pulley, and is adjustable to compensate for wear. The grinder shown has cast iron spindle bearings, while the two being built have babbitted bearings. The babbitt is poured around a mandrel considerably smaller than the finished size of the bearings. It is then hammered and bored and reamed to size. The spindle bearings are all draw filed to fit.

We are building two small friction-driven sensitive drill presses. As we have no boring machine, we are obliged to use a lathe, or drill-press, for work that is done with a boring-bar. As we have no lathe large enough to bore the base to receive the column, we found it necessary to use the upright drill for the job, as shown in Fig. 9. In the center of the table is a bushing to receive the boring-bar. The bushing has a key which enters the keyway in the bar, shown in Fig. 10. The bushing then, of course, revolves with the bar. The table of the drill-press we make is bored to receive the column by means of a boring-bar in a lathe, as shown in Fig. 11. The table is held on an angle-iron, as shown.

The head is bored to receive the column, as shown in Fig. 12, the head being held on an improvised jig. The cutter is held in a device which screws on the nose of the spindle. Both jig and cutting tool were made by the students in the evening school. When getting ready to bore the hole in the head, it is, of course, necessary to locate the head on the lathe, so that the spindle holes are in exact alignment with the axis of the lathe, in order to insure the spindle standing at right angles to the table when the drill press is assembled.

While we would welcome a horizontal boring machine as a part of our equipment, I am inclined to think that the use of a machine for purposes other than it was originally designed for gives the men a certain knowledge that may be of value to them when they find themselves confronted with a special job and no machine at hand especially adapted to it. When we do a piece of work in a manner different from that ordinarily pursued in a shop, the usual method is fully explained, in order that the man may know how to go to work when the proper machine is at hand, and also how to improvise a method for doing it, if necessary. When it is necessary to have any special fixtures or cutting tools—except gear-cutters—we make them, either in the evening school or in our day school.

By the way, we read at times in our mechanical journals articles regarding manual training schools that would lead one to think that little of practical value is taught in them. I do not claim to know much about such schools in general, but I do know what our boys get. Their work is exactly parallel to that given the men in the evening school. They build machines, special holding and cutting tools, repair the machines in our different shops, and, in fact, the work is as nearly parallel to actual shop work as we can make it.

Fig. 13 shows a number of the small parts of a press, other parts not being far enough along to photograph. We make it a point not to let anything go into the machines we are building that is not as nearly correct as would be found in the ordinary commercial article of the same type, but do not claim that as large a proportion of the pieces made pass inspection, as would be the case in a manufacturing establishment. Fig. 13 also shows two punch press blanking dies. The one at the left is for producing a blank, and the other receives a punch used in trimming the edge of the sheet.

Fig. 14 shows a two-jaw chuck for use on a large pattern-maker's lathe. The jaws are operated by means of the right- and left-hand screw shown. This chuck is about 15 inches in diameter.

In Fig. 1, at *B*, is shown an eccentric, and the eccentric mandrel *C* used in turning it. A large variety of eccentric work not shown in any of the photographs has been done. The individual pieces are designed to give some pupil the special training needed in his particular line of work.

At *C*, Fig. 2, is shown a fixture used in holding a sleeve that acts as a rack for moving the spindle of the drill press up and down, in the operation of drilling. The sleeve has rack teeth cut along one side to receive the small pinion shown

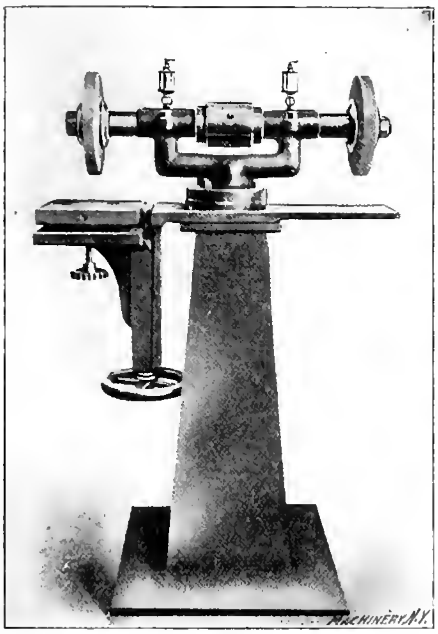

Fig. 8. Combined Surface and Tool Grinder built in the School Shops.

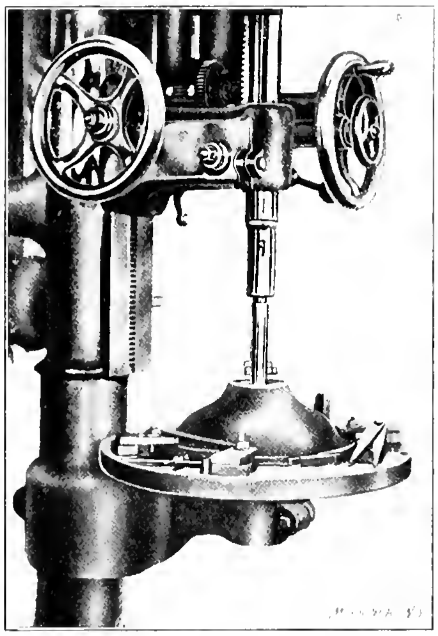

Fig. 9. Boring Small Drill Press Base.

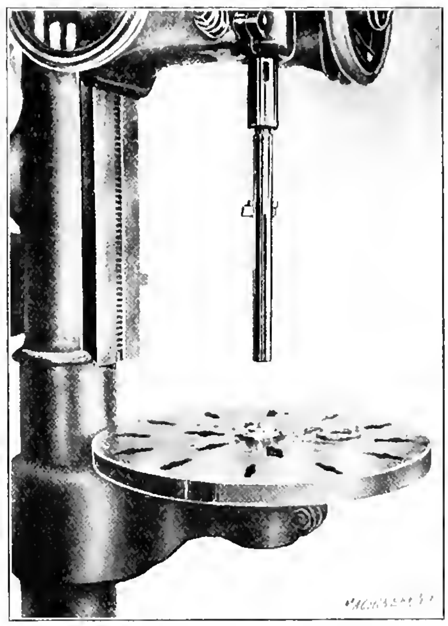

Fig. 10. Method of Guiding the Boring-bar while boring Drill Press Base.

in Fig. 13, by means of which it is raised and lowered. The opening to receive the sleeve was drilled, bored, and reamed to size, the piece being held on an angle-iron attached to the face-plate of a lathe. It was then placed on a special mandrel, having a straight holding portion, the ends of which were of exactly the same size. These ends were supported in V-blocks on the planer, and the bottom planed with a tongue as shown. This tongue fits one of the cross slots of our milling machine tables. By the use of this fixture the rack teeth are milled at right angles to the axis of the sleeve.

In cases where special fixtures are not absolutely necessary, they are still sometimes made, and the advisability of their use is explained to the men. When it is not necessary to make them, the advantage of their use in shops where many pieces of a kind are made, is explained to them. The men attending our evening school have shown a remarkable interest in the work. The attendance has been very gratifying. Quite a number have been able to materially better themselves since attending the school; some have had an increase in pay, because they were able to do a class of work that demanded higher wages; others have obtained better positions on account of increased knowledge. A little incident, extremely gratifying to those in charge, came to our attention a little while ago. In a certain shop it was necessary to cut a fractional thread on a piece of work. The gear plate did not show gears for this thread. Several of the men were asked to "figure out" the gears; but as the lathe was of compound gear construction none of those asked were able to do it. Finally one of the men as a joke said: "Get 'Jerry' to tell you what gears are needed." "Jerry" is an apprentice in the shop, and attends our evening school. "Jerry" was consulted, and was able to tell them the proper gears to use. He says that he would not have been able to "figure the gears" but for the knowledge gained in the school.

Each man attending the evening school is given a set of notes. These notes are written or compiled by the instructor. They are then typewritten and mimeographed at the office of the "Massachusetts Commission on Industrial Education," under whose supervision the school is run. The past year has been the first that we have given the notes in the form mentioned; before this they have been given in the lectures, the men taking such notes as they saw fit. By the present system much valuable time is saved, and the men have the notes in note-book covers. Each year we propose adding to them, and think that in a few years they will make a text-book that will be of value to the men.

We do not think our course is perfect and we are constantly endeavoring to improve it; but we have the satisfaction of knowing that some of the men have been materially benefited by attending the school.

* * *

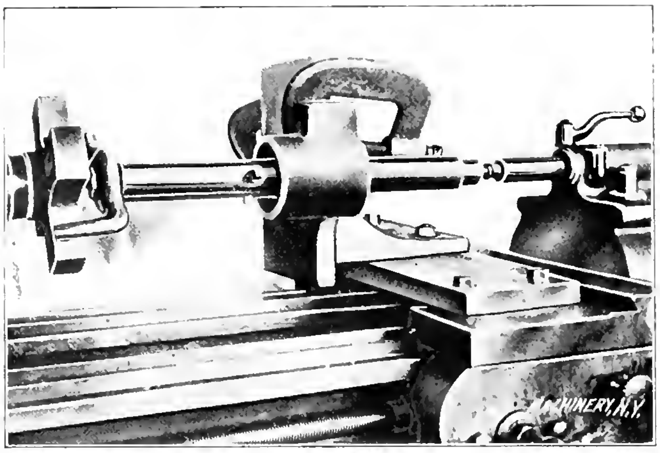

Fig. 11. Boring Column Hole in Drill Press Table.

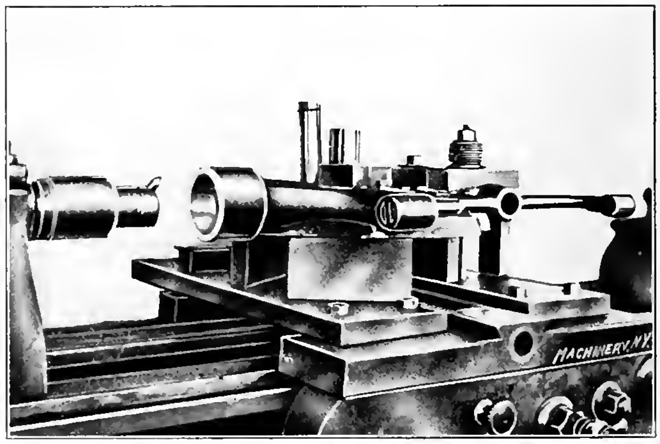

Fig. 12. Boring Hole in Head to receive Column.

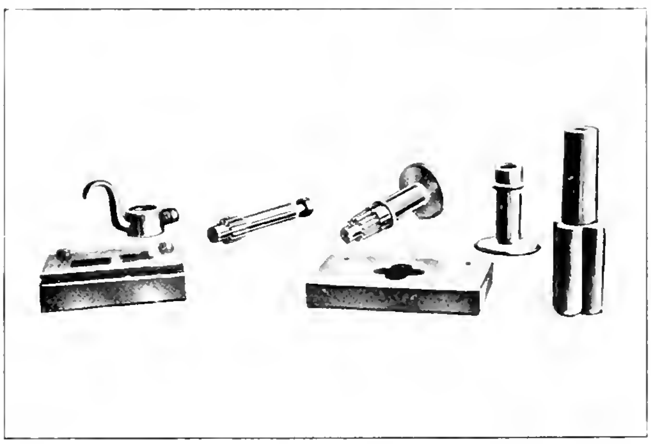

Fig. 13. Examples of Punch and Die Work, and Miscellaneous Jobs done in the Trade School

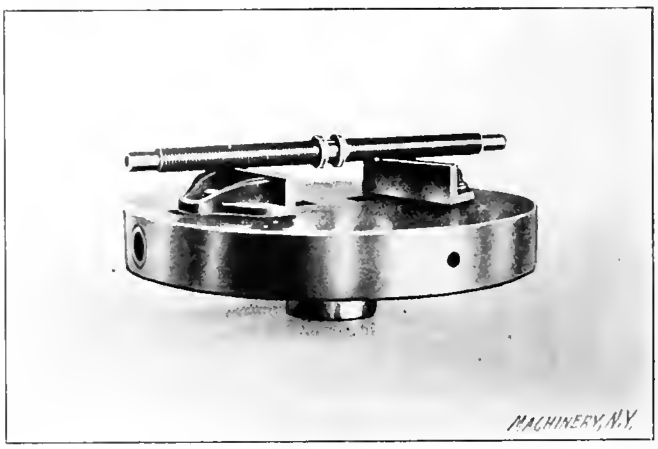

Fig. 14 A Two-jaw Chuck Completed in the Evening School.

It seems that the April fool joke in the technical journal mentioned in the May issue of MACHINERY was one on the inventor of the device as well as on the readers of the paper. Instead of being the inoperative apparatus the picture and description shows, the construction is really practical and unusually ingenious. The connecting tube is made of flexible armor construction with a waterproof cover which automatically collapses under the pressure of the water until its weight per volume is equal to that of the water which it displaces. When it is collapsed to this extent, it is in equilibrium and floats in water, and it attains this equilibrium automatically. The sleeves through which the work is done are not of loose flexible material, as would be surmised from the printed description, but are of metallic construction self-sustaining because of the lateral pressure to which they are subjected. This apparatus has been built by the Williamson Submarine Mfg. & Operating Co., Newport News, Va., and used in 30 feet of water, and has been employed in actual salvage work. Of all this, however, not a word was said in the paper to which reference was made.

* * *

The battleship *Georgia* of the Atlantic battleship fleet holds the world's championship record for rapid coaling. Several days ago she took aboard 1,779 tons of coal in five hours and twelve minutes. The best former coaling record was made by the German war vessel *York*, which took on 468 tons in one hour and 870 tons in two hours.

LETTERS UPON PRACTICAL SUBJECTS.

MILLING AND DRILLING FIXTURES FOR OFFSET ROD.

In Fig. 1 is shown a slender connecting-rod which is a part of a complicated machine. One end of this rod is 3/16 inch lower than the other, and it is necessary that the 5/32-inch holes should be parallel with each other. Should either one be reamed on an angle, there being such a long distance between the holes, it would destroy the free movement which is required. Several methods were tried in drilling the holes and milling the faces of the bosses, but none gave satisfaction until the fixture and jig shown in Figs. 2 and 3 were made.

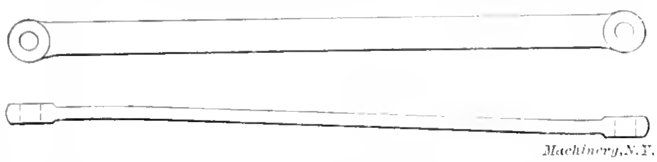

Fig. 1. Offset Connecting-rod which is milled and drilled in the Fixtures.

In Fig. 2 is shown a plan and elevation of the fixture used for milling the ends of the rod. The sides of the rod on each end are sized in one cut by a gang cutter, and the fixture is so designed that when one end of the rod is finished the other can be brought facing the cutter and yet have the required offset. The fixture consists of a cast iron body *A* with an attached part *B* which swivels about the bolt *G*. The lugs *C* on part *B* engage the slots *D* when *B* is turned one-half revolution, thus giving the rod, which is bolted to the hardened pieces *F* by the clamps *E*, the 3/16-inch offset. In setting the rod, it is passed under the clamps *E*, and against

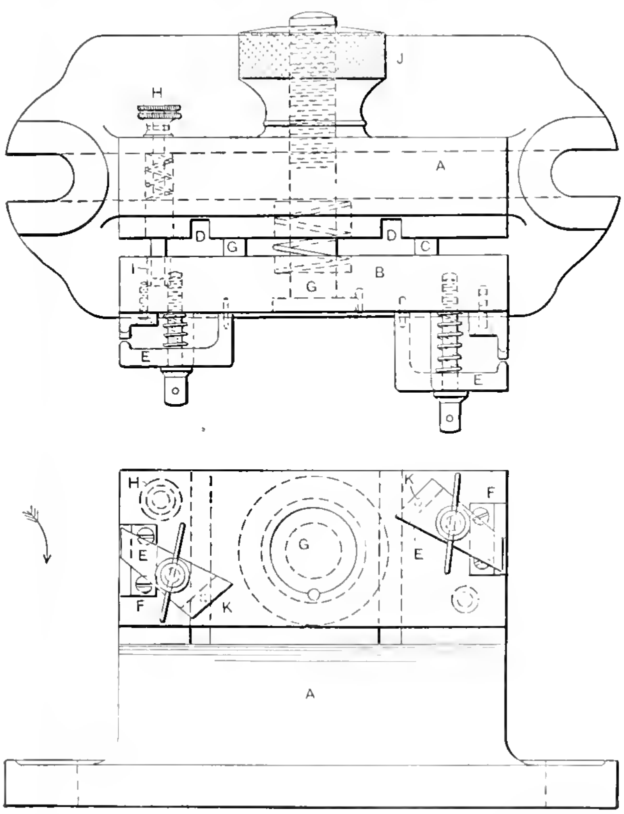

Fig. 2. Fixture for Holding the Rod while the Bosses are being milled

the stops *F*. The bearing points of both the clamps and stops are rounded off and made small, and directly opposite each other. This eliminates all possibility of the piece tipping when being clamped. As the cutter runs in the direction shown by the arrow, it has a tendency to hold the rod against the shoulders on the parts *F*. Consequently no heavy clamps are required. The lugs *C* and slots *D* are off center so that when the high side of the rod has been milled, the stud *G* is loosened and *B* is swung around bringing the opposite side to the cutters, and lugs *C* outside of the slots *D*, thereby raising the opposite end of the rod 3/16 of an inch and bringing it in line with the cutters. *H* is a locating stud which engages with the hardened bushing *I*, bringing *B* in position for the second operation. The part *B* with the work is held firmly by screwing up the nut *J*. Two small pins *K* prevent the clamps *E* from swinging around when not in use.

The drilling jig is shown in Fig. 3. The steel body *A* has a V-piece at each end, and under each of these there is a hardened base, having a 3/16 inch difference in their heights. The V-piece *B* is screwed down solidly, while *C* is movable, sliding on ways. There is a small pin *D* extending down into the body *A*, against which presses a small spring. The two clamps *F* swing around and engage the heads of screws *H*. When setting the rod in the jig, preparatory to drilling, one end is placed in the V-block *C* which is forced

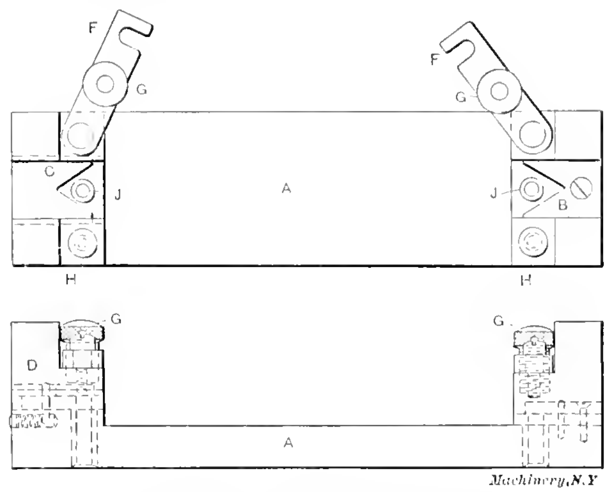

Fig. 3. Jig for Drilling the Ends of the Rod.

back until the other end of the rod drops into place. As the block *C* has a pressure on it, it keeps the rod located centrally. The clamps are then swung around under the heads of screws *H*, and the binding screws *G* are brought down on the milled surfaces of the rods, holding them securely while they are being drilled. These screws have clearance holes through them, and at *J* are the bushings in which are placed the drill and reamer bushings.

PEDRO.

IMPROVED DRIVING PLATE FOR THE MILLING MACHINE.

Everyone who is familiar with milling machine work knows how annoying it is to have the set-screw in the driving plate of the index head just miss the tail of the dog placed on the work, or, what is nearly as bad, strike it on the rounded part, so that when the screw is tightened it is apt to spring the

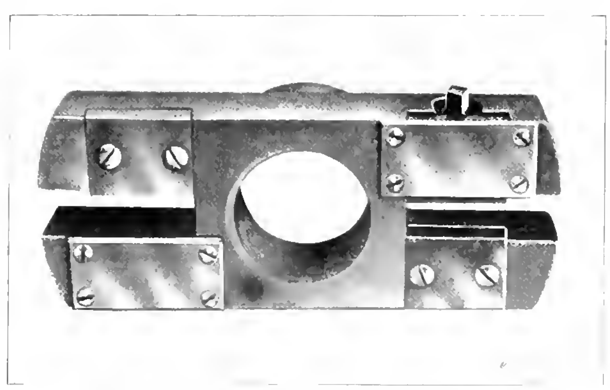

Fig. 1. Improved Form of Driving Plate for the Milling Machine

arbor, if it be a light one. In our shop the work necessitates several different sizes of dogs, and in order to remedy the trouble caused by location of the set-screws, the device illustrated in the accompanying halftones, Figs. 1 and 2, was made and applied to the plate as shown. This improvement was introduced about three years ago, and has been in satisfactory use ever since

In Fig. 1 the plate is shown exactly as it appears on the machine, while Fig. 2 shows the general construction of the device, which consists of four separate parts and six screws for each end. The stationary jaw is shown at *E*. This is made of hardened tool steel, and sunk into the cast iron plate, being held by two screws as shown. At *F* is shown an end view of the corresponding jaw which sets into the other end of the plate, and at *A* is shown the movable jaw, turned

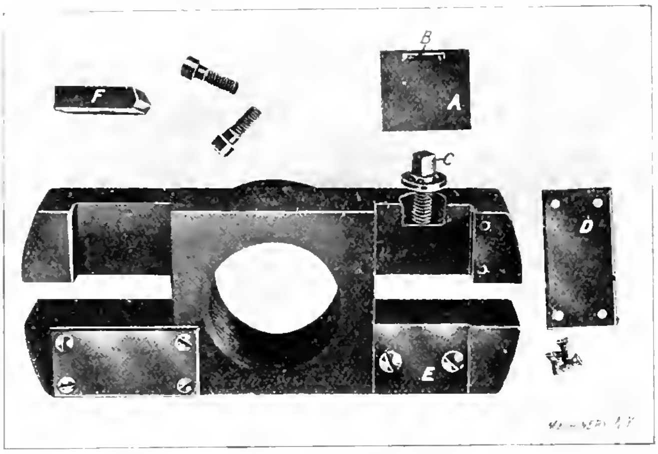

Fig. 2. Component Parts of the Driving Plate.

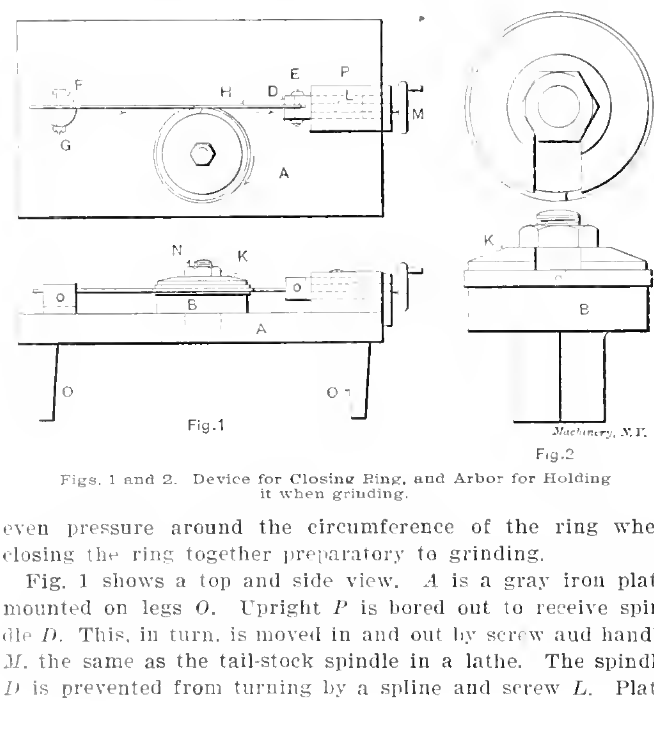
so as to shew the slot *B* into which the shoulder of the adjusting screw *C* fits. The inside edges of both jaws are planed to an angle of 90 degrees, similar to the face of a chuck jaw. The movable jaw is also made of tool steel and hardened, and the screw *C* is made of machine steel and case-hardened. The plate *D*, finally, is used to hold the movable jaw in place, and is made of machine steel.

The writer has wondered why the milling machine manufacturers have not introduced something similar to this, as a driving plate constructed in this manner is far superior to one provided with set-screws. Of course, this improvement increases the cost somewhat above the ordinary driving plate, but the usefulness and convenience of the device compensate for the extra expense. ETHAN VIALL.

Decatur, Ill.

FIXTURE FOR GRINDING PISTON RINGS.

After experimenting with many different devices for holding piston rings, with unsatisfactory results, we designed the arbor and fixture shown in the engraving, the object being to eliminate egg-shaped rings. All brother craftsmen in the automobile business know that this is a mean proposition. This fixture was built with the intention of producing an



Figs. 1 and 2. Device for Closing Ring, and Arbor for Holding it when grinding.

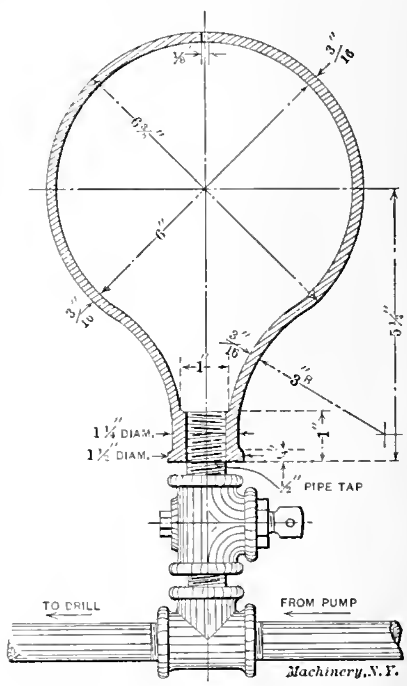
even pressure around the circumference of the ring when closing the ring together preparatory to grinding.

Fig. 1 shows a top and side view. *A* is a gray iron plate mounted on legs *O*. Upright *P* is bored out to receive spindle *D*. This, in turn, is moved in and out by screw and handle *M*, the same as the tail-stock spindle in a lathe. The spindle *D* is prevented from turning by a spline and screw *L*. Plate or base *A* has a square hole for arbor *B* to fit in. Stud *F* and end of spindle *D* are split to receive wire *H*, this being gripped tightly by drawing up bolts *E* and *G*. In operation, arbor *B* is placed in the square hole in *A*, a ring is put in place, the soft copper wire *H* is gripped in stud *F* and passed around the outside of the ring in the direction of arrows shown, and gripped again in the end of spindle *D* by bolt *E*. The wire *H* is tightened by the screw and handle *M*, thus drawing the ends of the ring together. The split collar *K* is put in place, then nut *N* is screwed against it, holding the ring firmly in a closed position. Now the wire *H* is released, and arbor *B* with ring in place is ready for the grinding operation. The face-plate of the grinder has a plate with a square hole that acts as a dog or driver for the arbor. Fig. 2 shows the arbor and work together. The body of the arbor, of course, is turned eccentric to suit the ring, and there is a mark to locate the ring in the proper position. This fixture produced rings that were round after grinding, the point being that the soft copper wire caused an even pressure all around the ring in closing it. E. W. NORTON.

North Tarrytown, N. Y.

RESERVE CHAMBER FOR PRIMING PUMPS.

The accompanying engraving shows a reserve chamber for pumping systems connected with drill presses, milling machines, automatics, etc., where individual pumps are used for oil or compounds of any kind. We found, in our drill press department, that whenever the drills stood still for a while, the pumps had to be primed before starting again, and by the way, some of the workmen were spending quite a large share of their time priming their pumps. To overcome this, we have put in use a reserve chamber which is used for priming. This chamber is placed in the pipe line between the pump and the point of discharge. The valve leading into the chamber is left open when starting the first time, and the chamber is allowed to fill up. The small hole in the top serves two purposes; it allows the air in the chamber to escape when filling, and also acts as a tell-tale to indicate when the chamber is full. After filling, the valve to the chamber is closed and the chamber is kept full, the compound flowing through the pipes as usual. The pump may be left any length of time now, and started again without the trouble of priming in the old way. The next time the pump is to be started, all that is necessary is to open the valve and allow the compound to fill the pipes. This does away with priming, and is very quickly and easily done. The chamber is now allowed to fill while the driller is drilling his first few holes, the valve is again closed as before, and everything is in readiness for starting the next morning.



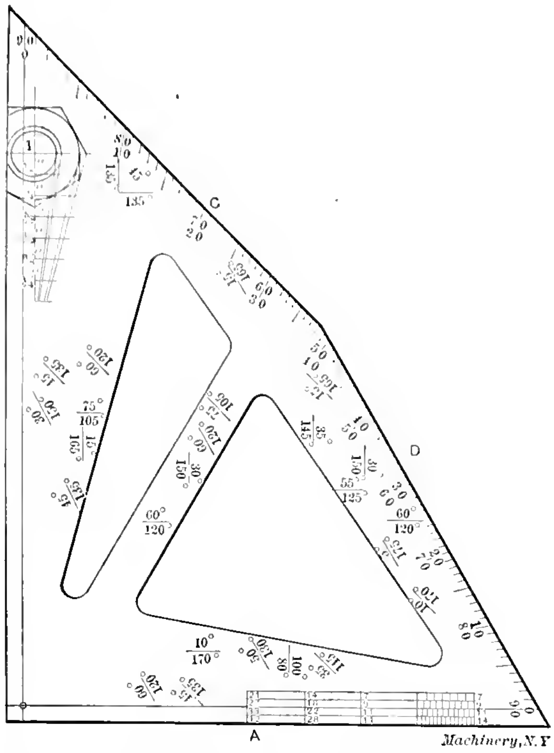
Reserve Chamber for Priming Pumps on Machine Tools.

TOOL DESIGNER.

IMPROVED DRAFTSMAN'S TRIANGLE.

The triangle which is shown in the engraving is one which I have used for a number of years, and I think that this form is an improvement over any which I have seen. One which I made for myself was of 1/16 inch transparent celluloid, with a vertical side 12¾ inches long; of course, the size could be such as would be most convenient. It will be

noticed that this is really a 60-degree triangle with the top cut to form an angle of 45 degrees with one side, while the inside is cut out to give various angles. In the top corner a one-inch nut is laid out, and the scale gives the sizes of tapping holes, sizes across corners and flats for nuts from ¼ to 1 inch in diameter. In the bottom corner there are scales with odd divisions not found on the ordinary scale. These could, of course, be varied, and others added if necessary. This



Draftsman's Protractor and Triangle.

triangle is also a large protractor which can be used for all angles up to 90 degrees by working from the small hole in the lower left-hand corner and the graduations along the edge. The figures shown with lines between indicate the angle of that particular edge to the T-square when that outer edge of the triangle which is parallel with the line is against the T-square. The accompanying table shows the large number of angles which can be obtained directly by placing the sides *A*, *B*, *C* and *D* against the T-square. It will be seen that there is a 45-degree side for all four positions, and a 30- and 60-degree side for two and three positions of the triangle, respectively, in addition to the various angles given in the table.

TRICKY FOUNDRY PRACTICE.

A friend of mine having made a complete set of patterns for a bench lathe (18-inch bed, 4-inch swing) and built a first-class, serviceable machine with lead-screw and gears complete to cut any standard thread, I decided that I would like a similar machine, so I borrowed the patterns and took them to the nearest foundry and ordered a set of castings to be made. I attended to this business through the office, and was told to call for the castings in three or four days. However, as I was impatient to begin work upon the little lathe, I went around the second morning about eight o'clock and went directly into the foundry where the molders were getting ready for the day's work, and the helpers were cleaning castings. As the foreman was not on the floor at the moment, I inquired among the men until I found the molder who was working with my patterns. He informed me that they had *only got one of the lathe beds out, but had two sets of head- and tail-stocks and carriage pieces*. I asked him how many he had been told to make and he replied, "Three sets." I said I guessed one set would do me, and, gathering up the patterns, I took them out and put them in the rig I had brought, and then went back for the coreboxes, which I soon found and also deposited with the patterns. Next I hunted up the foundry foreman and got him to gather all the castings that had been made from the patterns and weigh them. He was surprised that I should order three sets and then go with only about one and a half. However, he went up to the office to get the bill while I put the castings into the rig.

I judged by the look on his face that all the surprise at my action had died away through certain things he had learned in the office, but I did not make any remarks, and paying the amount due, I drove off. The question involved is whether the proprietors of a foundry have any right to make castings for their own use from patterns brought to them by customers. Personally I think not, unless by permission. W. L. McL.

EFFICIENCY OF AUTOMOBILE TRANSMISSION.

We noticed in the June issue of Machinery a report of a test made by the H. H. Franklin Co., Syracuse, N. Y., in which the loss in transmission between the motor and the rear wheels is given as 6 2/3 per cent with direct drive, and 8½ per cent with intermediate gear, giving a mechanical efficiency of 93½ and 91½ per cent, respectively. While this test shows that the transmission of the car is very efficient, it is probable that the tire losses were not considered. If they were, the efficiency would be considerably lower.

As to the statement that the mechanical efficiency of automobiles, in general, is rated at 75 per cent, the test made on the Automobile Club of America's dynamometer shows that many cars develop much less power at the ground than their engine rating, and that, in general, the effective power at the ground is approximately 75 per cent of the nominal engine rating. This statement, however, should not be interpreted to mean that the efficiency of the transmission, including the tires was 75 per cent or less. The power developed by the engine is *not* determined in the Automobile Club of America's dynamometer tests. The fact has caused considerable misunderstanding, especially in the automobile trade, and it should be distinctly understood that the dynamometer does not show the efficiency of the automobile, but only the effective horsepower at the ground, and that the 75 per cent statement refers only to the rated engine power of cars in general.

E. H. Waring.

Ampere, N. J. Crocker-Wheeler Co.

TAPER PER FOOT OF WHITWORTH OR ENGLISH TAPER PIPE TAPS.

In Mr. Charles E. Smart's article in the June issue of Machinery on Whitworth or English taper pipe taps, he states that the dimensions of these taps should be based upon the standard Whitworth pipe tap gages, made in England by the Whitworth Company which have a taper of 1 inch per foot.

If Mr. Smart will refer to paragraph 7, page 6 of the "Report on British Standard Pipe Threads for Iron or Steel Pipe and Tubes," of April, 1905, issued by the Engineering Standards Committee, he will find the taper of Whitworth pipe is equal to ¾ inch per foot. Before this report was issued, it was the custom to make these taps with a taper of 1 inch per foot.

This information should put an end to any question in regard to the taper per foot of Whitworth pipe taps.

Greenfield, Mass. G. W. Carpenter,

Wells Bros. Company.

NOTES ON HIGH-SPEED PULLEYS.

In looking over some notes the other day I ran across the accompanying sketch and data regarding pulleys, which may prove of interest. These pulleys were designed for fast-running machinery, and finished on both the outer and inner surfaces of the rims, and also on the hubs. The pockets *H*, between the arms, were cored for lead balances, the lead being calked in place as required. The average belt speed was approximately 3,000 feet per minute. The practice of one shop was to place the set-screw on the quarter as shown by the sketch, while that of another was to place it directly over the key. I think the former way the better one as it gives a three-point contact on the shaft, while with the latter method the pulley has but a two-point contact and has a general tendency

to rock and work. The first column in the table gives the approximate horse-power transmitted by each pulley, and the second column the horse-power transmitted per inch width of belt. It will be noted that the power transmitted per inch of width increases with the size of the pulley and the corresponding thickness of belt; a single belt being used on the first three sizes of pulleys, light double on the next three, and heavy double on the last four. The principal dimensions of the pulleys are given by the table. WM. SANGSTER.

Covington, Va.

SHRINKAGE AND EXPANSION OF STEEL IN HARDENING.

When hardening two tools of the same grade of steel and both of the same dimensions, why will one shrink and one expand? This question has been asked many times by

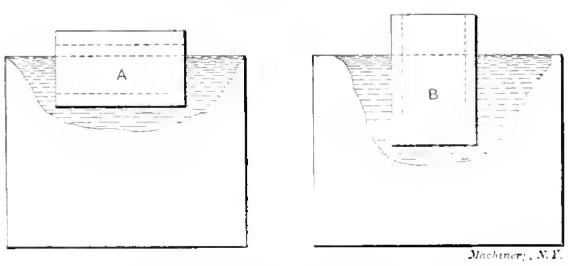

Fig. 1. Methods of Cooling when Hardening, to cause Shrinkage or Expansion.

mechanics. The answer is simply this: they do not receive the same treatment, although the inexperienced hardener is sure that they do. Take, for instance, a couple of small cams, collars, or any pieces at hand, just so they are the same in regard to make and finish, and have the hole in each fit to the same plug gage. Then number them so they will not get mixed in the operation, heat both to the same degree of heat, and dip one as shown at *A*, Fig. 1, and the other as shown at *B*. Put each piece under the water and remove when cold; then try the plug gage. I claim that the piece *A* will not go on, while *B* will fit looser than before heating and dipping.

Not long ago we had a job of shrinking a collar on a shaft that was wanted in a great hurry. When the work arrived in the forge department, the man about to do the shrinking

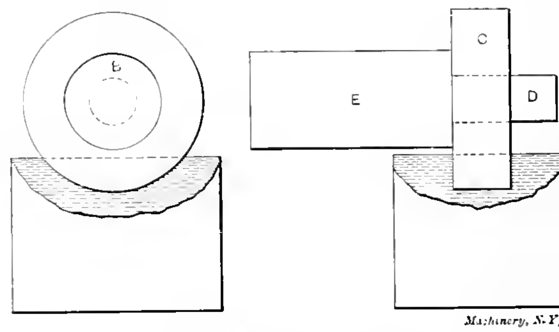

Fig. 2. Method of Shrinking a Collar on a Shaft which is Smaller than the Bore of the Collar.

called my attention to the fact that the collar would already go on the part it was supposed to be shrunk on. Knowing the piece was wanted in a hurry, I told the man to heat the collar *C*, (Fig. 2) to a very low red, and after placing the collar on the end *D* of shaft *E*, to cool it, as shown in the illustration, turning the work rapidly without letting the shaft come in contact with the water, it was impossible to move the collar, when cold, with a good-sized arbor press. Both collar and shaft were machine steel. A great many mechanics have an idea that it is necessary to have the internal piece quite a bit larger than the external piece, but this is not necessary. Of course, if the piece to be shrunk on is large and has a 6- or 8-inch bore, and is of cast iron, it is advisable to leave it 1/64 inch smaller than the internal piece, as cast iron expands more than steel.

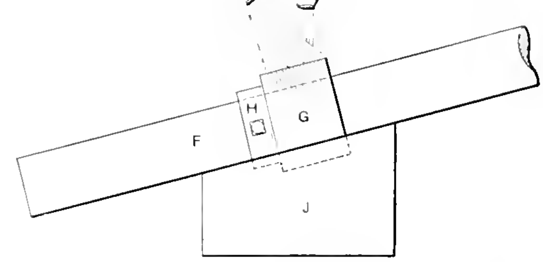

Fig. 3. Arrangement of Cooling Tank when Shrinking Collars on Shafts.

Several years ago I worked for a firm that built saw-mill machinery and tools for repairing all kinds of circular and cross-cut saws. Among the tools was a machine steel shaft about 3 inches in diameter, on which was shrunk a collar of high carbon tool steel. This collar had to be very hard, and after it was shrunk on the shaft, the shaft was turned up and the collar ground. These collars were always bored so as to be shoved on with the hands. In Fig. 3 is shown a shaft *F*, with tool steel collar *G*, and another small collar *H* held by a set-screw. This collar was used to form a shoulder for the tool steel collar *G* to rest against. When shrinking the collar *G* on the shaft, a tank *J* was used, constructed as shown. Another tank having two spouts *K* was arranged above this one. This upper tank was filled with cold salt water and sulphuric acid, there being about one gallon of acid to twenty gallons of water. The collar was heated to about 1,400 degrees F., quickly placed on the shaft in the proper position, and the above solution turned on full force. This chilled the outside of the collar quickly; then the shaft was removed to a tank of oil where it remained until cold. This particular job gave the best of satisfaction.

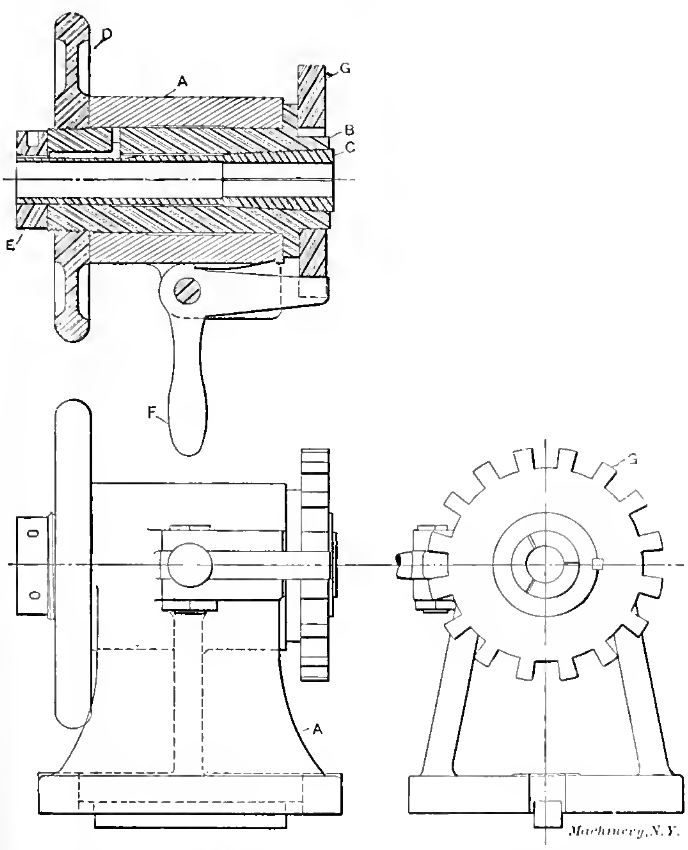
It is very annoying, after making an expensive punch and die, to have them vary in size after hardening. Sometimes

the die will be larger and the punch smaller, rendering them useless. It is a good idea to harden the die first, then leave the punch large enough to grind to fit if it is in such shape as to allow grinding. If a punch is completely cooled in water it will be smaller than if just hardened on the outside enough for the purpose and then removed to oil to relieve itself and cool off slowly. This has been proved to the writer's satisfaction. If the outside of the die is chilled before the inside it will become smaller, but if chilled on the inside before the outside it will be a trifle larger.' It is an easy matter to chill the outside first, but the reverse is not so easy. It can, however, be done by covering the outside with asbestos cement before placing in the furnace for heating. I have had punches and dies of large dimensions delivered to me for tempering, and they were in such shape as to be useless if they came out the same as they were before heating; for instance, if the die was too large for the punch, by using a little care, as explained, I was unable after the hardening to place punch inside of die before grinding. This cannot be accomplished by heating and cooling in a haphazard manner, as so many hardeners are apt to do. J. F. SALLOWS.

Lansing, Mich.

SIMPLE INDEXING DEVICE.

In the engraving is shown a device for holding and indexing a spindle, which has, at the middle, a pinion in which the teeth are to be cut. In the particular case in question, the spindle was $\frac{5}{8}$ inch in diameter, 20 inches long, the pinion being $\frac{1}{8}$ inch in diameter and located 7 inches from one end of the spindle. The spindle was supported by an ordinary center at one end, but the other end was held in the device



Section and Elevations of the Indexing Device.

shown, by a split chuck *C*, which was tightened by the nut *E* at the other end of the head of the device, this nut drawing the chuck through the steel sleeve *B*. This steel sleeve is keyed to an index plate *G*, notched on its circumference as indicated, and located in position by the index pawl *F*. When located, the index plate is clamped by the hand-wheel *D*, the hole of which is threaded as shown. The sleeve *B* when not locked by the hand-wheel *D* is free to revolve in the head casting *A*. When in operation, the spindle having the pinion to be cut is inserted in the chuck *C* and tightened by the nut *E*, the hand-wheel *D* is loosened, and the pawl *F* is moved out of the notch in the index plate *G*, thereby releasing it. By means of the hand-wheel *D*, which has a tight thread, the index plate is turned to the next notch and then the pawl *F* is again permitted to enter the notch, locating the spindle in its proper position for the cutting of the next tooth, the hand-wheel clamping the sleeve with the chuck and spindle in position. This operation is repeated for each tooth cut. A great many of these pinions have been cut by this device, and it has been found very satisfactory, as it is quicker and safer to operate than the regular dividing head for this kind of work. J. B. HASKELL.

Hamilton, Ohio.

HOME-MADE MACHINE FOR BORING LATHE SPINDLES.

The illustration shows a home-made machine, designed and built for boring hollow lathe spindles, which has given us satisfaction. We had orders for some 30-inch swing lathes with hollow spindles, $2\frac{1}{2}$-inch hole, and we first attempted to buy a machine in the market that would do this work, but were unable to get hold of one at a reasonable cost that would answer our requirements. The machine shown will bore a $2\frac{1}{2}$-inch hole through a lathe spindle 48 inches long, and do it right.

Home-made Machine for Boring Lathe Spindles.

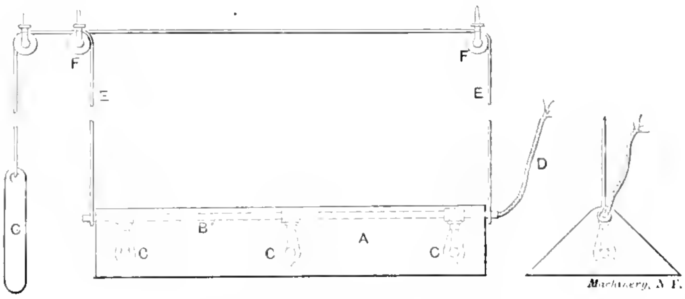
The foundation part of the machine had originally been built for reaming gun barrels. The framework was constructed of $\frac{1}{2}$-inch by 2-inch steel, there being four pieces 10 feet long, with long washers between bolted together, making two parts 12 inches wide. These formed the uprights, both being exactly the same. The two uprights were joined together by a $\frac{1}{4}$-inch steel plate 20 inches wide, extending from the floor up about 6 feet. This made a very stiff steel frame 10 feet high and 20 x 12 inches on the floor. At the top a 2 x 3-inch steel piece 30 inches long was bolted between the two middle sections of the uprights and extended to one side about 10 inches. Below this and parallel to it was erected a duplicate piece. The two pieces had holes bored through the projecting ends for the vertical spindle on which was mounted a bevel gear, and a screw chuck at the lower end. The horizontal shaft driving the vertical spindle also carries a spur gear of large diameter, and meshing with this is a pinion gear on the cone gear shaft. The spindle to be bored is fastened to the lower end of the vertical spindle and revolves with the shaft, while the drill remains stationary. The drill is fed upward from the bottom and relieves itself of chips by gravity. The feed rigging shows, in the illustration, between the spindle being bored and the frame. It is driven by a belt from the horizontal drive shaft.

Eugene, Ore. ED. B. ERY.

THE LIGHTING OF DRAFTING-ROOMS.

This is a subject often discussed without reaching a satisfactory conclusion for all cases; each one must necessarily be governed by local conditions. In the January number of MACHINERY, an editorial under the above title reminded me of a system used where I once worked. The apparatus is cheap and efficient, and for artificial illumination, when electricity is to be used, has proved to be entirely satisfactory in actual practice.

Referring to the illustration, the shade *A* was made of tin, painted dark green outside, and white inside, through which was passed a pipe *B* with T-connections at *C*. The insulated wires *D* were drawn through the pipe and connected with ordinary 16-candle-power incandescent lamps which were fastened at these T-connections. The whole thing was suspended from the ceiling by cords *E* drawn over pulleys *F*. The cords were attached to the counter-balance *G*, and to the shade as shown, allowing the lights to be raised entirely out of the way when not required, or lowered directly over each board



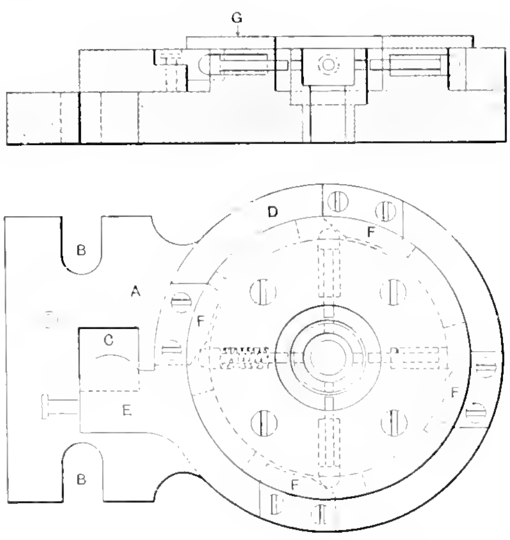
Adjustable Light for the Drafting-room.

sufficiently to shield the eyes of the draftsman and reflect the light over the entire board. The length and number of globes will, of course, depend upon the length of board.

This arrangement may be modified to meet the requirements of the more refined tastes willing to pay for elaborate furnishings. However, the leading features should remain the same: A suspended individual light of wide range, adjustable for height, while permitting the full swing of beam compasses or drafting machine, without encountering supporting brackets. It casts no shadows and protects the eyes of the workman. E. P.

MULTIPLE PIERCING TOOL.

A multiple piercing tool used for thin cup work is shown in the accompanying illustration. This tool can be used for stock from 18 gage down as thin as practicable to work. Of course, it could be made for thicker material, but this would mean very strong springs for stripping the punches, and hard work for the press. The reason I designed this tool was principally to avoid any chance of an accident to the operator's fingers, as in the multiple punches the punch or upper part of the tool covers a large part of the surface of



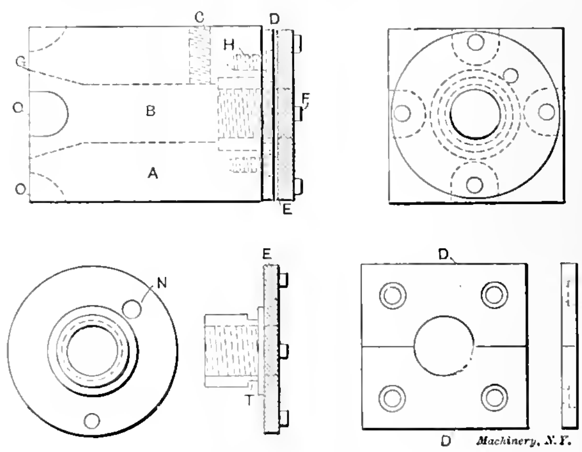
Section and Plan of Multiple Piercing Tool.

the die, thus subjecting the operator's hand to the danger of serious injury when putting the work on or off. This is a point that is not studied as much as it should be in tool design, and it is the duty of every tool designer or person in charge of a machine department to give this matter every attention. Referring to the illustration, *A* is a cast-iron base with two slots *B* for bolting to the bed of the press. A round or square hole *C* is cored through this base, into which the punch enters. A ring *D* having a projecting arm *E* fits over a boss on the base. The arm *E* comes into contact with the punch, which rotates the ring with the cams *F*, which are held in position by two screws. These cams, in turn, operate the four piercing punches and force them into the die. The punches are stripped off the work by spiral springs. A shell die is used so that the scrap from the piercing will fall through. A plate *G* is fastened to the base *A*, which serves to keep the ring *D* in place. A spring (not shown) is attached to the ring *D*, and serves to bring the ring back into position after being rotated by the punch. A plain punch, with a shank to fit the gate or slide of the press, is used. The working end, or the end which comes into contact with the arm *E* is tapered to an angle suitable to the stroke of the press. This style of tool can be designed for perforating almost any number of holes, and, obviously, it can be worked at a high speed with no danger to the operator. CHAS. PETIJEAN.

E. C., London, Eng.

SPRING CHUCK BLOCK.

The accompanying illustration shows a very handy tool for use in the tool-room for slotting screw heads, milling small counterbores, fluting taps, and numerous jobs of like nature. A steel block *A* is machined square, and with all sides parallel to the axis of the hole *B*. The hole *B* is bored to fit the drawn-in spring chucks of the bench lathe. Set-screw *C* engages with the spline on the spring chuck, and keeps it in position while releasing and tightening the work, by the member *E*. Grooves *O* are milled in the face of *A* for cutter clear-



Spring Chuck Block.

ance when milling work of small diameter. The rear end of *A* is counterbored out to receive the member *E*, which is held in place by two plates *D* which fit in groove *T*. These plates are held by four set-screws *H*. Piece *E* has four lugs *F* allowing *A* to be used in a vertical position. Hole *N* in *E* is in line with the set-screws *H*, and it is a little larger than the heads of the screws in plates *D*, thus making an easy job of assembling the parts. As the thread in *E* fits the thread on the spring chucks, it is obvious that when the chuck is in place it may be opened or closed by turning *E* to the right or left. All parts of the chuck block are hardened, it is inexpensive to make, and, with a fair assortment of chucks, makes a nice combination. E. W. NORTON.

North Tarrytown, N. Y.

CUTTING STEEL WITH A BAND-SAW.

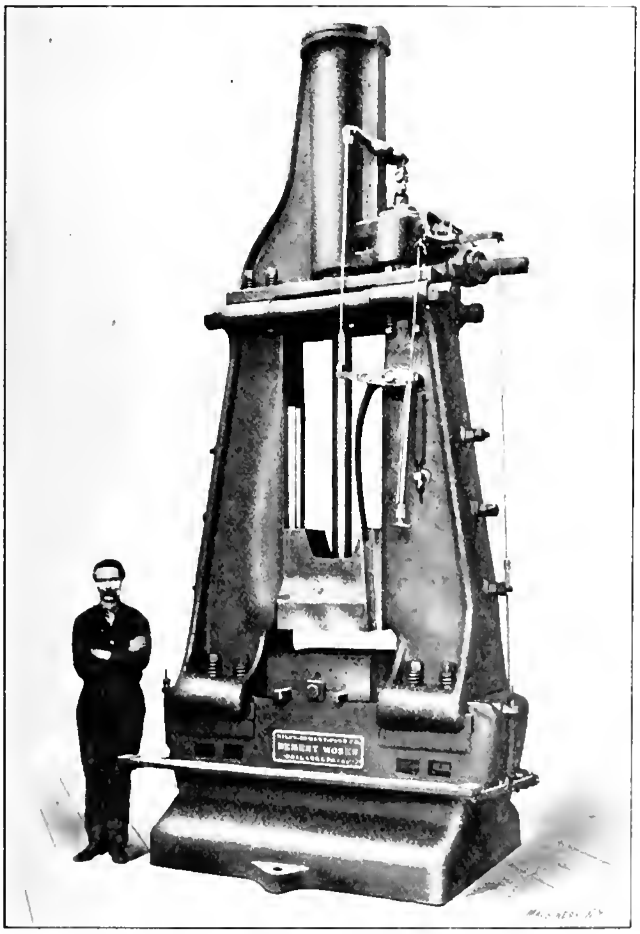
There is a shop on Clinton St., Chicago, that keeps three big band-saws constantly busy cutting tool steel. They do a good business cutting steel for numerous shops in the vicinity, charging seventy-five cents an hour. The band-saws cut very rapidly and accurately and with little waste, only a sixteenth being cut away. A band-saw will cut more than double the amount of steel that a number of common hack-saws costing the same money will do. Another great advantage of a band-saw is that it cuts continually, while a hack-saw only cuts half the time. The steel bars are fed up to the band-saw by a carriage running on slides and moved by weights which are varied to suit the different thicknesses of steel, otherwise the saw frame is practically the same as those used in wood shops, but the saws are made especially for metal.

Decatur, Ill. ETHAN VIALL.

THE DEVELOPMENT OF STEAM DROP HAMMERS.

Attention has been drawn to the article appearing on page 739 (engineering edition), June issue of MACHINERY, headed "Chambersburg Line of Steam Drop Hammers." This publication places the Chambersburg Engineering Co. as pioneers in steam drop hammers, which is very much in error.

Without raising the question as to who was the pioneer, but protesting against the wrong party receiving the credit, I have to make it known that Mr. F. B. Miles, who later became a member of the firm of Bement, Miles & Co., designed in 1872 what seems to be the first steam drop hammer made by his company, and which was sold to the Baldwin Locomotive Works. Since that time this class of machinery has grown to be a large factor in the product of Bement, Miles & Co., and now the Niles-Bement-Pond Company, of which the Bement Company became a part. It was something like a quarter of a century after the date mentioned that the Chambersburg Engineering Co. came into being, and this fact is sufficient for substantiating my claim that the above mentioned company were not the pioneers, for the very good reason that they did not depart in the construction of their



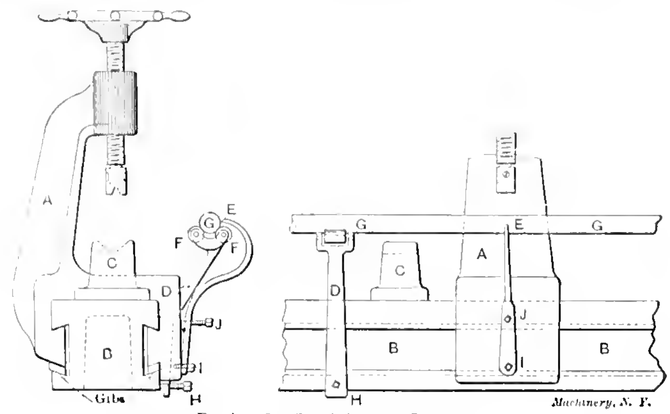
Steam Drop Hammer built by the Niles-Bement-Pond Co.

hammers from the principles involved in the older concern's designs. Since the first hammers were made by Mr. Miles, there has been little change in the important points of construction, such modifications as have been made being simply augmentation, with the vital or working parts as he conceived them. As a proof of the good design Mr. Miles produced, I have to point out that most, if not all, steam hammers manufactured in this country to-day are constructed on the same lines, and the illustrations of them point very strongly to direct copies of what has become known throughout the trade as "Bement hammers." Herewith is an illustration of a steam drop hammer as offered to-day by the Bement Works of the Niles-Bement-Pond Company, and very similar to the one you submitted with the Chambersburg article. The photograph simply shows a growth of the same mechanism produced over thirty years ago by practically the same company, and with no radical differences in principles.

Philadelphia, Pa. W. J. HAGMAN,
General Manager Bement-Miles Works.

DEVICE FOR STRAIGHTENING SHAFTS.

The engraving shows a handy press for straightening. The shafts require no centering in the ends, and can be straightened as perfectly as if they were straightened on centers. The press frame *A* is shown placed approximately at the center of the bed plate *B*, which latter can be made of any length. On the bed plate are placed two supporting V-blocks *C*. The bracket *D* of which there are also two in the complete device, carries hardened rollers *F* on which the shaft is resting while it is being tested by the test needle *E*.



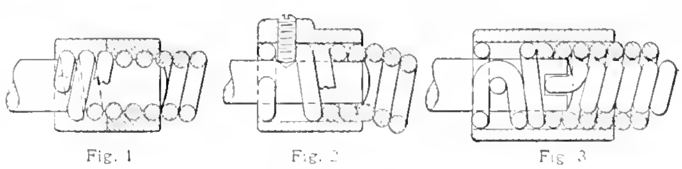
Device for Straightening Shafts.

This latter is secured to the press frame at *I* and adjusted by set-screw *J*. The bracket *D* is dove-tailed into bed plate *B*, but is a loose fit and is secured in position by means of set-screw *H*. The method of operating this device is obvious from the engraving. For rapid straightening it has proved very valuable. The straightening screw is screwed down from the top to give more or less pressure according to how much the shaft needs straightening.

TESTING ROOM.

FLEXIBLE SHAFTS.

A cheap substitute for universal joints or flexible shafts is a helical spring. Effective couplings between the shaft end and spring are shown in the sketches. The shaft is threaded (Fig. 1) for a few turns to a somewhat coarser pitch than that of the spring, and to a somewhat larger diameter at the bottom of the thread than the internal diameter of the spring, with a half-round groove which ends in a drilled hole. The spring has the end bent in toward the center. This end enters the drilled hole on the shaft when the spring is threaded over it. A two-part sleeve threaded internally, the threads having the same pitch as those on the shaft, is screwed over the spring and tightly checked together. The extreme end of the shaft may be slightly tapered and the outer end of the sleeve bell-mouthed so that the spring may not be too rigidly confined at that point. Fig. 2 shows a much cheaper arrangement in which the end of the spring is



Methods of Coupling Springs to Shafts.

looped around the end of a set-screw. Fig. 3 illustrates a method I employ for a flexible shaft using two springs. The outer spring was wound to be a tight fit over the end of the shaft and the sleeve bored to a pushing fit over the spring. A taper pin fastened the sleeve and spring to the shaft the free end of the spring being brought around back of the taper pin to form a hook. The inner or core spring is made as large as will draw freely into the outer one, and has its ends formed into loops which engage the slotted end of the shaft. The two springs are wound opposite hand so that the torsion tends to close in the outer one and open out the inner one. Arranged in this manner the shaft is very effective and is cheaply constructed. GEO. W. ARMSTRONG.

Norwich, Conn.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

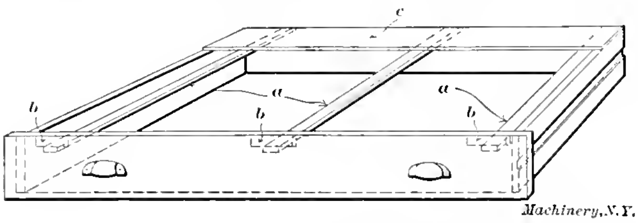
FIBER WEDGE FOR SECURING HAMMER TO ITS SHAFT.

A wedge made of fiber, particularly of the hard quality used for washers on automobiles, is an excellent substitute for the wood or steel wedge that ordinarily secures a hammer head to the handle. DONALD A. HAMPSON.

Middletown, N. Y.

DRAWER FOR DRAWINGS.

A simple and cheap method of making drawings lie flat in drawers is shown in the accompanying engraving. It consists of three blocks *b* fastened to the inside of the front of the drawer, a back top *c*, and three slats *a*, which are slipped

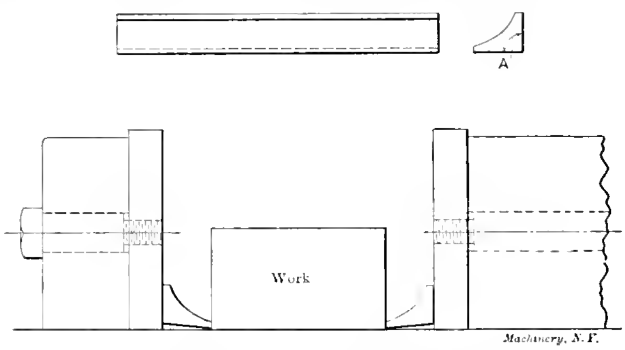


in under *c* and *b*. These slats keep the drawings from curling up and catching in the drawer case. By using a drawer of this description, the capacity is increased from three to four times. JOHN B. SPERRY.

Aurora, Ill.

CLAMPING APPLIANCES FOR THE PLANER.

The illustration shows a pair of handy hold-downs for holding work in the vise of a planer or shaper. A detailed view of the appliance is shown above clearly indicating how it is made. The angle *A* should be slightly more than a right



angle, so as to prevent the clamping piece from bearing on its bottom surface when used. These clamping pieces are especially handy for clamping thin pieces. The engraving plainly shows how they are used. C. W. R.

TOOL-MAKERS' DRILL PAD.

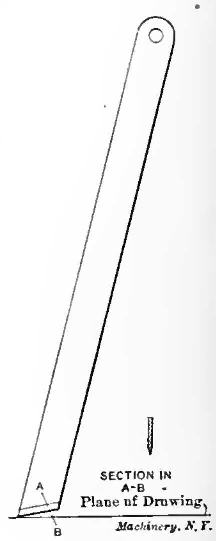
The engraving shows a simple device, made of leather, for carrying drills back and forth from the bench to the drill press, instead of using the ordinary drill block. It struck

me as being a very convenient and compact way of taking care of a set of drills. Most tool-makers know how handy it is for anyone to come along and pick out a drill from the ordinary drill block on the bench and return the drill in a very poor condition. I would make one improvement to the drill pad, and that would be to rivet a small piece of brass where each drill is placed and stamp the number of the drill on; then any drill could readily be selected. This drill pad can be rolled up and stuck in the pocket, which makes it mighty convenient when one has some heavy tool or jig to carry to or from the drill press. A. J. DE LILLE.

Minneapolis, Minn.

REMOVING INK FROM DRAWINGS.

One of the best tools for removing ink from a drawing, before using a rubber eraser, may be made from a worn-out hack saw blade. The accompanying illustration shows such an instrument. About six inches is broken off one end of the blade, the teeth are ground off, and the broken end is sharpened as shown. This end should be ground very thin, and on one side only. To prevent cutting the drawing, the edge is rounded slightly at the extreme point. Not every hack saw blade, however, will make a good scalpel. The blade should be evenly tempered from the teeth to the back, if possible, and no retempering will be necessary. To use the tool, hold it between the thumb and first finger, so that the edge is almost parallel to the surface of the drawing, but touches it at the point only.

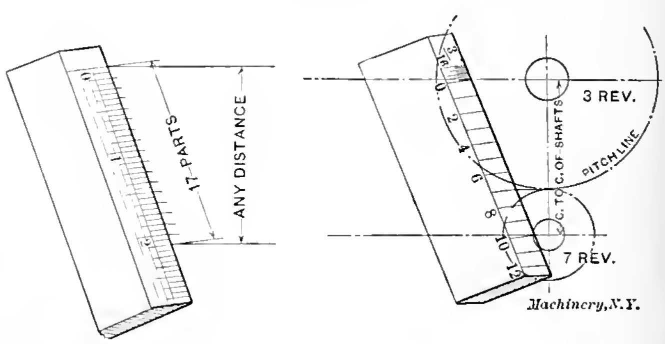


Detroit, Mich. A. L. CAMPBELL.

THE USE OF THE ORDINARY RULE FOR DIVIDING.

The operation of dividing a line into any number of equal spaces is a very simple one, and one of the first exercises in geometry, but however familiar men might be with its execution, I have rarely seen anyone use the rule for this purpose. When it is required, for instance, to draw a certain number of lines or a certain number of threads per inch, in a given space, sometimes the length of the single spaces will be figured, or a diagonally drawn line will be spaced off with the dividers and the spaces transferred with the triangles.

The shortest way is to use the ordinary or draftsman's scale. Use the graduation, nearest suitable to the eye, place the zero mark on one end of the space to be divided, and the number corresponding to the parts required on the line marking the end of the space, or its continuation, mark off points at every graduation, and with triangle or T-square draw parallel lines through these points. At the left is shown two lines, the distance between which is to be divided into 17 equal parts. In this case the regular scale of an



ordinary rule is used; after the points are marked off, parallel lines are drawn through them. This use of the rule for dividing without going to the trouble of figuring is applicable in a great number of cases. The distance center to center of two shafts is given, and a transmission of spur gearing of the ratio 3 to 7 between them is wanted. The pitch circles can be drawn immediately without figuring their diameters or number of teeth. Draw the distance between centers to scale, hold the zero mark of rule on a line through one center and the graduation 10 ($=3+7$) to a parallel line through the other center; the graduation 7 marks the line tangent to the two pitch circles, as illustrated in the right-hand view. MARTIN JOACHIMSON.

New York City.

FINISHING FLY-WHEELS, HOIST DRUMS AND PISTON RINGS ON THE LIBBY TURRET LATHE.

An illustrated description of the Libby turret lathe appeared in the March issue of MACHINERY. In this description some of the characteristic features of its design were pointed out; one of the most interesting features there called attention to was the unusual construction of the tool-post carriage. This carriage does not extend across the bed, as in the usual designs of this class of machines, but it is supported by a front

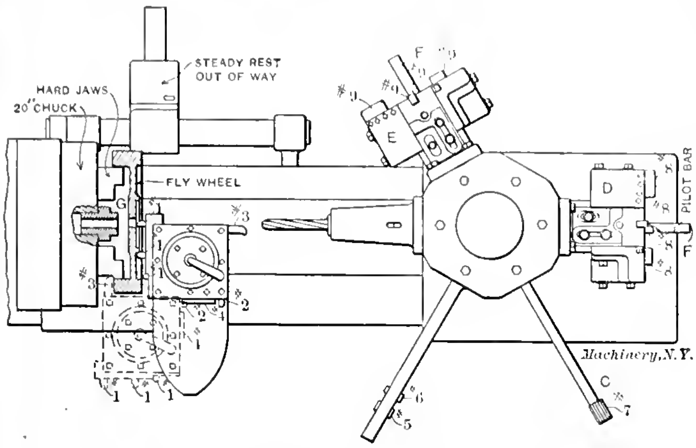


Fig. 1. Finishing a Fly-wheel in the Libby Turret Lathe. First part of First Operation.

way and by a V-guide at the bottom of its apron, bearing on a corresponding way on the lower edge of the bed. This permits the tool-post carriage to be moved past the chuck mounted on the spindle at the head-stock end. The turret can thus be used close up to the chuck, and overhanging tools, usually required to reach over the tool-post cross slide, can be avoided. Another advantage gained is also that, on account of its construction, practically the full capacity of the machine can be swung over the carriage.

In the present article a number of interesting operations, as performed on this machine by the International Machine Tool Co., of Indianapolis, Ind., are described. The operations which we will here deal with are the finishing of automobile fly-wheels, in two settings, the finishing of hoist drums, and the making of piston rings.

Finishing Automobile Fly-wheels in Two Settings.

The finishing of automobile fly-wheels on the Libby turret lathe is illustrated in the three line engravings, Figs. 1, 2, and

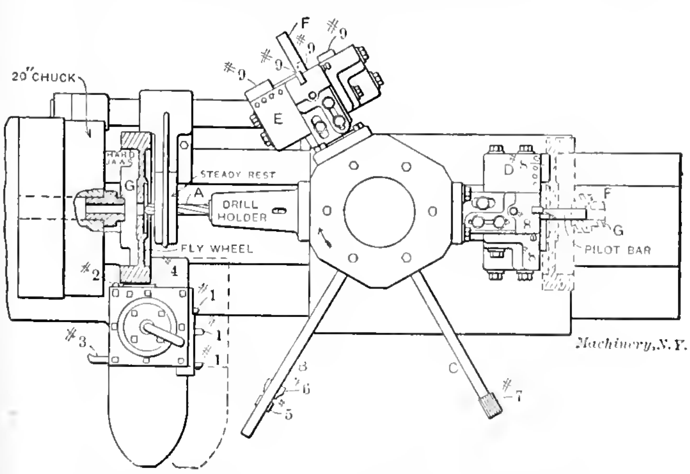

Fig. 2. Finishing a Fly-wheel in the Libby Turret Lathe. Second part of the First Operation

3. The fly-wheel is chucked from the inside by the hard steel jaws of the chuck, sufficient space being left between the chuck and the rim of the fly-wheel so that the tool for facing the back side of the rim of the wheel will have ample clearance, as shown by the dotted lines in Fig. 1, where tool No. 3 is indicated as finishing the back side of the rim.

The gang tools No. 1 are now set as shown in Fig. 1, and the tool-post carriage is brought into position, as shown, so as to rough all the faces at one operation. The tool-post carriage is next brought into position, as shown in Fig. 2, permitting the use of tool No. 2 for roughing the outside diameter of the fly-wheel. The steady rest, which was swung out of the way in Fig. 1, is brought into position for supporting the drill and boring-bar used for the hole in wheel in Fig. 2. This hole is being drilled and the rim of the wheel rough-turned, simultaneously. The cutter bar *B*, with cutters Nos. 5 and 6, is then used to bore the hole in the fly-wheel preparatory to reaming by reamer No. 7.

When the center hole is reamed, the roughing facing head *D* is brought into position. While the roughing head *D* is in operation, the tool-post carriage is placed in position so as to use tool No. 3, as shown by the dotted lines in Fig. 1, already referred to. This tool then rough-turns the rim of the fly-wheel next to the chuck. Finally, the finishing facing head *E* with the tools No. 9 is brought into position to be applied to the work, and the tool-post carriage at the same time set so that the broad finishing tool No. 4 finishes the outside diameter of the wheel, as shown in Fig. 2. The cutters Nos. 8 and 9 in the heads *D* and *E* are adjustable to cuts of various sizes and depths, within the range of the holders. The pilot bars *F* on the facing heads *D* and *E* are employed to steady the heads while in action, the pilot bars receiving their support from the bushing *G* in the chuck.

One side of the fly-wheel is now finished. For the second operation the wheel is held by the outside finished rim by soft jaws, as shown in Fig. 3. The gang tools No. 10 in the tool-post carriage are then used for rough-turning the web of the wheel. After that the roughing head *D* and the finishing head

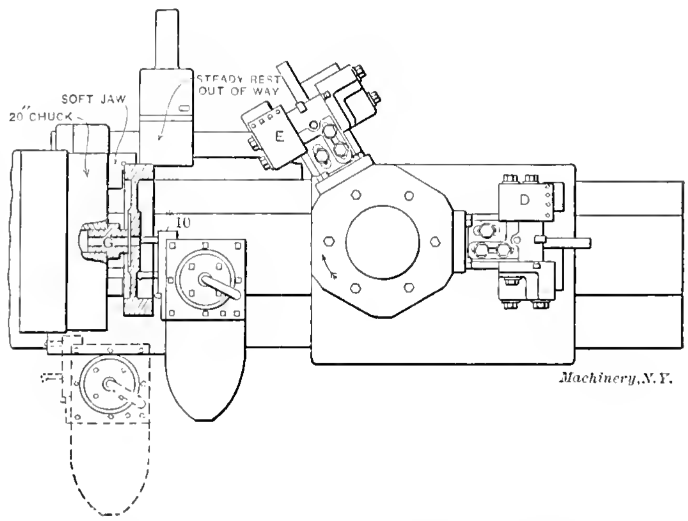

Fig. 3. Finishing a Fly-wheel. Second Operation

E are brought into position consecutively, the operations being the same as previously described for the finishing of the other side of the wheel.

Finishing 20 x 19-inch Hoist Drums.

The finishing of hoist drums 20 inches in diameter is ordinarily done on a vertical boring mill, or on a 32-inch engine lathe, or on a turret lathe, which then, when provided with a cross slide of the ordinary construction, requires a machine of 35 inches swing. On account of the peculiar construction of the tool-post slide of the Libby turret lathe, it is possible to finish drums of the size mentioned in a 21-inch Libby lathe, at one setting, the operations performed being the boring and reaming of the holes in the two hubs, the facing of one hub, the turning of the outside diameter of the drum, and scoring the drum for the rope as shown in Fig. 4.

The drum is chucked from the inside of the rim, the holes in the hubs are rough-turned by the boring-bar *A* and finish-bored by the boring-bar *B*. The tools Nos. 5 and 7 are for boring the holes in the hubs, and Nos. 6 and 8 are for facing. After boring, the holes are reamed with reamer No. 9 on bar *C*. It should be noted that bar *C* is long enough so that the projection reaches through the drum and acts as a pilot bar, the further end being supported by the bushing *F* in the chuck, this insuring true alignment of the holes when reamed.

The steady bar or arbor *D* is now brought in position into the reamed holes in the drum. The large diameter of this bar fits closely the reamed holes in the hubs, and the small

part *E* is of such a size that it will fit the bushing *F* in the chuck. This bar supports the drum while turning and scoring it on the outside. The advantage of being able to bring the turret close up to the work, on account of the peculiar construction of the tool-post slide, already referred to, is here plainly in evidence. The supporting bar can be made correspondingly short, and will consequently be more rigid, the turret being brought up very close to the end of the drum. The drum and brake band is now rough-turned with tool No. 1, and finished to size with tool No. 3. After that the edges on the flanges are rounded off with tool No. 4. Finally, tool No. 2 is used for scoring the drum to the required pitch, which, in this case, is one inch lead. Other leads may, of course, be obtained by simply changing the change gears. The four last-mentioned tools are all mounted in the tool-post carriage, as shown in Fig. 4. The position of this carriage as indicated by the dotted lines should be noted, the carriage in this case being opposite the chuck on the spindle.

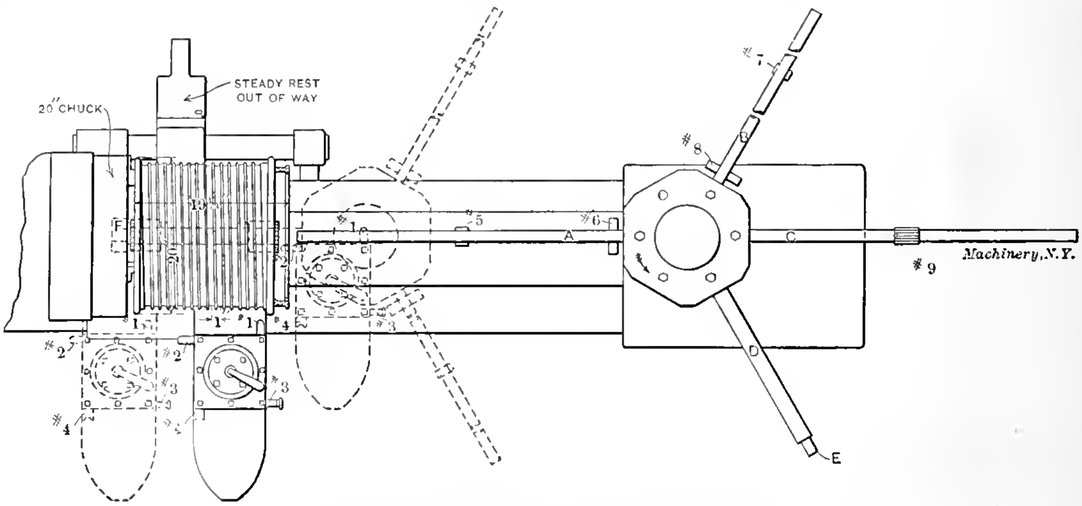

Fig. 4. Boring and reaming the Holes, facing the Hubs, and turning and scoring the Outside Cylindrical Surface of a Hoisting Drum, in One Operation.

This particular drum only requires the facing of one hub. If the other hub is required to be faced, this may be done by placing a cutter in the bar after it is inserted into the holes, provided that sufficient room is left for the cutter when the drum is chucked.

Making 18-inch Piston Rings.

In Fig. 5 is shown the method and tools used for making 18-inch piston rings on the Libby turret lathe. The line engraving shows the piston ring casting, which has had the lugs faced off, and is bolted to a shifting face-plate of the eccentricity desired in the rings. This face-plate, in turn, is fastened to the chuck after removing the jaws. Tool No. 1 in the tool-post carriage is used for roughing off the outside of the rings, and tool No. 2 for finishing. Then the shifting face-plate is adjusted so as to provide for the eccentricity desired in the rings. Now the roughing cutter head *A* is brought into action for roughing the side of the ring, it being followed by the finishing cutter head *B*. Each of these cutter heads has four cutters and is also provided with a pilot bar long enough to reach through the ring and engage with the bushing *C* in the chuck, thus providing for rigid guiding.

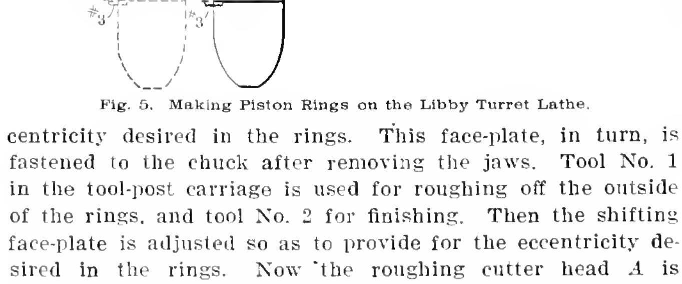

Fig. 5. Making Piston Rings on the Libby Turret Lathe.

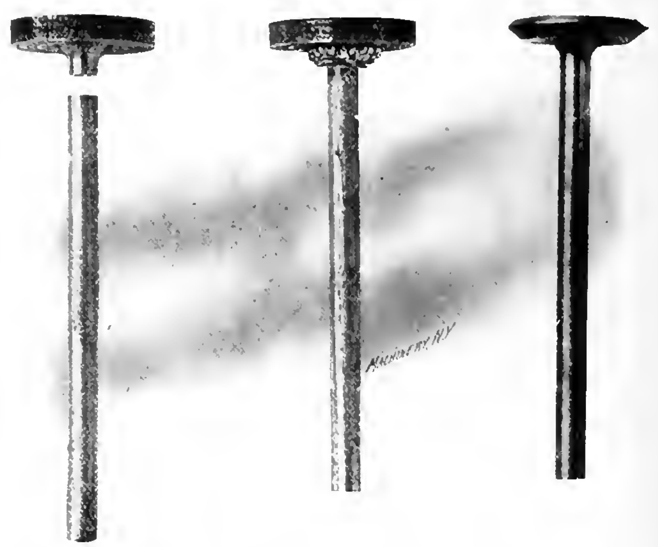
The gang tool No. 3, mounted in the tool-post, is now brought into service. This gang tool is provided with seven cutting-off tools, and so arranged that each cutter, commencing at the right, is set slightly in advance of the one to the left. The longest, or the extreme right-hand cutter, is used as a gage, and will cut off its ring first; then each ring will be cut off in turn, and not all at once. As the inside of the ring is bored true with the spindle and the outside is eccentric, the tools will cut through and cut off the ring all around at the same time.

ELECTRIC WELDING OF DISSIMILAR METALS.

In the April, 1908, issue, examples of electric welding were illustrated, and the various electric welding processes were briefly described. A valuable feature of the Thompson process of electric welding is that the dissimilar metals can be perfectly joined. This possibility permits combination of metals best suited to the conditions of use to be made, as well as very substantial economies in the use of high-priced materials. The accompanying illustrations show specific examples of electric welding of dissimilar metals done by the Electric Welding Products Co., Cleveland, O., formerly the Cleveland Cap Screw Co.

The poppet valve shown in Fig. 3 is one of the exhaust valves of a high-speed gas engine. It is made up of a carbon steel stem, electrically welded to a nickel steel head. The parts before welding are shown in Fig. 1, and the combination immediately after welding in Fig. 2, while the finished valve is illustrated in Fig. 3. By making the head of nickel steel, of an alloy suited to the purpose, the very best metal is put in the head of the valve, which is the part subjected to the hardest usage. Nickel steel is peculiarly suited to the trying conditions surrounding gas engine exhaust valves, as it does not pit, warp nor corrode, as does common steel in

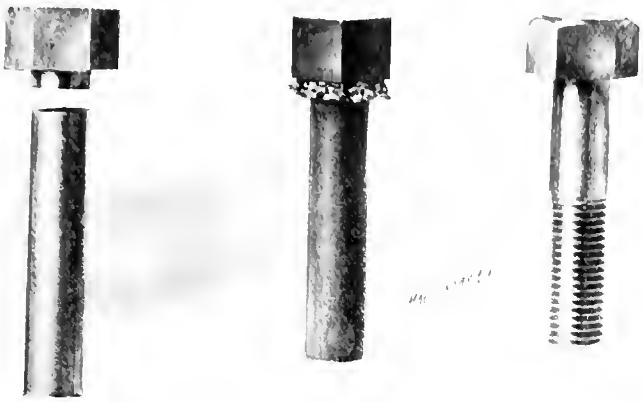


Figs 1, 2, and 3. A Poppet Valve made by electrically welding a Carbon Steel Stem to a Nickel Steel Head.

such a situation. Moreover, it is much tougher, and is not apt to break because of the hammering it receives. The stem, being made of carbon steel stands wear in the guide better than a nickel steel stem; it is stiffer also and can be hardened on the end. The latter consideration is important, inasmuch as high percentage nickel steel cannot be satisfactorily hardened to withstand the cam blow of the valve mechanism. Another important advantage of the combination is the saving of high-priced metal and the obvious

saving of labor over that required for making and machining a forging.

The cap-screw illustrated in Fig. 6 is made with a brass head and steel body. Figs. 4 and 5 show the parts of the welded screw before finishing. This screw is 50 per cent stronger than an all brass screw, and answers the practical requirements equally well or better, inasmuch as the body is stronger than a brass body. This combination was made for use in places where an ornamental finish was required, and as the head only shows, a brass body was not required.



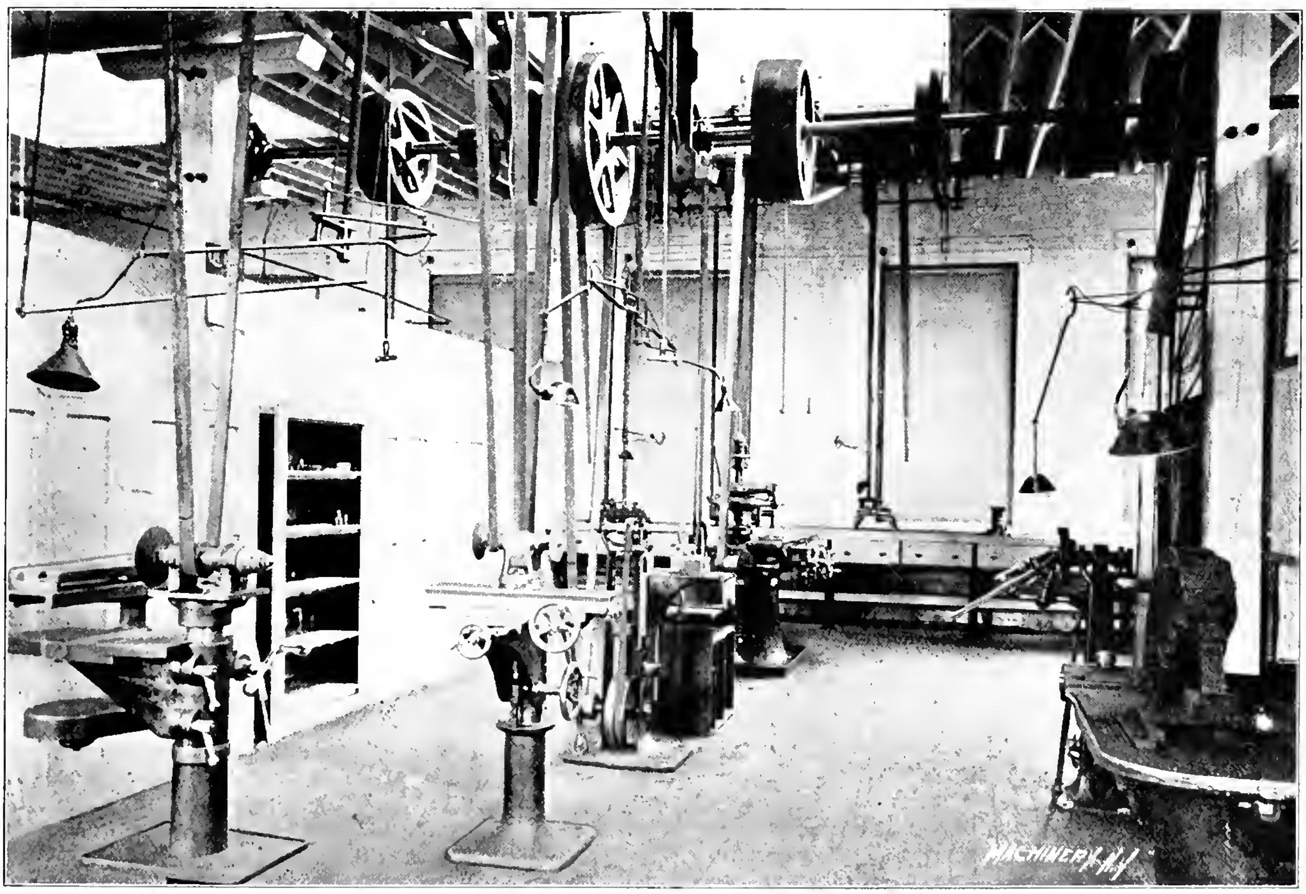
Figs. 4, 5, and 6. A Cap-screw made by electrically welding a Steel Body to a Brass Head.

Other valuable combinations of dissimilar metals could be mentioned, but the foregoing will serve to illustrate the advantage of electric welding in this line. The chief business of the company is the manufacture of all sorts of steel bolts and screws, and it has been engaged in it for several years. The claim made for electric welded all-steel bolts and screws is that they are stronger than when made by the ordinary methods. The reason is that the die-drawn surface of the stock is retained on the body, this portion of the body being much stronger than the center which is left when the bar is turned down to the body size from the head size. In the case of forged bolts this objection, of course, does not hold, but it is common practice to use inferior grades of stock which are unreliable in service. This fact is indicated by tests made of electric welded cap-screws and cap-screws made by twelve makers, from ordinary stock. The tests show that the average tensile strength of ½ to 1¼ inch electric welded cap-screws was 97,862 pounds per square inch, while the average of the ordinary stock screws was only 56,570 pounds per square inch. The difference in favor of the electric welded screws was 73 per cent.

As indicated in the foregoing, the process employed by the company is the Thompson process, which is believed to have advantage over the arc, forge and gas blowpipe methods. In the Thompson process the metals are heated for welding by their resistance to the electric current. The parts are gripped in copper-faced jaws of the welding machines, and in the case of large parts are forced together by hydraulic pressure. The interior of the parts heats first, and when the surface has reached the incandescent point, the interior has surely reached the proper welding heat. The great heat generated burns out all oxides and impurities, and the pressure exerted causes the joint to flow and brings the parts into intimate contact; thus only ordinary care is required on the part of the operator to make perfect joints.

INDIVIDUAL MACHINE LIGHTING.

The accompanying engraving shows the grinding room of the H. Mueller Mfg. Co. and the form of lamp brackets used. An ordinary pipe flange is fastened to the ceiling or to the hanger boards and into this a pipe of suitable length is screwed. A cast iron bracket is slipped on the lower end of this and held in place by a set-screw. The bracket arm can be swung in a horizontal plane, and the pipe extension which has a circular end passing through a hole in the end of the arm, can be moved in any direction, horizontally or vertically, and is held in place by friction only. There is also a wall bracket used, as shown over the bench near the windows. Both the clamshell and bell shades are used, according to the individual liking. For this photograph and description we are indebted to Mr. Ethan Viall, Decatur, Ill., who says that the fixtures are ahead of anything that he has seen.



Grinding Room of the H. Mueller Mfg. Co., equipped with a Simple Form of Adjustable Lamp Bracket

Most people would know more if they didn't take so many things for granted.—*The Silent Partner.*

MACHINE SHOP PRACTICE.*

GRINDING A GEAR-CUTTER.

Experience has taught the advisability of keeping keen cutting edges on all tools, whether used for working in wood or metal; and milling cutters, in particular, when in constant use, should be sharpened frequently, as a cutter with a keen cutting edge is the one that will produce the best results, both as to the quantity and quality of the work. When a cutter becomes dull, it rapidly becomes worse, the friction is greatly increased, and the resulting heat often impairs the temper of the tool, with the result that the cutting edges are

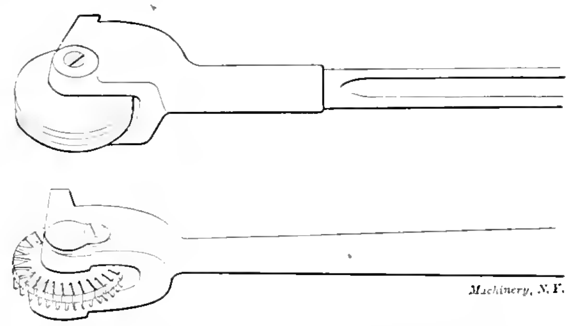

Fig 1. Two Types of Emery-wheel Dresseres.

rounded, which means considerable grinding in sharpening. More power is, of course, required for driving dull tools, and the wear and tear on the machine is also increased.

The gear-cutter which we are considering is a cutter of the formed type, which may be re-sharpened without changing its profile, provided the sharpening is done properly. The first thing which is essential in connection with any grinding operation is a true wheel, as an untrue wheel is not only a source of danger, but the work done by it poor in quality. The diamond, which is the hardest known substance, is best adapted to this work, owing to the hardness of the abrasive materials used for grinding. When the wheels are large and coarse, this method is somewhat expensive, and tools known as emery dressers are often used. Two types of these tools in common use are shown in Fig. 1. They consist of shanks, having mounted on a spindle on the end, hardened disks, the shapes of which vary in different makes. These disks are brought into contact with the wheel, and traversed across its face. As they revolve rapidly small particles of the abrasive are broken from the wheel's periphery, and it is trued. A diamond truing tool, which is extensively used, especially on small wheels, is shown in Fig. 2. It consists of a shank *A*, having a handle on one end and a small diamond *B* set in the other. This tool is applied to the wheel in various ways. Holders, similar to the one shown on Shop Operation Sheet No. 67 of the Supplement accompanying this issue, are often used, but some oper-

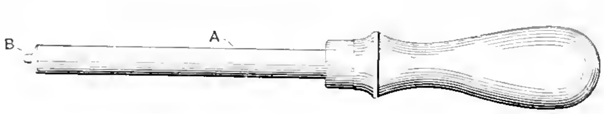

Fig 2. The Diamond Truing Tool.

ators prefer to support the tool on the foot-stock center, truing the wheel by traversing it or the table back and forth. A diamond of good quality will stand much use without showing any great amount of wear, but because of its brittleness, it should be brought very gradually to the face of the wheel to avoid the shock which would be the result of a sudden application.

The selection of a wheel suitable for grinding cutters is governed largely by conditions. Wheels which work satisfactorily on cutters made from carbon steel, are not so well adapted for high speed steel, which is ground with better results with a coarser and softer wheel than is used for the carbon steel. A wheel of medium fine grit, and medium or soft grade is best adapted for cutter grinding. Grit as used here refers to the size of grains of the abrasive, while grade is the degree of tenacity with which the bond holds the grit in place. For this particular operation a wheel having a beveled side, as shown in Fig. 3, is necessary in order that it may clear the work when grinding the inner faces of the teeth. If the working surface of the wheel is glazed, this should be removed with the diamond before using, as otherwise, the temper may be drawn from the teeth of the cutter, owing to the increased friction. Glazing can also be removed by a carborundum crystal, which is only inferior to the diamond in hardness. A glazed surface on the wheel does not necessarily mean that it is not adapted to the work, as oil or grease on the cutter is often the cause of this.

When the gear-cutter is being ground it is mounted on a fixture, similar to the one shown on Shop Operation Sheet No. 68. A stud on the fixture fits a hole in the cutter, which is kept from turning while being ground by a tooth-rest which bears against the backs of the teeth. The knee of the grinding machine is adjusted vertically until the axis of the wheel lies in a plane midway between the sides of the cutter. The table is also adjusted until the axis of the stud on which the cutter is mounted is in line with the grinding face of the wheel. It is very important that gear-cutter teeth be ground radially, or so that the faces of the teeth lie in a plane passing through the axis of the cutter. In Fig. 3 is shown the correct and incorrect way of grinding the teeth. As will be seen, the face of the tooth *A* is on the radial line, while tooth *B* is not. Teeth not ground radially, if sunk to the correct depth in the gear blank, cut a tooth space which is wide at the top, and the result is, of course, a gear having improperly shaped teeth which means that it will work unsatisfactorily. One reason why teeth are not ground radially is because they are thinnest at the top, and because of this are sharpened in less time by grinding them away faster at this point. This is, however, bad practice, for while the cutter may appear sharp, it will not only produce inaccurate work, but cut badly, owing to the negative rake. As the wheel contact on a gear-cutter is considerable, owing to the width of the teeth, it is inadvisable to attempt to do the work rapidly by taking heavy cuts, as this will result in drawing the temper of the cutter. Light cuts should be taken, and the work traversed rapidly across the wheel.

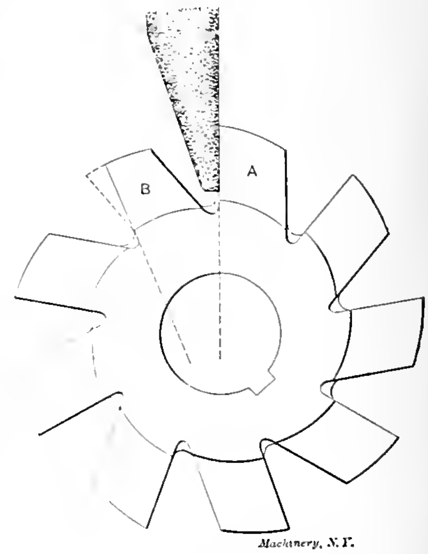

Fig. 3. Correct and Incorrect Methods of Grinding Gear-cutter Teeth.

* * *

In a recent address to a university student body in a Canadian town, Rudyard Kipling said, "*Take everything seriously and earnestly, except yourselves.*" What a wealth of meaning there is in those few words! Doubtless there is no other fault more prominent in the average college graduate than an exaggerated idea of his own importance. He confidently expects to step from his college work to a place all prepared for him, and fittingly compensated as his great ability deserves! In the language of the street, he usually has a "swelled head." The chief part of the first few years of his practical education, which we call experience, is largely learning his relative unimportance to the world at large. The engineering student learns with much disgust that many of the beautiful theories so carefully and positively expounded by his instructors apply only in the remotest degree to his actual work. He finds that engineering is nine-tenths plain hard work on common-sense matters, and that his theoretical knowledge may apply to some extent to the other one-tenth. His knowledge of theory is not nearly so important as his personality and general attitude to his fellow employes.

* With Shop Operation Sheet Supplement.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

POTTER & JOHNSTON 6-INCH AUTOMATIC CHUCKING MACHINE.

The readers of MACHINERY are familiar with the Potter & Johnston chucking machine from the very complete description we have recently given of it. (See article "The Setting Up and Operation of the Potter & Johnston Automatic Chucking Machine," in the April and May, 1908, issues, and "New Machinery and Tools" in the April, 1908, issue.) The builders of this machine have recently added to their line a smaller size which they designate as their 6-inch automatic chucking machine. This is shown in the three accompanying engravings. While it involves the same principles in its construction as used in the larger machine, the actual mechanism employed is different in a number of particulars, and is of sufficient interest to warrant the full illustration and description herewith given.

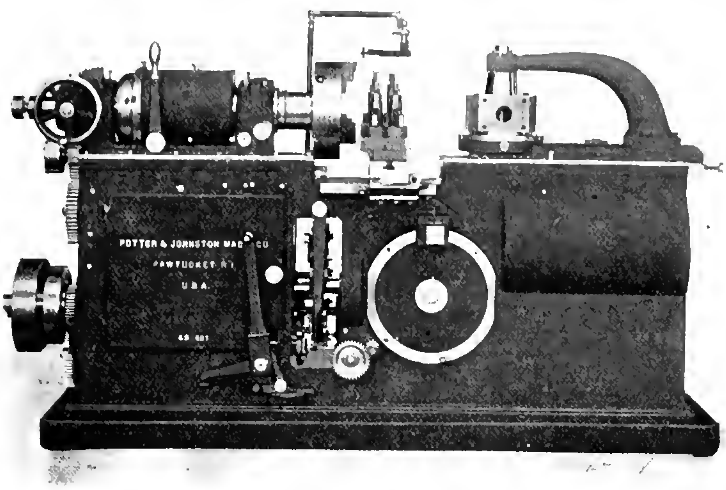

Fig. 1. A Small Size and New Design of the Potter & Johnston Automatic Chucking Lathe.

General Description of Machine.

The plan of the machine is very simple, consisting, as it does primarily, of a single bed casting with an adjustably mounted head-stock and driving mechanism on one end, and turret slide on the other, with longitudinal ways between them on which the base for the double-acting cross-slide is adjustably mounted. The cross-slide and turret-slide are operated by cylindrical cams, driven from a feed shaft at the rear of the machine, which also operates the governing disk seen in the opening in the center of the bed. This disk carries dogs and pins which control the rapid and slow movements of the feed shaft, and the spindle speed changes, of which there are three, controlled automatically. The slow or feeding movement of the feed shaft is operated from the spindle movement, and is proportional to it. The rapid movement is operated from the constant speed driving pulley, and always runs at the highest practicable speed. A large supply of gears, both for speeds and feeds, is provided, covering all ranges of work within the capacity of the machine.

A front view of the machine is shown in Fig. 1. A notable characteristic, which will at once be seen, is the completeness with which the mechanism is enclosed in the single rectangular box-shaped casting. Another feature which catches the eye is the provision made for the longitudinal adjustment of the head-stock to suit work of different lengths. This has been done in preference to making this adjustment between the cam roll and the turret slide, as it is thereby possible to make the parts with less over-hang, and so give the machine greater rigidity and greater cutting power.

Spindle Driving Mechanism.

The machine is driven from a constant speed pulley at the base of the machine, seen at *A* in Fig. 3. This pulley is keyed to shaft *B*, which runs through the head-stock end of the base, and carries a set of three gears, *C*, *D*, and *E*, of varying diameters, meshing with corresponding gears *F*, *G*, and *H*, running loosely on short shaft *J* above it. The largest of these gears, *F*, is connected with shaft *J* by a roller ratchet mechanism, so that the drive is normally through this pair of gears, *C* and *F*. The other two sets are provided with clutches, either one of which can be thrown into operation, as will be described later. When either of them is engaged, shaft *J*, thus driven at a faster rate than that given by its normal connection through gear *F*, runs away from that gear, being permitted this liberty by the roller ratchet drive. It will thus be seen that three changes of speed are provided for shaft *J* by the operation of two positive clutches.

Shaft *J* is connected by change gearing *K* and *L* with a shaft *M* above it, which extends out through the back end of the bed, where it carries gear *N*, which drives a mating gear *O*, keyed to a shaft running lengthwise of the head-stock, between the ways on which the latter is adjusted. This shaft carries a pinion which engages the driving gear of the spindle. The shaft is splined a sufficient length to give a full drive on the pinion at any adjustment of the head. The change gears *K* and *L* furnished for connecting shafts *J* and *M* in the base, provide for six rates of speed, which, with the three clutch changes available, gives eighteen changes in all.

Handle *P* on the head-stock controls a double-acting clutch which engages the spindle with either the driving gear on one side, or with a stationary brake member on the other.

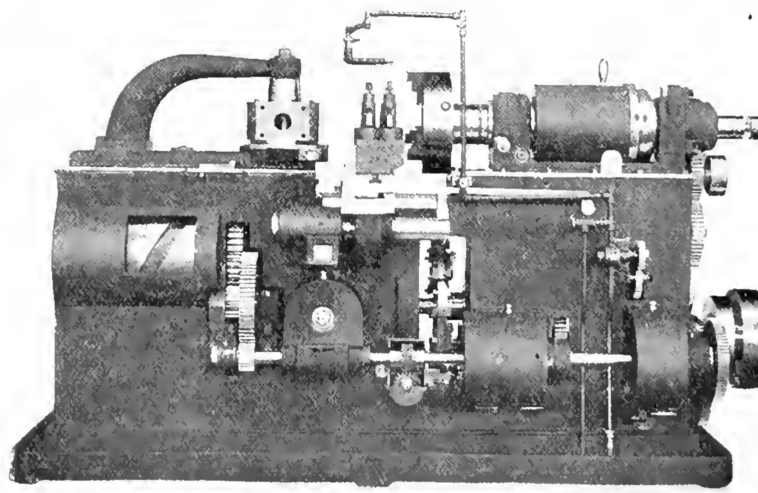

Fig. 2. Rear View showing the Feed Shaft and its Connections with the Governing Disk and Cross- and Turret-slide Cams.

This is a great convenience and a time saver as well, since it enables the operator to stop the spindle instantly for the purpose of removing and inserting work. Hand-wheel *Q* at the rear bearing of the spindle operates a rugged back facing attachment, consisting of a stiff stationary bar supported from the back end and extending the length of the spindle with a facing tool on the front, by means of which the inner hub of work held in the chuck may be conveniently finished.

Driving Connections of the Cam and Governing Mechanisms.

The feeding movement for driving the cross-slide and turret-slide cams is driven from pulley *R* at the rear end of the driving pinion shaft, so that it always revolves proportionally with the spindle, thus making all feeds proportional to the

spindle speed. The conditions are thus the same as in the lathe, where the number of revolutions per inch of feed is constant, whatever the rate may be at which the spindle revolves. Pulley *R* is belted to pulley *S*, which runs loosely on shaft *B*. Change gearing connects this pulley *S* with the feed shaft seen in Fig. 2, running along the back of the bed near the base. This feed shaft has also geared connections with constant speed driving shaft *B*, which connections are controlled by the vertical lever *T*, see Fig. 3. By means of this lever, the motion of the feed shaft may be arrested entirely, it may be given the constant speed rapid movement from shaft *B* required for the idle motions of the machine, or it may be connected with the spindle for the cutting movement through pulley *S* and the gearing just described. These changes may also be made automatically, as will be described later. The considerable reduction required for the feeding motion between the loose pulley *S* and the feed shaft at the rear, is effected by a differential gear train encircling the latter shaft, and enclosed within the casing shown at the right-hand end of the bed in Fig. 2. The casing shown just at the left of this and on the same shaft, encloses the gearing and mechanism by means of which connection is made with the rapid movement derived from the constant speed shaft *B*.

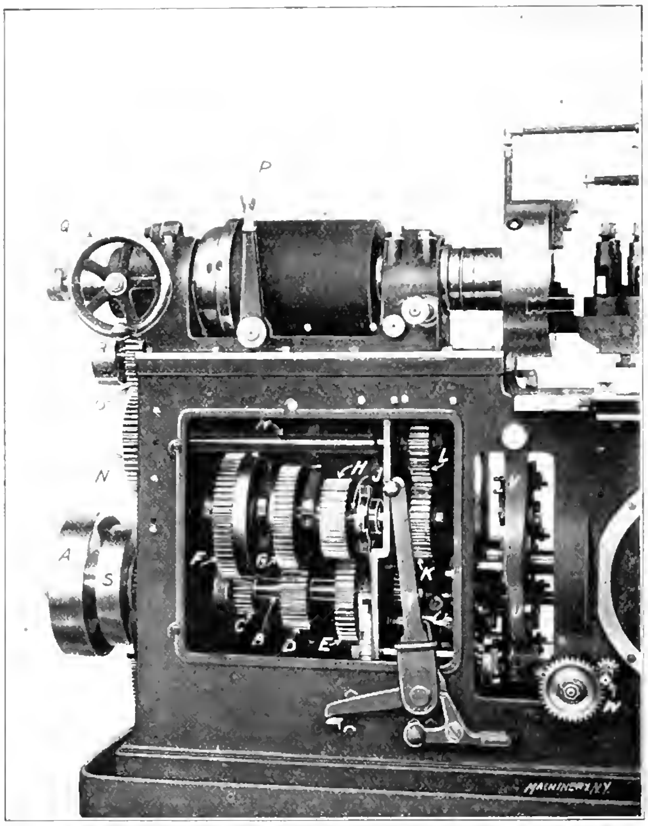

Fig. 3. Door in Base removed to show Spindle Driving Mechanism.

The Speed and Feed Governing Connection.

The feed shaft at the back of the machine, as may be seen in Fig. 2, drives three separate mechanisms. The first connection, through the spiral gearing shown and a set of worm gearing, is with the short shaft on which is mounted the governing disk, seen also in Fig. 1 and at *U* in Fig. 3. To the periphery of the disk are attached dogs which engage a pin on the end of lever *V* at the front of the machine. This lever is mounted on a rock shaft which extends through the machine and is connected in the rear with levers and a link to the mechanism for operating the speed change clutches in the base of the machine for gears *G* and *H*, as previously described. To the left side of the governing disk, in the position shown in Fig. 3, are attached dogs carrying pins which operate a ratchet mechanism, revolving a cam shaft, by means of which the feed shaft is connected with either the constant speed rapid movement, or the slow speed feeding movement operating from the spindle, as desired. The worm shaft by which this governing disk is driven is extended out to the front of the machine, where it is geared to a short stud *W* with a squared end, by means of which the movements may be manually operated when setting up the machine.

The Cross- and Turret-slide Cams and Connections.

The second member driven from the feed shaft in the rear is the cross-slide cam. This is of the cylindrical type, mounted on a shaft extending through the bed from back to front, and driven by worm gearing from the feed shaft. The circular cover plate for the chamber holding the cam may be plainly seen at the front of the machine, below and just to the right of the cross-slide in Fig. 1. This cover plate is removed for giving access to the cam drum when changing the cross-slide cams for setting up new work. The guiding surfaces of the cam operate a roll, fixed to the under side of a square bar, which extends through the machine, with bearings at the front and rear. This bar has rack teeth cut on its upper side at the rear, meshing with a pinion on a stout rock shaft, which in turn is keyed to a sliding pinion held in the cross-slide base. This latter pinion engages the teeth of a rack fast to the cross-slide. It will thus be seen that the movement derived from the cross-slide cam is transmitted through the square bar to the rock shaft, and thence to the cross-slide—a very direct and powerful connection, which still permits freedom of adjustment for the cross slide base on the bed, to suit the work being operated on. The cross-slide carries two tool-post blocks.

A third function of the feed shaft is the driving of the turret slide cam. This cam (which may be seen through the opening in the rear of the bed in Fig. 2), like that for the cross slide movement, is of the cylindrical type and is enclosed in a cylindrical chamber. It is of cast iron, with an inserted steel working face for that part of the surface where most of the wear comes, during the feeding of the tools. It will be seen that this cam is connected with the feed shaft by spur gearing, instead of by worm gearing as in the case of the cross-slide movement. The turret cam with the four-sided turret used makes four revolutions to one of the cross-slide cam, or for each piece of work completed. To avoid the necessity of a complicated automatic turret clamping mechanism, a supporting arm is provided for the turret stem, which stiffens it so as to adapt it for even the heaviest forming cuts.

It will be seen that ruggedness is a prime characteristic of this machine. The bed is one solid piece of double box section, while the turret slide and head-stock are both low and very firmly gibbed to the stiff bed. The machine is built by Potter & Johnston, Pawtucket, R. I., and, as a large proportion of the work for which their older machines are adapted is in the vicinity of 6 inches in diameter or smaller, this machine should find a large field awaiting it.

GOULD & EBERHARDT STOCKING CUTTER.

During the past decade the development of gear-cutting machinery has been rapid, and the improvements in this class of machine tools has perhaps been more radical than in almost any other class of machines. While the development of the gear-cutting machines themselves is of supreme importance, one must not lose sight of the fact that the actual methods of producing the gear tooth, by means of a rotary cutter, have also presented a field for improvement. To obtain good results, if accurate and noiseless running gearing is the object sought, it is required that a gear tooth should first be roughed out with a roughing out or stocking cutter, before the tooth is finally finished with an ordinary gear tooth cutter of the regular type.

Some five or six years ago, the firm of Gould & Eberhardt, of Newark, N. J., brought out what they term their "stepped style" of stocking cutter, for roughing out the teeth of coarse pitch gearing, previous to the finishing operation with a standard gear tooth cutter. The advantages claimed for these cutters over the ordinary square saw or slotting cutter, which had previously been used most generally, was that by having steps provided in the cutter, the chips were broken up, and

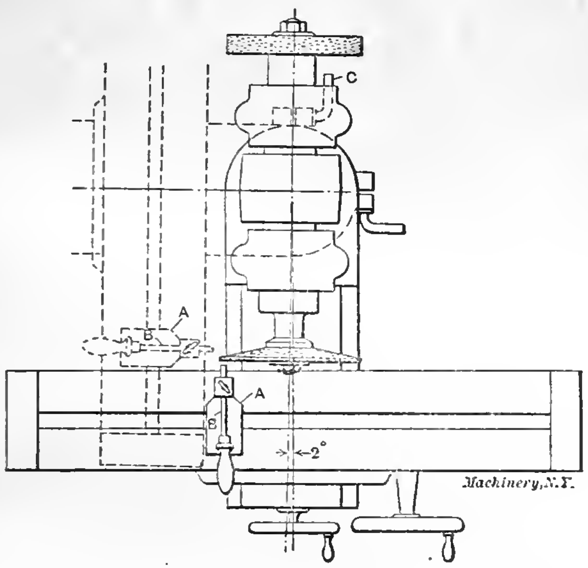
Operations for the Article in this number entitled "Machine Shop Practice—Grinding a Gear-cutter."

SHOP OPERATION SHEET NO. 67.

Ethan Viall. MACHINERY, July, 1908.



Grinding a Gear-cutter—Truing the Emery Wheel.

1. Be sure that there is no play in the grinder spindle, that it runs freely and is well oiled; also see that the table ways are clean and free from grit and have oil enough so that the table can be moved easily.

2. Select a free-cutting saucer-shaped emery wheel about 6 inches in diameter, of medium grade and grain, and one that will not glaze or wear too fast.

3. Place the wheel, with the concave side out, on the end of the spindle which has a right-hand thread on it, which is the end that turns to the left when facing it.

4. Bolt the diamond holder *A* near the right-hand end of the table and clamp the diamond truing tool *B* in place.

5. Swing the knee around until the table is parallel with the spindle, and in the position indicated by the dotted lines. Adjust the table vertically until the diamond point is slightly below the center of the spindle, and then tighten the clamp *C*.

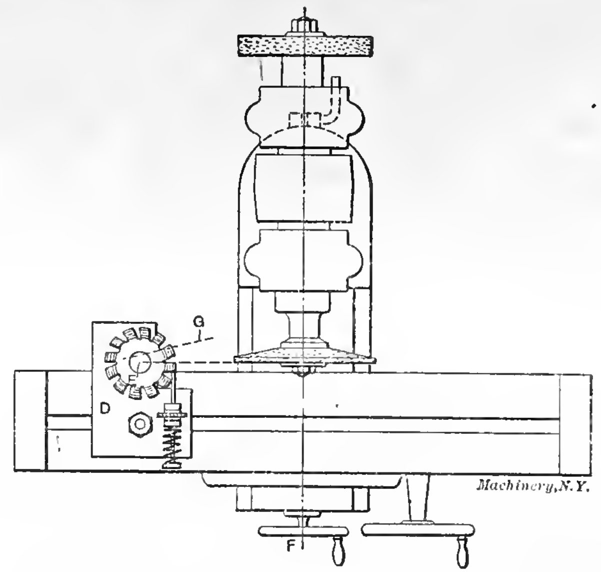
6. Start the grinder, and true up the wheel by feeding the diamond across its periphery.

7. Move the diamond truing tool and holder to the left end of the table. Loosen the clamp *C*, and swing the knee around until its center line makes an angle of 2 degrees with the axis of the spindle, as shown in the illustration, and again clamp the knee.

8. Bring the diamond truing tool into contact with the face of the wheel, and beginning at the edge, true at least a half-inch of its surface, and more if needed. Cut deep enough to remove all old glaze, and to true the wheel perfectly.

SHOP OPERATION SHEET NO. 68.

Ethan Viall. MACHINERY, July, 1908.



Grinding a Gear-cutter—Lining up Center of Cutter with Face of Wheel.

1. After truing the wheel as described in the previous operation sheet, carefully wipe off the table and clean out the slot.

2. Bolt a gear-cutter fixture *D* to the left end of the table, and place the cutter to be ground on the pin *E*, so that the teeth on that side of the cutter which is next to the wheel, will have their faces toward it. Loosen the table clamp and adjust the table vertically until the centers of the cutter teeth are the same height as the center of the grinder spindle.

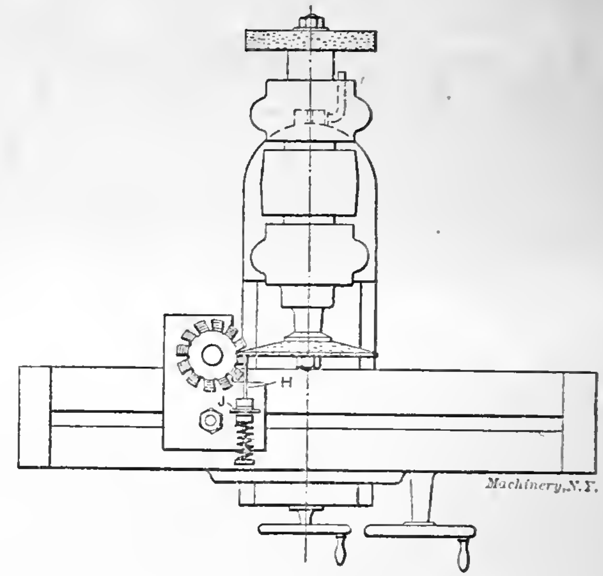
3. Carefully line up the table so that it is parallel with the face of the wheel. If there are no graduations on the machine for this purpose, set the table with the trued surface of the wheel, using a straight-edge.

4. With the jig and cutter far enough to the left to be clear of the wheel, lay a straight-edge across the face of the wheel and move the table out or in by means of the wheel *F* until the center of the pin *E* holding the gear-cutter is exactly in line with the outside face of the wheel. When the cutter is set in this way, the faces of the teeth will be radial or in line with the axis of the cutter.

NOTE.—It is important that the teeth of a gear-cutter be ground radially in order that the form of the teeth shall not be changed. If the top of a tooth is ground back faster than the base, and the face of the tooth be in the plane indicated by the line *G*, the shape of the tooth space cut is distorted, and a gear with badly shaped teeth is the result. In addition to this, the cutter works badly owing to the negative rake.

SHOP OPERATION SHEET NO. 69.

Ethan Viall. MACHINERY, July, 1908.



Grinding a Gear-cutter—Setting the Stop and Grinding.

NOTE.—It is assumed that the axis of the cutter is in line with the face of the emery wheel, and that the wheel has been trued.

1. Adjust the table longitudinally until the edge of the wheel rests against the bottom of one of the flutes between the teeth of the gear-cutter, and then tighten the table stop in the proper position to prevent the wheel from grinding the flute to a greater depth.

2. Turn the gear-cutter until a tooth rests lightly against the face of the wheel, then adjust the spring-stop *H* against the back of the tooth so that the cutter can be indexed freely, and also so that it will be held firmly against the wheel.

3. Move the cutter to the left until it is clear of the wheel and start the machine.

4. Carefully grind each tooth in turn, taking light cuts, then feed the teeth forward slightly by turning the knurled nut *J* which feeds the spring-stop *H*. Continue grinding until all cutting-edges are sharp and even.

NOTE.—When grinding cutters, light cuts must be taken to prevent the temper from being drawn from the cutting-edges, which would, of course, spoil the cutter. The face of the wheel which comes in contact with the work should be narrow, especially for dry cutter grinding, in order that the heat generated may be reduced to a minimum. If the cutter gets warm while grinding, remove it and cool in water. A moderately heavy and well-balanced wheel placed on the opposite end of the spindle will cause the grinder to run more steadily.

IX.—TABLE OF IDEAL MOMENTS.

All values may be read in hundreds or thousands of inch pounds.

M_t = Torsional Moment

M_b = Bending Moment

T = Ideal Torsional Moment

B = Ideal Bending Moment

$T=\sqrt{M_t^2+M_b^2}$ and $B=M_b+\sqrt{M_t^2+M_b^2}$

These ideal moments being for use with the Polar Section Modulus.

The values at right of heavy zig-zag line across upper right-hand corner are for the bending moments 2,000 to 4,500, inclusive, in right-hand column.

Contributed by John S. Myers.

Contributed by John S. Myers.

consequently less power was consumed by the operation, and the strain on the machine and parts was not as great. At the same time, the lower step of the cutter removed the wide flare of the gear tooth space between the top of the teeth which the square stocking or slotting cutter did not do, and in this way left a more nearly uniform amount of metal all around the tooth outline to be removed by the finishing cutter.

Fig. 1. Gould & Eberhardt Improved Stocking Cutter for Gear Work.

While this idea was not new at the time, it was the first time that cutters of that kind were manufactured for the trade. Since then the firm has still further improved this class of cutter, and has recently brought out and patented a new stepped style of stocking cutter, shown in the accompanying illustration, Fig. 1. The improvement embodied in the new form will be most readily seen by comparing the new and the old style as shown in the accompanying line engraving, Fig. 2, where the new style is shown to the left, and the old style to the right. It will be seen that the new stocking cutter finishes the bottom of the tooth space, thereby relieving the finishing cutter of this duty, and saving the latter where it usually wears out first. It also approaches the finished outline at the top of the tooth more closely than did the old style. The essential feature of improvement, however, is the recessing of the tops of the cutting teeth, as shown most plainly in the half-tone illustration, Fig. 1, so that each tooth practically cuts out about half as much as formerly. This permits a maximum amount of stock to be removed with a minimum amount of power consumption, because the cutting edges, being staggered, will be more thoroughly lubricated while cutting. As com-

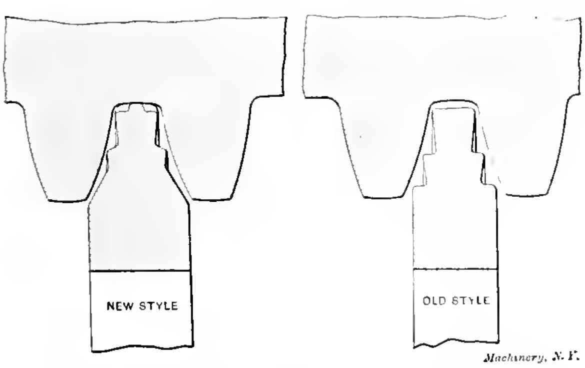

Fig. 2. Comparison between New and Old Form of Stocking Cutter, Indicating Improvement embodied in New Design.

pared with the ordinary saw stocking cutters, the superiority of the new design needs, of course, no demonstration. The large corners left by saw stocking cutters are entirely removed by the present design, and the cutters can be made considerable wider at the hubs, thus lessening the liability for the keys to shear off; in consequence of all this, faster speeds and feeds are permissible without the strains on the machine itself being increased, but rather lessened.

MOTOR DRIVE FOR THE FOX LIGHT MILLER—UNIVERSAL DIVIDING HEAD.

The Fox Machine Co., 815-825 North Front Street, Grand Rapids, Michigan, has been for a number of years building small hand and power milling machines for light manufacturing, having originally become interested in this line from filling the requirements of the Fox Typewriter Co., an allied corporation. The company has recently designed a belt-connected motor drive for its line of small millers which is interesting in the simplicity of its adaptation to machines of standard type, as well as in its effectiveness. The machine to which this drive is applied in Fig. 1 is a No. 3½ hand and power feed milling machine of the builder's standard design, which was furnished to the Charleston navy yard and built to meet the requirements of the government's standard specifications for motor-driven machines.

As shown, the miller is mounted on a supplementary floor base, which is also provided with suitable connections for supporting the motor. The latter, as may be seen, is hinged at the left-hand side to this base, and is supported on the right by the short end of a foot lever, whose outer end is connected with a treadle and a foot-operated catch, by means of which the motor may be raised about its hinge or allowed to fall by gravity, at the will of the operator. A counter-shaft carrying a cone pulley and a driving pulley is supported over

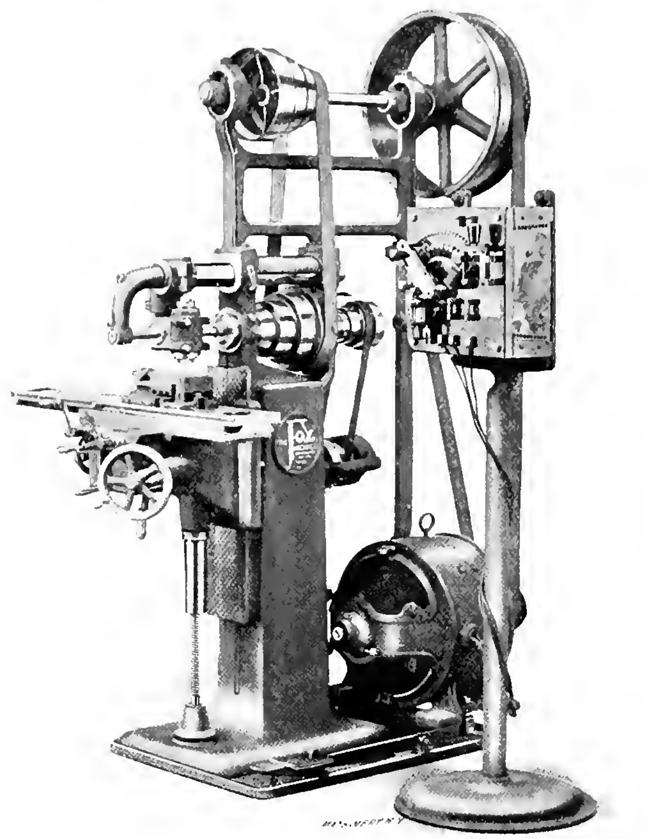

Fig. 1. The No. 3 1-2 Fox Light Miller, arranged for Motor Drive.

the machine by a cast framework, attached to the top of the milling machine column and to the motor base. The driving pulley on this counter-shaft, which has two diameters and is flanged, is belted to the double flanged pulley on the armature shaft. The hinged connection of the motor and the foot lever operated movement provided for it, are employed for starting and stopping the machine. The raising of the motor slackens the belt and thus stops the counter-shaft, while the dropping of it tightens the belt so that the whole power of the motor may be transmitted. It will be noted that the arrangement permits the use of a cemented or "endless' driving belt.

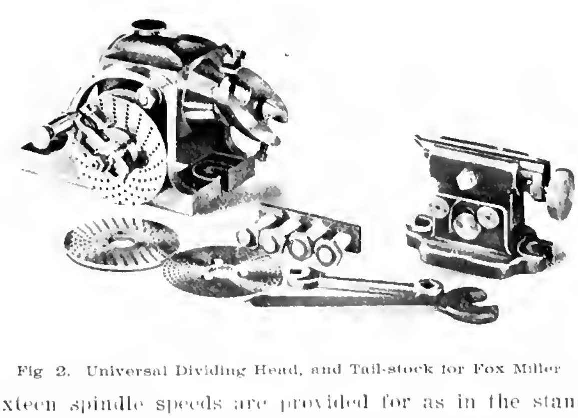

Fig. 2. Universal Dividing Head, and Tail-stock for Fox Miller

Sixteen spindle speeds are provided for as in the standard belt-driven machine with double friction counter-shaft. This number of speeds is obtained from the two-step armature and counter-shaft pulleys, the four-step driving cones and the back gearing of the machine. In the particular case shown, a variable speed motor is used, still further increasing the num-

ber of speed changes. The starting switches and controller are mounted on a pedestal, as shown, which may be set in any position convenient for the operator.

Among the accessories with which these machines are provided may be mentioned the vertical milling attachment shown in place on the machine, and the dividing head shown in Fig. 2. The former is provided with an angular adjustment which may be swiveled through an arc of 90 degrees from the vertical to the horizontal. By reversing it, it will cover this range in the other direction, giving a full movement of 180 degrees. It may be adjusted transversely of the spindle as well from any convenient distance from the base of the column.

The universal dividing head- and tail-stock shown in Fig. 2 are new and are especially designed for the No. 3½ miller, though they may be used on other sizes of the builder's machine for small work. The spindle is held in a long taper bearing and may be securely locked by the knurled thumbscrew shown at the top. The spindle may be elevated to any angle from the horizontal up to the vertical, and when in the latter position is especially stable, the height of the work above the table being reduced to a minimum. The tail center may be raised or lowered or tilted for taper work. The index plates furnished are drilled on a special automatic machine having a master worm gear 18 inches in diameter, thus insuring great accuracy. They give all divisions from 2 to 50, and the principal divisions up to 360. The device will be found useful for cutting small gears, milling squares, hexagons, etc., fluting taps and reamers, and doing a large variety of other work of this class.

BARNES SLIDING EXTENSION GAP LATHE.

The Barnes Drill Co., Inc., 602 South Main St., Rockford, Ill., is building the extension gap lathe shown in the two accompanying half-tones. The advantages of this form of gap lathe are well-known and indisputable. Essentially, the idea consists of mounting the bed of the lathe on a base on which it may be adjusted longitudinally close up against the head-stock, or as far away from it as may be necessary to suit the width of any work of such diameter as to require the use of the gap. Fig. 1 shows the lathe with the gap closed for ordinary work, while Fig. 2 shows it extended, with the large swing face-plate in use. This design has an advantage over the lathe of fixed gap in that the width of the opening between the shears and head-stock may be made as little or as much as is required to swing the work, thus making it possible to bring the carriage and tool close up to the surface being turned. It obviates the necessity also for a filling-in piece, such as is sometimes used for extending the ways across the gap to support the carriage on ordinary work, for cuts close to the live center.

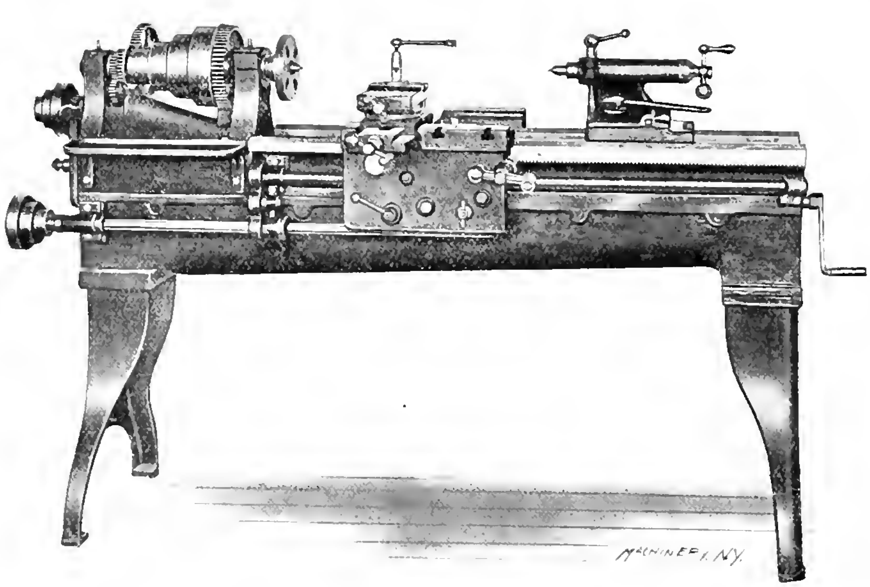

Fig. 1. The Barnes Sliding Extension Gap Lathe.

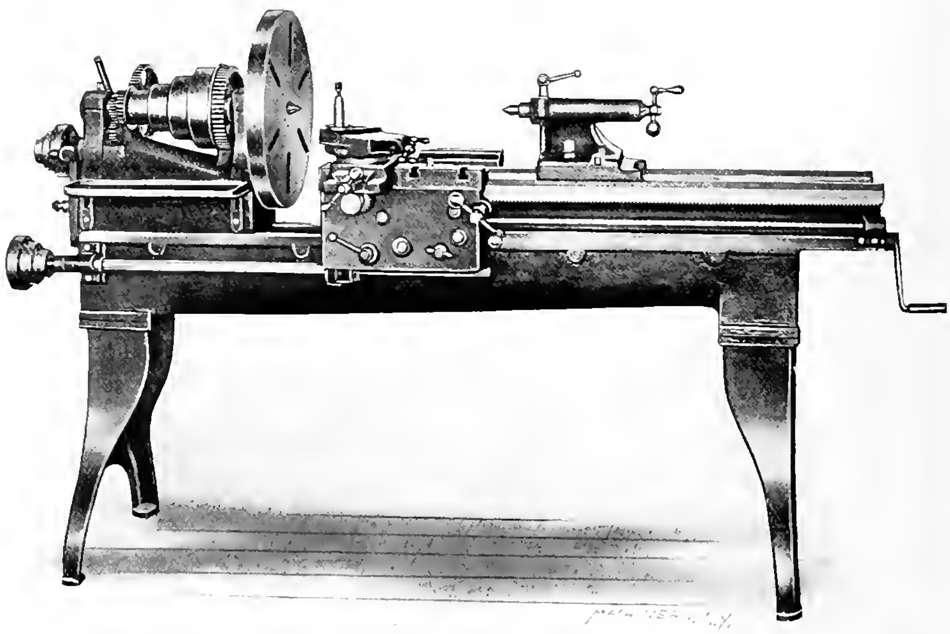

Fig. 2. Lathe with Supplementary Bed shifted, opening Gap for Full Swing.

The upper bed is adjusted on the base by means of a screw operated by a crank, shown at the rear end. The two beds are fitted together by dove-tail construction which permits them to be firmly clamped together at any adjustment by means of clamp bolts passing transversely through the main bed. The carriage has the cross-slide bridge located to the left, so as to bring the tool close to the work. For large diameter cuts, the cross-slide ways are extended in front to make provision for facing up to the full diameter without overhanging the tool or the tool-holder. Power cross feed and a compound rest are provided. The carriage is fitted to the bed with a V-bearing in front and a flat bearing at the rear. It is gibbed at the rear and may be clamped for cross-slide work. It is also fitted with T-slots for holding work for boring, etc.

The lathe is arranged for screw cutting as well as for turning. The splined feed-screw is carried well up under the ways, as in the lathes of standard construction, but is connected by gearing to a splined driving shaft, which is carried down below the gap so as not to interfere with work of the full diameter. The three-step cone pulleys may be used for the feeds, or they may be removed and the connections made with change gears for positive turning feeds or screw cutting.

The head-stock gearing gives the necessary power for turning full diameter of the gap. The head-stock casting is heavy and strong. The spindle is hollow, made from a good grade of steel, accurately ground and running in bronze bearings, carefully scraped and fitted. The cone pulley has four steps and is back geared, giving eight changes of speed in all. A push pin connection is used for locking the gear with the cone, so that a wrench is not required when throwing the back gears in or out.

The lathe is furnished with a friction counter-shaft, change gears, center rest, large and small face-plates, and the necessary wrenches. The swing over the carriage is 8½ inches; over the bed, 13 inches; and over the gap, 22½ inches. A

lathe with a 5½-foot bed takes 36 inches between the centers when used as an ordinary lathe, and 54 inches when extended; the gap opens 18 inches wide. It will be seen that the extension feature of the bed is useful in increasing the distance between centers, as well as in giving greater swing. The arrangement is such that when used as a simple lathe it has all the conveniences expected in machines of its type, the gap feature being obtained without any sacrifice of utility of ordinary work. The machine should be especially useful for garages and repair shops.

A REMARKABLE BROACHING MACHINE AND ITS WORK.

We show in the accompanying half-tones a Lapointe broaching machine provided with special cutting tools, and engaged on what is, without much doubt, the heaviest broaching operation ever undertaken. The size of the hole to be broached is approximately 8 inches square, though the hole is not really square, being of the special shape shown in Fig. 2. Not only is the work remarkable on account of its size, but also in the fact that the surfaces had to be broached on a taper, the outer end of the hole being ½ inch further across than at the bottom, while the work is rendered still more difficult from the fact that the opening is closed at the small end. Thus the only way of broaching is to commence at the bottom and work outward. A recess 3 inches long and about

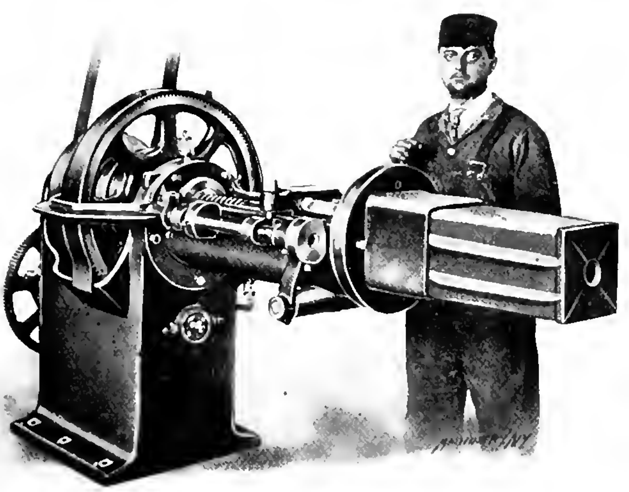

Fig. 1. The Machine with the Work in Place.

¼ inch deep is furnished at the bottom, however, to allow the starting of the broach. The stock to be removed on each of the finished surfaces of the work is about 1/16 inch thick; the total area to be broached is 14 inches long, with a developed width of 24 inches. In the center of each face of the hole, it will be noticed that there is a half-round recess; no broaching is done in this part. This piece of work is a steel casting.

The machine used is the largest of the line of broaching machines made by the builder, the Lapointe Machine Tool Co., of Hudson, Mass. The construction of these machines has been previously described. (See New Machinery and Tools, in the July, 1907, and May, 1908, issues of MACHINERY.) The mechanism consists primarily of a threaded draw bar or ram, operated by a revolving nut, driven by suitable gearing and reversing mechanism, this mechanism being operated by dogs and adjustable stops to give the required length of operating and return strokes. Practically the only special feature of the equipment is the special broaching head and broaches used. These are of such unusual size and ingenious construction as to be of decided interest.

Fig. 2. The Hole which is to be Broached.

The construction of the broaching head is perhaps most plainly shown in Fig. 3. It consists essentially of a central square mandrel, tapered to the taper of the hole to be finished in the work, and provided with ways in which slide four separate broaches, one for each corner of the work. These broaches are connected with the head of the ram of the

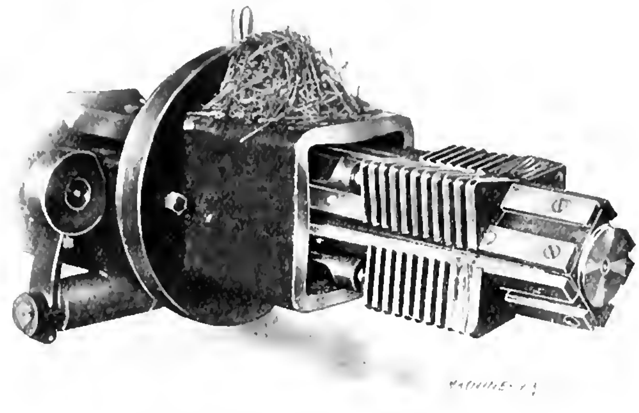

Fig. 3. The Taper Broach and the Chips it produces; note the Flexible Pulling Rods.

machine by bars, which are milled down to such a thinness as to have sufficient flexibility to permit the broaches to spread apart as they approach the inner end of the stroke, and come together again as they return to the starting position on the outer end of the mandrel. Each of the broaches is made of a solid piece of tool steel, with a series of 13 teeth of suitable shape milled in it.

In operation the ram is first extended to the outer limit of its stroke, with the broaches at the outer and smaller end of the square central mandrel. The work is then placed over the mandrel as shown in Fig. 1, in which position the broaches nearly touch the closed bottom of the hole. The outer teeth in this position are in the recess. The machine is then started up, and the revolving nut, and threaded ram pull the broaches up on the tapered guides of the square mandrel, by means of the flexible pulling rods. As the broaches are thus drawn inward on a gradually expanding form, they cut the required shape in the interior of the steel casting. The broaches first are tapered, so that the outer end is 1/32 inch larger than the end to which the pulling rods are connected, this being the amount which is to be removed from the work in each operation.

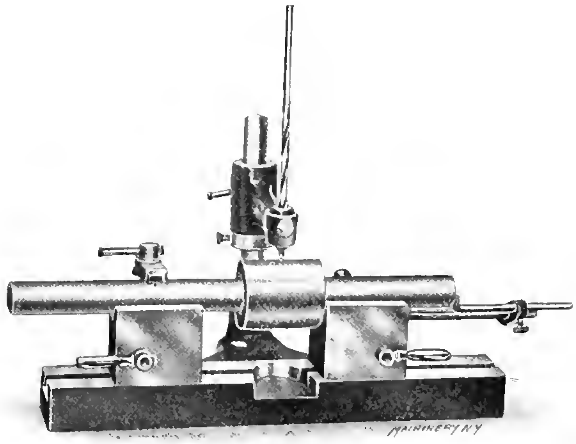
As is shown in the engraving, a special abutment or base is provided for taking the thrust of the work as it resists the action of the cutters. Piled up on this special base, in Fig. 3, will be seen the chips produced at one stroke of the machine. It will be noted from their character that a cutting action of the most desirable kind is effected by the broaching blades, indicating that the work is done in a very superior way. The approximate pulling strain on the four rods operating the broaches is estimated by the builders to be from 75 to 100 tons.

ADJUSTABLE DRILL JIG.

The Cleveland Specialty and Mfg. Co., 3001 Searsdale Avenue S. W., Cleveland, Ohio, has brought out an interesting adjustable drill jig, as illustrated in the accompanying halftone. This jig is intended to eliminate the laying out of certain classes of work for drilling, and is intended particularly for circular pieces of work which can be placed in the V-blocks shown. It is, of course, especially valuable when drilling duplicate pieces of this character. A great deal of time is spent in laying out simple work for drilling, hunting for V-blocks and clamping devices, and placing the work on the drill press; and, finally, when the piece is drilled, it is often found that the hole has not been correctly located, on account of defective lay-out or setting up, or because the drill has run out.

Difficulties of this kind will be eliminated by the use of this adjustable jig. The design is very simple. The base of the device is finished at the bottom, where it rests on the drill press table, and on the top, where two V-blocks slide back and forth. The blocks are provided with dovetails to fit a corre-

sponding dove-tail slot in the base. The levers shown at the front of the V-blocks serve the purpose of clamping them in place wherever desired. A clamping device for fastening the work in the V-groove is provided, as indicated in the engraving, and at the right-hand end an adjustable stop is arranged for. This can be extended out to any length required for long pieces, or pushed in close to the V-block for short pieces. The stop and the clamp may be used on either block, and when



Cleveland Specialty Co.'s Adjustable Drill Jig for Cylindrical Work.

short pieces are being drilled, one V-block only may be employed. In the middle of the base-block at the back of the device is a boss which supports a steel stem on which the arm holding the drill guide bushing is mounted. This arm can be adjusted up and down on the stem to suit the work, and it can also be swung to one side if it is required that a larger drill or reamer should follow the first drill, so the drill bushing does not have to be removed for this purpose.

As a great deal of the drilling work in most machine shops consists of drilling and reaming pin-holes in shafts, holes to be tapped for set-screws in collars or levers, spotting of shafts for set-screws, etc., and, as it is seldom considered profitable to build special jigs for these purposes, a universal appliance like the one shown, will undoubtedly prove of value in nearly every machine shop where there is a premium placed on the accuracy and rapidity of the operations performed.

KELLY ADJUSTABLE REAMERS.

The accompanying half-tone illustration and line engraving show the appearance and application of a new type of reamer and boring tool, placed on the market by the Kelly Tool Co., Cleveland, Ohio. As will be seen from the half-tone, which shows a front view of the tool, it consists of a rectangular holder into which are inserted two cutters, one on each side of the holder, and inclined at an angle of 45 degrees. These

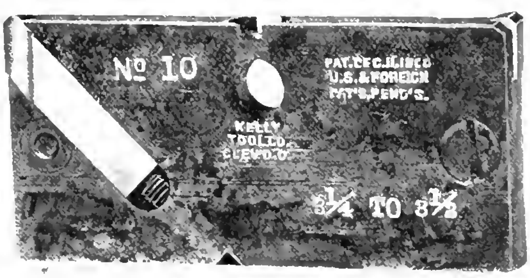


Fig. 1. The Kelly Adjustable Reamer and Boring Tool.

cutters constitute the cutting edges of the reamer, and are adjustable, so that each size of reamer covers a range of ¼ inch, the reamers being made in seventeen sizes, from 1 inch up to 5¼ inches. The tool may be used as a boring tool, as well as a reamer, the cutters being held absolutely rigid in position by the binding screws, the head of one of which is shown near the right-hand edge in the half-tone illustration. The reamer holder, as shown in Fig. 1, is in turn held in a bar, as indicated in Figs. 2, 3 and 4. In Fig. 2 is shown a bar used either for "floating" or rigid work, a pointed screw being used to hold the holder in place when it is not desired to have it floating. Fig. 3 shows the arrangement used when the tool is used for work where it is required that the cutters finish a hole clear down to the bottom. It will be seen that the holder is held by a plate on the end of the bar, fastened in place by four screws, and also by a screw passing through the tapered hole on its center line. Finally, in Fig. 4, the tool is shown placed in a boring-bar, and used as a double boring cutter, permitting the use of the front end of the bar as a guide or pilot.

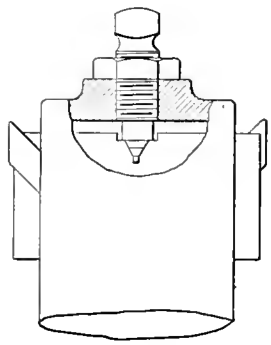

Fig. 2

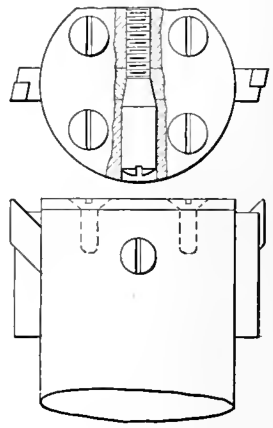

Fig. 3

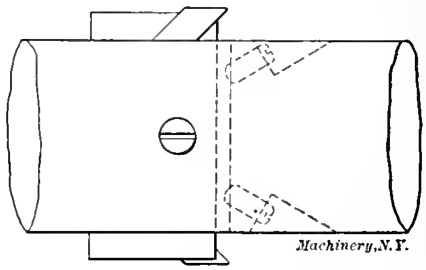

Fig. 4

Figs. 2, 3, and 4. Different Applications of the Kelly Adjustable Reamer.

The simple construction of this tool, including the adjustable features, the comparatively small number of tools necessary for the complete set, the ease of setting and adjustment, all tend to make it valuable in machine tool work, and its application to any kind of turret machine, lathe, boring mill or drill press, makes it as universal a tool as can well be conceived of.

LUCAS HORIZONTAL BORING, DRILLING AND MILLING MACHINE.

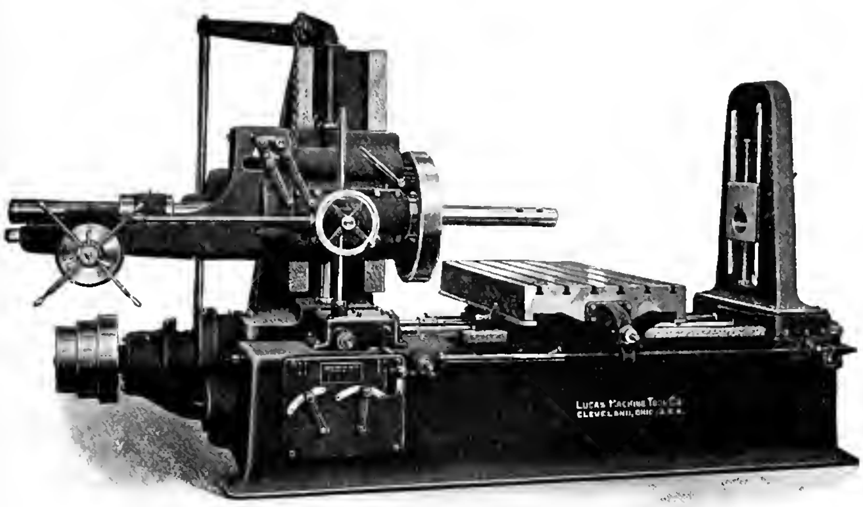
The machine illustrated in the accompanying half-tone is quite extensively used in railway shops on account of its adaptability to a wide range of work. Special attention has been given in the design and construction of this machine to the production of a high-grade manufacturing machine, equally useful for tool-room work requiring great accuracy and for general manufacturing where power and rigidity are the principal essentials. A good example of the work which is being done on it in railroad shops is a tumbling shaft in which the holes may be bored, and the hubs faced parallel and true with the holes by milling, at one setting; also, air pump cylinders, which may be bored, and both ends faced by milling, at one setting.

The principal feature of this machine is the raising and lowering of the spindle head, which is a constant weight, instead of raising and lowering the platen with its load, which is widely variable. This construction allows the use of a deep box bed of great stiffness, which gives a solid foundation to the other members of the machine, and keeps them in accurate relation to each other in all positions and eliminates the necessity of building a foundation under the machine. As a foundation is not necessary, the location of the machine is not confined to the ground floor.

The advantages offered by this machine are, in short, that work can be bored, drilled, and milled at one setting, and all the work done accurately without any measuring, trying or

"papering up," all of which the precision screws and the graduated dials make unnecessary. Further, this construction allows the addition to the machine of a vertical power feed for milling purposes, which is a most valuable feature for many classes of work.

The spindle is made of un-annealed hammered crucible steel, and is accurately ground its entire length, and has a long bearing in the sleeve. It is forged and rough turned at least six months before it is finished, and is allowed to season between every operation. The front of the driving gear forms a face-plate to which the facing head or face milling cutters or other large tools may be attached.



Lucas No. 3 Precision, Horizontal Boring, Drilling, and Milling Machine.

Milling feeds to platen and head (which includes the outer support for the boring-bar) make the machine universal and capable of finishing at one setting many kinds of pieces which would otherwise require resetting and finishing in other machines, and the addition of a graduated revolving table allows holes to be bored and drilled and surfaces to be milled at various angles. A power cross-feed is provided for the platen to make the machine complete for milling purposes. This greatly increases the usefulness of the machine and makes it easy to do many jobs which would otherwise be difficult. It may be mentioned that the length of the cross-feed to the platen is sufficient so that one job of boring may be made ready on one end of it while the machine is boring another piece on the other end.

The yoke is adjusted along the bed with a wrench, and as there is a geared connection between the two screws that respectively adjust the spindle head and the outer support for boring-bar, which is in the yoke, the outer support is kept in automatic alignment with the spindle, and cannot be thrown out by chips getting under the yoke, because it is fitted to the bed. The yoke may be altogether removed and then put back in its original position without destroying the alignment of the outer support for the boring-bar with the spindle, which is a valuable feature where it is required to do work on pieces which are longer than the nominal capacity of the machine. The outer support for the boring-bar is bored out after the machine is assembled, which insures its perfect alignment with the spindle.

The driving gears in the speed box are made of steel and are controlled by two levers on top, giving nine changes of speed. The two levers on the head of the machine, which are interlocking, multiply these speeds by two, giving a total of 18 changes of speed in geometrical progression. At each spindle speed, only such gears are in mesh as are used to obtain that speed, and there is therefore no friction loss due to the revolving of idle gears. The driving pulley runs on a stationary bushing. The main driving clutch is operated by a lever at the front end of the machine, within easy reach of the operator, and when the machine is stopped, only the driving pulley continues in motion. A direct connected motor drive can be applied if desired.

The feed motion is taken from one of the driving shafts which runs at a higher speed than the spindle. This makes it possible to obtain coarse feeds without gearing up, thus avoiding excessive strain on the feed gears and bearings. The fine feeds are obtained by reduction gearing. Another point of advantage of the arrangement is that it gives two series of feeds, a coarse series with the back gears in and a fine series with the back gears out. This gives a greater total range of feeds without excessive increments. There are 18 variations of feed, 9 for either position of the spindle back gears from 0.005 inch to 0.537 inch per revolution of spindle. The rate of feed is the same for every part to which it is applied.

The adjustments of the spindle head, the outer support for the boring-bar and the platen are made by precision screws. The screws are provided with dials graduated to read thousandths of an inch, thus allowing holes to be bored or drilled, and surfaces to be milled an exact distance apart, making it possible to produce interchangeable work without the use of jigs, or jigs may be originated on the machine more quickly and accurately than by any other method. The platen is of extra size and thickness and has six finished T-slots. It will be noticed that it is especially deep, the aim being to make it so stiff that with ordinary care, there will be no appreciable springing when work is clamped upon it.

The machine is regularly supplied with automatic feed to the spindle, automatic cross-feed to the platen and vertical feed to the head. The head and outer support for the boring-bar may be quickly moved by power, and may also be moved by hand from both the front and end of the machine.

This machine is at present the largest of the various sizes made and sold by the Lucas Machine Tool Co., Cleveland, O., and has a spindle 4 inches in diameter with 60 inches total traverse; the greatest distance between the face-plate and outer support for the boring-bar is 6 feet; the greatest distance from the top of the platen to the center of the spindle is 26 inches; and the platen, which is 30 inches wide and 48 inches long, has a cross-feed of 36 inches.

THE LANDIS CORRUGATED GRINDING WHEELS.

An interesting departure in the making of grinding wheels is illustrated in the half-tone below, which represents the construction of the Landis corrugated grinding wheels, invented and placed on the market by Ezra F. Landis, Waynesboro, Pa. It will be noticed that the corrugations in both of the two styles of wheels shown extend from the sides of the wheel to the center, and leave no continuous or unbroken cutting surface on the periphery of the wheel. This construction insures a much greater positive cutting action of the wheel, the principle of cutting being similar to that of a milling cutter. Comparative tests, undertaken with two 8-inch carborundum wheels, one of the ordinary plain

Corrugated Grinding Wheels for Rapid Grinding.

type, and the other of the corrugated type illustrated, on a plain grinder, using a lever with a weight to press the work against the wheel, indicated that with this construction of wheel it is possible to cut nearly four times as much as with a plain wheel, both wheels being of the same grit and grain. The increased wear on the corrugated wheel was only 25 per cent, in spite of the increased efficiency, and this amount of wear can be reduced by using a much harder wheel when corrugated. The advantages claimed for this construction, however, are not only that it will increase the cutting capacity, but that a wheel made on the corrugated principle will cut all kinds of stock, aluminum, hard and soft steel, wrought or malleable iron, bronze, brass, copper, hard rubber, wood fiber, leather, bone, ivory, marble, granite, and in fact anything grindable, with a great deal less liability to glazing of the wheel. These wheels are made either of carborundum, emery or corundum, and by either the vitrified or silicate process.

CLIMAX CHAIN BLOCKS.

The Climax Hoist Co., 1753-55 North Howard Street, Philadelphia, Pa., has designed and constructed a line of hand-operated chain hoists which are believed by their builders to combine a great number of points of excellence. The purpose of the designer (an engineer of long experience in hoist and crane work) has been to produce a high degree of efficiency, simplicity and durability, with a low manufacturing cost, in such a way as to give great value for comparatively little money.

The exterior of the hoist is shown in Fig. 1, while the construction may be followed from the line engraving, Fig. 2. Its simplicity will be at once appreciated. The hand-wheel *A* is threaded to the hub of the friction plate *B*, the latter being fast to the driving shaft *C*. To the other end of *C* is fastened the driving pinion *D*, which meshes with the internal gear *E*, mounted on a stationary stud supported by the cover *F*. The

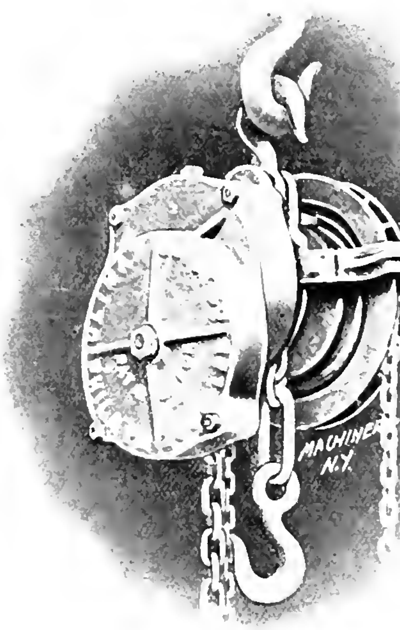


Fig. 1 The Climax Hoist

teeth of the pinion formed on the hub of *E* engage the internal teeth of the load gear *G*, on whose extended hub is keyed the load chain sprocket *H*. The long hub on *G* is supported by roller bearings at *J* and *J* in the main frame *K*; this hub also serves as the bearing for driving shaft *C*. Gears *G* and *E* run submerged in oil in casing *F*.

It was stated that sprocket wheel *A* was threaded to the hub of friction plate *B*. This is required by the automatic brake mechanism, which is provided to keep the hoist from running backwards under a heavy load when the workman releases the hand chain *L*. In lifting work by the hand chain, the sprocket wheel is turned in a clock-wise direction, as indicated in the sectional view, Fig. 2. In doing this it is screwed inward on the hub of *B* until it clamps between the flange on *B* and its own web, friction washers *O* and ratchet plate *P*, thus making *A*, *O*, *P*, *O*, and *B* revolve as a solid unit, raising the work through the medium of the gearing previously described. If the hand chain is released, the load tends to revolve shaft *C* and friction plate *B* backwards. This, however, is prevented by the ratchet teeth on *P* which engage with the pawl *Q*, which is fast to the casing of the hoist. By this means the rotation of *C* is prevented and the work remains safely suspended.

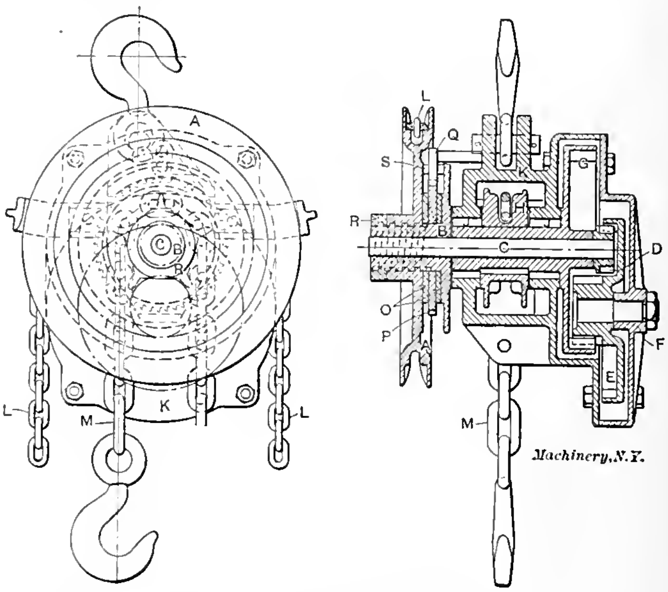

Fig. 2. Elevation and Section showing Gearing and Automatic Brake.

When the operator desires to lower the load, the left-hand side of the chain *L* in Fig. 2 is pulled, revolving the sprocket in a counter clock-wise direction. This unscrews sprocket *A* on the hub of *B* from contact with friction washers *O* and ratchet *P*, leaving *B* and drive shaft *C* free to be revolved by the load, which is thus allowed to descend. If the load has been removed so that there is not enough weight to cause the mechanism to run back by its own weight, the continued pulling of the left-hand chain screws the sprocket wheel against collar *R* on the hub of *B*, which is thus positively revolved in the proper direction to lower the hook.

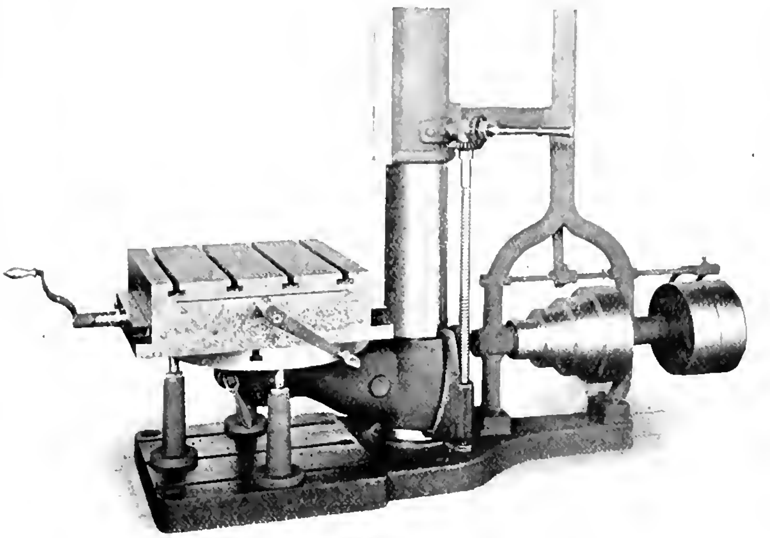
On the other hand, if the workman has been lowering the load, as previously described, and he removes his hand from the chain, the mechanism is positively braked as follows: The turning of the hand-wheel by the operator in a clock-wise direction having ceased, this latter is quickly brought to a stop by the action of friction plug *S* in pawl *Q*. This friction plug serves the double purpose of arresting the movement of sprocket-wheel *A*, and of keeping the pawl in contact with ratchet plate *P* when required. The plug is forced against the web of *A* and the flange on *B* by a spring in its interior. Wheel *A* thus being arrested and the motion of *B* continuing under the weight of the descending load, *A* is immediately screwed inward on the threaded hub of *B*, clamping friction washers *O* and plate *P*, thus arresting the movement of all of these parts against pawl *Q*. When the wheel is being revolved in the opposite direction friction plug *S* raises pawl *Q* so that there is no disagreeable clicking sound, as would be the case if it were held in contact with the ratchet by a spring. As soon as the wheel starts to revolve in the other direction, however, this same plug brings it quickly into contact with the ratchet.

The points of superiority claimed for this design of hoist are—low cost, due to the few parts and simple construction; high efficiency, also resulting from the simple construction, from the use of roller bearings for supporting the load, and from the fact that the gears are enclosed and run in oil; and durability. The parts are all interchangeable so that superior construction is attained at low cost, and repairs are easily effected.

This hoist is arranged with different load chain connections, in seven sizes, to lift from 1,000 to 10,000 pounds.

COMPOUND TABLE FOR UPRIGHT DRILL PRESS.

The illustration shows a compound table for upright drilling machines made by the Mechanics Machine Co., Wyman and Mill Sts., Rockford, Ill. It can be applied to the machines built by this company or to any other drill press. The table is of the European type generally used abroad, being made with two slides at right angles. Combinations of the two movements bring any part of the work directly beneath the drill spindle. The top of the table is provided with four T-slots for bolting down work. The dimensions are 18 x 20 inches, and the



The Mechanics Machine Co.'s Compound Drill Press Table.

sliding movements are 13 and 16 inches. A compound table is a useful adjunct to the drilling machine for work other than drilling, it being practicable with it to use a well-built machine for a variety of milling and profiling operations.

KEARNEY & TRECKER THREE-SPINDLE ATTACHMENT FOR MILLING SPIRAL GEARS.

The arrangement shown in the accompanying half-tone and line engraving was built by the Kearney & Trecker Co., of Milwaukee, Wis., for a manufacturer of cream separators, to be used in cutting the halves of the herringbone pinions which form a part of the drive for the separator bowl. Since these were to be made in great quantities, it was considered worth while to plan out quite carefully the problem of manufacturing them as cheaply as possible. The very satisfactory result of this planning will be appreciated from a study of the device as built.

The arrangement consists essentially of an adjustable attachment fastened to the face of the column for supporting and driving a long spindle carrying three cutters; and of corresponding means for indexing and supporting three work arbors, holding as many gangs of pinion blanks. The cutter arbor, which is in reality an auxiliary spindle, has bronze bearings adjustable for wear. It is carried in a frame, which supports it at right angles to the main spindle, and is connected by spur gearing at the upper end with the short secondary shaft, which is, in turn, connected with the main spindle though a pair of bevel gears. The spur gearing runs in an enclosed box, submerged in oil, the same oil being used to lubricate the bearings. This drive permits the spindle of the attachment to be set to any angle, so that it is unnecessary to swivel the table, as is the practice when cutting the spirals in a universal milling machine. The machine used in this case is one of the builders' No. 2A manufacturing milling machines, which is not furnished with table swivelling adjustment. Of the three cutters carried by the spindle, two are supported between the main and outer bearings, and the third on the overhanging end of the arbor. In these positions they are centered with the three work arbors provided.

The dividing head is provided with means for rotating the work for the spiral cutting, and for indexing for the number of teeth, all three work arbors being connected and operated simultaneously for these movements. The construction of the head will be best understood from the line drawing, Fig. 2. The feed-screw *A* of the milling machine table is connected with the worm-shaft *B* of the head, through simple change gearing. This is done to avoid complication as much as possible. It is often possible to use simple in the place of compound gearing for obtaining spirals of given lead, if the calculations are carefully made. Idlers between the table feed-screw *A* and worm-shaft *B* are used for changing from right-hand to left-hand spiral, or *vice versa*.

The connection between the last gear, *C*, of the change gear train and the worm-shaft *B*, as shown, is effected through the index plate *D*, and the index crank and pin *P*. The plate provided has as many holes as there are to be teeth in the gear, being specially made in this way so as to avoid all possibility of error in dividing.

Worm-shaft *B* and the worm formed on it drive worm-wheel *E*, which is keyed to a short shaft, on the outer end of which is fastened bevel gear *F*. This bevel gear meshes with two others, *G* and *H*, the former keyed to the central spindle *J*, and the latter revolving loosely upon it, but pinned to the hub of spur pinion *K*. *K* meshes with pinions L_1 and L_2, keyed respectively to spindles J_1 and J_2. It will thus be seen that spindle *J*, driven by bevel gear *G*, rotates in the same direction as spindle J_1 and J_2, driven by bevel gear *H* and spur gears *K*, L_1 and L_2.

The whole mechanism of the head is enclosed, and is provided with means for thorough lubrication. The spindles have the same provision for holding and forcing out the taper shanks of the work arbors as are used in the regular milling machines. It will be seen that great care is necessary in the construction of the gearing in the head-stock to prevent back lash in the small bevel and spur gears. The accurate results which have been obtained in the practical use of the device are an evidence of the good workmanship which was put into the construction of these parts.

At the tail-stock end an angle plate is used, clamped to the top of the table and provided with suitable holes for holding tail-stock centers of ordinary construction. These holders are provided with studs which pass through holes in the knee and are clamped by nuts on the other side. The tail-center for

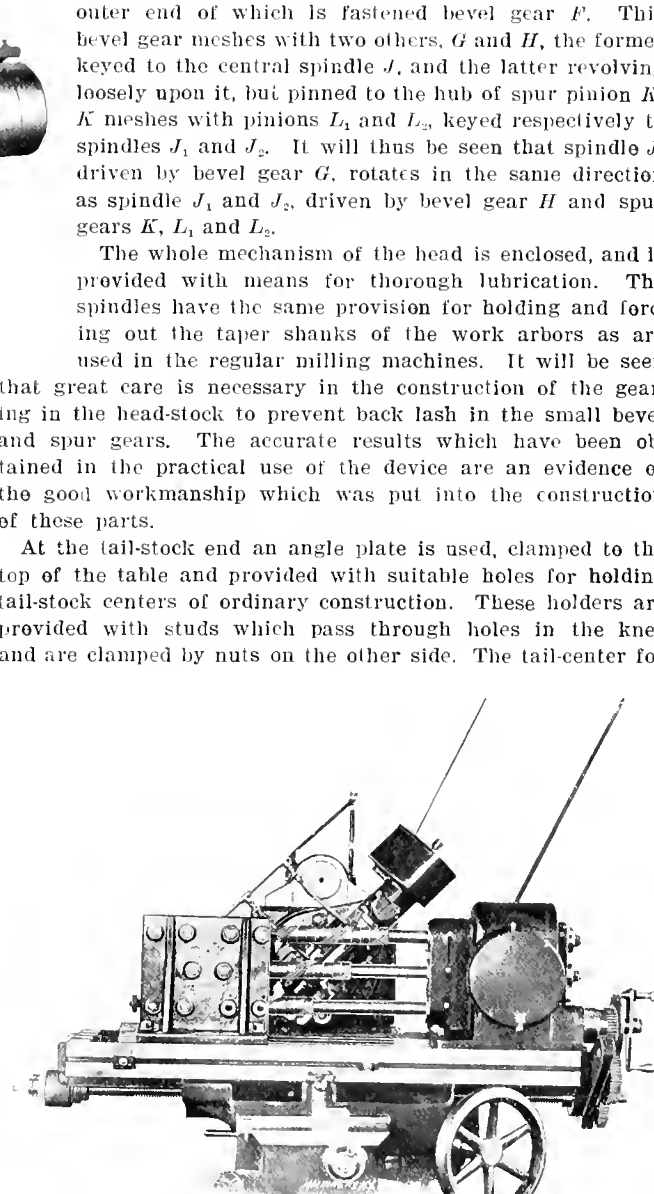


Fig. 1. Adjustable Angular Cutter Spindle and Triple Spiral Head Attachments used on Milwaukee Plain Miller.

the central work arbor is fixed in position, while those for the upper and lower tail-centers may be shifted to positions to accommodate the different lengths of work arbors. In the case shown, the upper work arbor is short and the lower one long, necessitating corresponding positions of the centers. The three arbors are made of these different lengths to provide for the setting of the spindle on the angle. When so set, with the arbor arranged as shown, it will be seen that all three cutters start their work at once and finish at the same time on the three stacks of pinions, each of which is of the

same length. For cutting right-hand pinions with the spindle head reversed to the same angle on the other side, the upper and lower work arbors are interchanged in the spindles in the dividing head, requiring the upper dead center to be moved outward and the lower one inward to correspond.

Cutting oil is supplied to each of the cutters by a system of piping, leading from the regular oil supply equipment of the Milwaukee miller. The final arrangement was somewhat different from that shown, permitting the head to be swung over to the other angle for cutting right-hand gears, without necessitating disconnecting the piping.

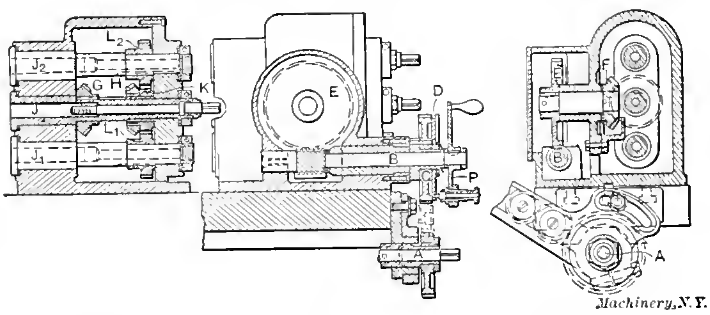

Fig 2. Elevation and Sections of Triple Spiral Cutting Attachment

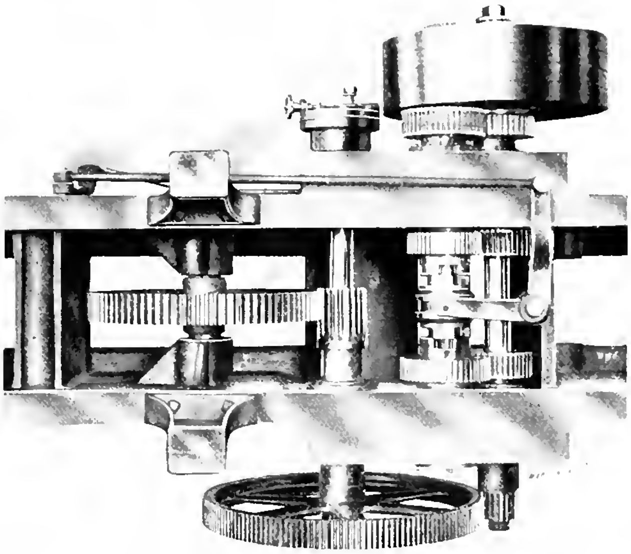
It is interesting to note that the manufacturers for whom this device was furnished have gear hobbing machines in this device was furnished have gear-hobbing machines in being their experience that more accurate work is possible with this method than in the hobbing process. The gear is run at such high speed that defects soon show themselves. No figures are given as to the comparative cost of the two methods of cutting gears.

VARIABLE SPEED DRIVE FOR THE WOODWARD & POWELL PLANER.

The accompanying illustration shows an underneath or a "worm's eye" view of the arrangement of a new two-speed driving mechanism, which has been applied by the Woodward & Powell Planer Co., Worcester, Mass., to its planers. The device is particularly interesting from the simplicity with which it provides two cutting speeds, instantly obtainable, leaving the return speed constant.



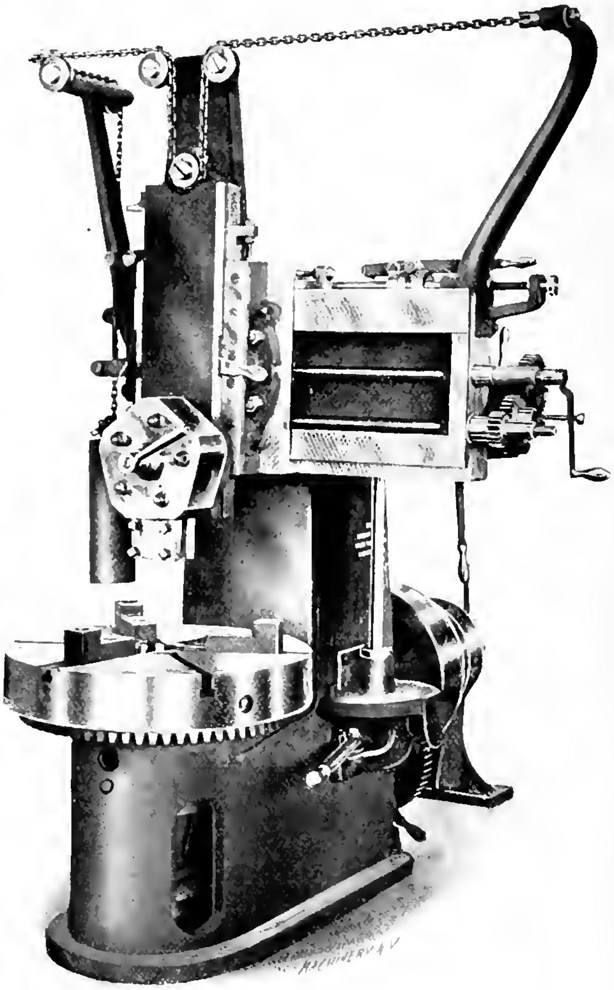
View, from Underneath, of a Planer Drive which gives Two Forward Speeds with Constant Reverse.

The tight and loose pulleys for the return speed are mounted on the driving shaft as usual. The tight pulley for the forward speed runs loosely on the driving shaft, and has a long hub on which the loose pulley for the same belt freely revolves, and to which is keyed a driving pinion, meshing with a raw-hide gear on an intermediate shaft. This intermediate shaft has keyed to it, inside the frame of the planer, a double-ended jaw clutch, adapted to engage corresponding jaws in the hubs of two gears of different diameters, which are loosely mounted on it. These gears engage, in turn, raw-hide mating gears, fast to the driving shaft. The double-jawed clutch is connected by a horizontal bent lever and a reach rod to a vertical shifting lever at the side of the machine, within convenient reach of the operator. The two loose clutch gears on the intermediate shaft are self-oiling and together with the clutch, are of massive construction, and so designed that there is no danger of the teeth slipping out of engagement, except when forced out by the lever.

The arrangement is simple and easily understood. When driving forward, the power is transmitted to the pinion on the hub of the driving pulley, thence to the raw-hide gear, driving the intermediate shaft, and from there to that one of the two gears in the bed which is engaged by the clutch to the intermediate shaft. From that gear the power is transmitted through the driving shaft, and thence through the usual gearing to the table. On the return stroke, the belt drives a pulley fast to the driving shaft, which operates the planer table in the ordinary way, at the same time driving freely the intermediate shaft, which is connected through the gearing with the other driving pulley. The ordinary variation obtained is in the ratio of $1\frac{1}{2}$ to 1.

NILES-BEMENT-POND 30-INCH TURNING AND BORING MILL.

The advantages of the horizontal revolving table of the boring mill over the face-plate of the lathe for chucking heavy pieces are well known. The work does not need to be elevated so high in the boring mill, and it rests on the table by its own weight while it is being centered and clamped. These considerations give the boring mill a great advantage in the



Niles-Bement-Pond 30-inch Vertical Boring Mill.

rapid production of heavy duplicate parts which require chucking operations. To take advantage of these good qualities, the Niles-Bement-Pond Co., Trinity Building, 111 Broadway, New York, has brought out the boring mill shown in the accompanying engraving.

The base and upright are cast in one piece, strongly ribbed to insure stiffness under the heaviest cuts. All bearings are of liberal size, and particular care has been taken to make

the machine run smoothly, and easy to handle. The cross rail is of sufficient depth to insure a minimum of deflection under the strain of the cut, and has a wide face offering a broad bearing to the saddle.

The table is 30 inches in diameter, corresponding with the rating of the machine. It is supported on a spindle of ample proportions running on a step bearing submerged in oil, and it is supported laterally by a long split sleeve, adjustable for wear and having a conical bearing on the bed. This preserves the alignment permanently, and insures a true running table. The working surface of the table, as regularly built, has a 3-jaw combination chuck, capable of holding work from 4 to 25 inches in diameter. In addition to the jaw slides, there are three radial T-slots for bolting on work. The jaw slides are of steel, built into the table. The chuck jaws are reversible and may be readily removed, leaving the surface of the table entirely clear for irregular work requiring special clamping fixtures.

The table is driven by an accurately cut bevel gear which, as may be seen in the illustration, is nearly the full diameter of the swing. The machine is driven by a 4-step cone provided with back-gears giving eight speeds; this number is doubled by the use of the 2-step counter-shaft provided. Thus a range of 16 speeds covers the work for which the machine is adapted by small gradations, insuring the proper speed for each case. The total gearing ratio of 27 to 1 insures a maximum cutting power on large diameters. The turret slide is supported in a saddle which slides on the permanently located cross rail. Either the vertical movement of the turret slide in the saddle, or the horizontal movement of the saddle on the cross rail, may be effected positively through the feed motion provided. There are 16 changes of feed driven by positive gearing, thus making many of them available for screw cutting. The gears regularly furnished with the machine give 16 pitches from 4 to 48 threads per inch. Additional gears may be furnished at a slight extra cost so that the machine may be used for cutting threads of any desired pitch. All the feed changes, including the reversing of the feed motion, which is effected by the lever at the base of the vertical feed shaft, may be effected from the operating side of the machine, thus making the manipulation simple and rapid, and increasing the output of the tool. The turret has five large holes for tool-holder shanks which are securely held in position by large bolts and binder plugs. The flat sides with which the turret is provided give a broad bearing to the back faces of the tool-holders, thus preventing lateral deflection under heavy cuts.

It will be seen that the machine besides being stiff and powerful, is simple in construction and convenient in operation, thus adapting it especially to manufacturing purposes.

BAUSH VERTICAL AND HORIZONTAL MULTI-SPINDLE DRILLING MACHINES FOR STRUCTURAL WORK.

The two multiple spindle drilling machines illustrated in Figs. 1 and 2 have been designed by the Baush Machine Tool Co., 200 Wason Avenue, Springfield, Mass., especially for the Bethlehem Steel Co. for drilling structural steel made in the "Bethlehem" sections, and manufactured by the Grey process. The equipment installed by the Bethlehem Works consists of eight double-head horizontal machines of the type shown in Fig. 1, and four single-head vertical machines as shown in Fig. 2. The vertical machines are arranged in a line, every other machine being placed on a sliding base so as to accommodate the drilling of various lengths when required. The horizontal machines are intended for drilling the flanges of the rolled sections, and the vertical machines are designed for drilling the web. In the case of the horizontal machines, each head takes the thrust of the drilling pressure of the opposite head.

The design of these drills is very plainly shown in the half-tones. The horizontal machines in particular, embody an entirely new departure in multiple drill design, so far as the arrangement of the details is concerned. These are made in two sizes. The capacity of the heads of the larger size is 12 x 48 inches—that is, the adjustable drill spindles will cover any

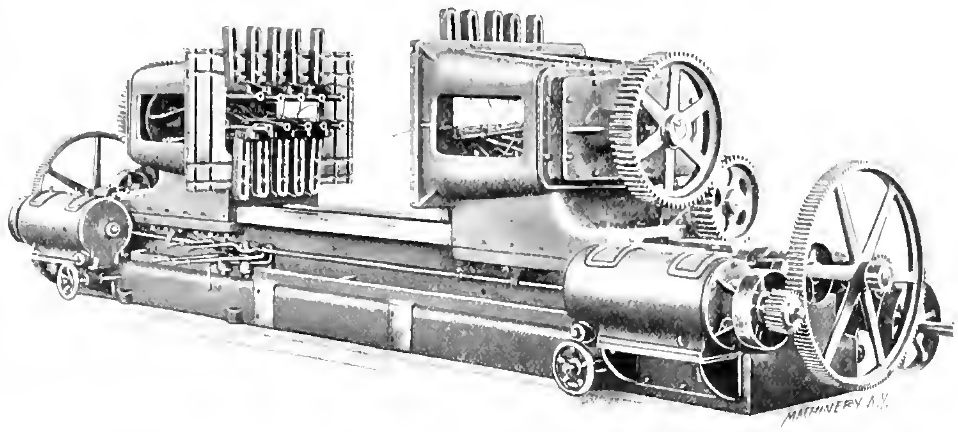


Fig. 1. Double-head, Ten-spindle Baush Horizontal Drilling Machine.

large lay-out within a rectangle 12 inches high by 48 inches wide, eighteen spindles being provided in each head. The smaller size horizontal machine carries heads of a capacity of 12 x 24 inches, each head being provided with ten spindles. This size is the one illustrated in Fig. 1. Both heads on the horizontal machine are operated independently or together, as required. All spindles are provided with No. 3 Morse taper sockets, and the machines are designed for drilling one-inch holes in soft steel, at a speed of 55 feet per minute at the periphery of the drill, with feeds ranging up to 0.01 inch per revolution of spindle. Each head is equipped with an oil pump, pan, reservoir and connections to each spindle, to allow oiling each drill independently.

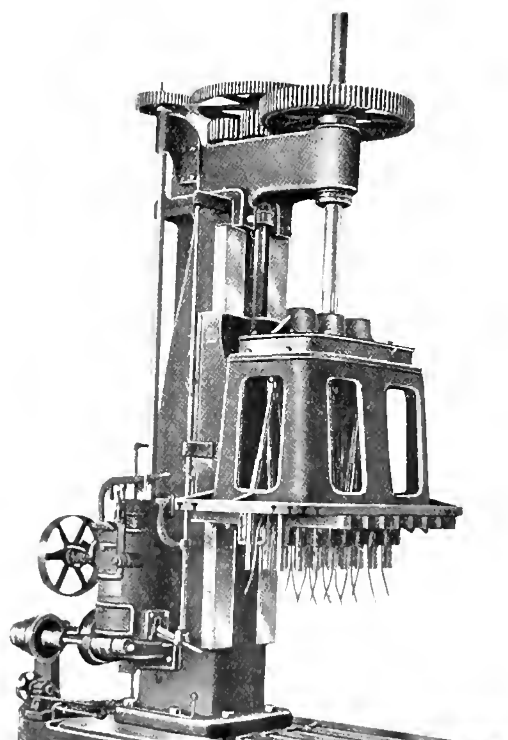

Fig. 2. Sixteen spindle Baush Vertical Drilling Machine.

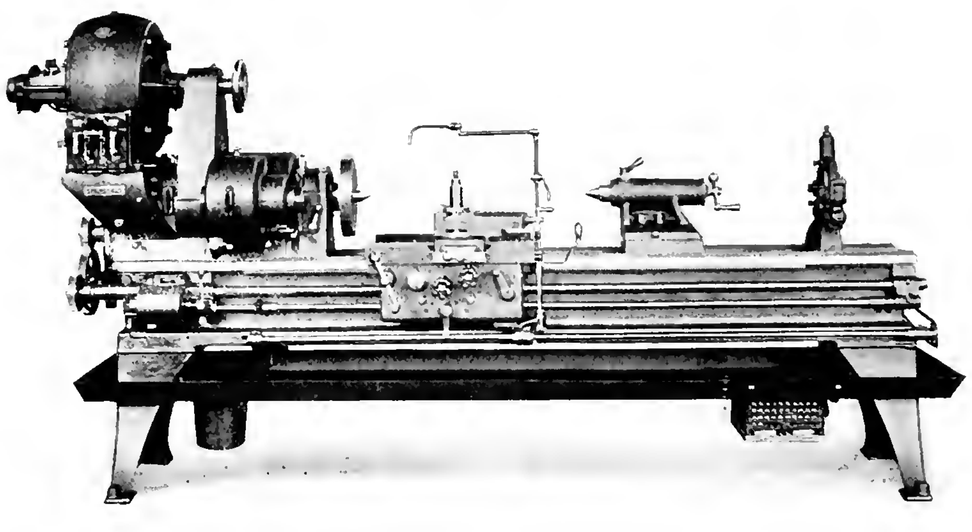
The vertical machines are also built in two sizes, the larger size carrying sixteen drill spindles, and having a capacity of 12 x 36 inches. This is the size illustrated in Fig. 2. The

smaller size carries ten spindles, and has a working capacity of 12 x 24 inches. The spindles in these machines are also provided with No. 3 Morse taper sockets, and designed for drilling holes of the same size at the same speed and feeds as the horizontal machines. The oil pump and oiling arrangement are also of the same character as already mentioned in connection with the machine shown in Fig. 1.

In both styles, the machines are motor-driven, the eighteen spindle-heads being driven by a 25 horse-power motor, and the sixteen spindle-heads by a 20 horse-power motor, while the ten spindle-heads are driven by a 15 horse-power motor. The drills are all provided with a two-speed quick return. The vertical machines weigh about 11,000 pounds, and the double-head horizontal machines about 25,000 pounds, without the motors.

SPRINGFIELD HIGH-POWER MOTOR-DRIVEN LATHE.

The motor-driven lathe shown in the accompanying illustration is built by the Springfield Machine Tool Co., 631 Southern Ave., Springfield, O., and is known as the company's No. 3 high-power rapid-reduction lathe of 19 inches capacity. One of the most noteworthy features of departure from previous designs is the system of drive employed. On this type of lathe the power is transmitted by means of a silent chain drive, instead of by a train of gears. A heavy, cumbersome construction is thereby avoided, and a neater and more compact appearance given to the machine.



Springfield No. 3 High-power Rapid-reduction Lathe.

The motor is a 7½ H.P. variable speed motor, the speed variations being within the limits of 500 and 1,000 revolutions. The fast speeds of the spindle are obtained by direct drive through the silent chain mentioned, from the motor to the spindle. The next series of slower speeds are obtained through a train of gears consisting of one set of spur gears and one set of helical gears. The smooth action of the helical gears eliminates any chatter marks when taking fine cuts in finishing work. The slowest series of speeds are obtained by a double set of back gears. By the arrangement outlined spindle speeds from 10 to 285 R.P.M are obtainable. The clutches used throughout the geared head are positive steel clutches, but so arranged that the machine does not have to come to a dead stop before changes can be made. A belt-driven model of this lathe is also built, which has ten speed changes for the lathe head itself, which, with a two-speed counter-shaft, gives twenty different speeds. This machine is designed to give a constant cutting speed of 80 feet pr minute for all diameters, from 1½ inch to 18½ inches. When motor-driven, if a constant speed instead of a variable speed motor is used, eight mechanical speeds are obtainable.

The operating lever for the control is placed on the right side of the apron, where it is out of the way of the operator, and yet very convenient of access. The cross-feed screw and compound rest screw have micrometer dials, permitting accurate adjustments. The friction knobs for throwing in and out the gears and longitudinal feeds are made with a series of small ridges around the outer circumference, so that the operator can readily get a good grip. The lathe is equipped with a rapid feed change gear box, which gives six feeds in geometrical progression. The machine shown in the illustration is also equipped with a modification of the change gear system generally in use, but the lathe may also be equipped with the "Ideal" rapid change gear system, used on the lathes of the Springfield Machine Tool Co. Using either system of change gearing, the lathe is equipped with automatic stop and reverse. The latter can be controlled either from the head or apron as desired by the operator.

The machine is of an exceptionally heavy design throughout. The head is heavily ribbed; the spindle runs in large journals, which are oiled by means of babbitt rings of triangular shape, carrying a profuse stream of oil, and thereby preventing any possibility of heating the boxes. The back-gear shaft is oiled in the same manner. In actual tests this lathe has proved itself capable of taking cuts with a feed of 5/32 inch and a cutting speed of 60 feet per minute, with a cut ¾ inch deep in 60-point carbon steel.

BESLY PISTON RING DISK GRINDER.

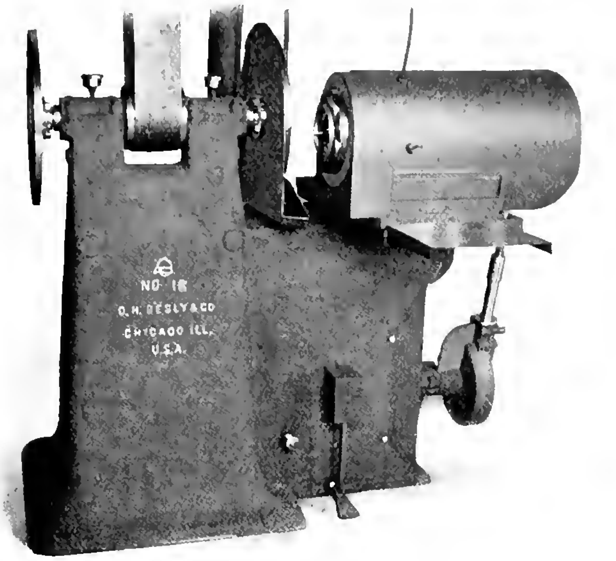
The accompanying half-tone illustrates a new type of grinding machine built by Charles H. Besly & Co., 15-17-19-21 South Clinton Street, Chicago, Ill. This machine has been designed especially for grinding the sides of piston rings rapidly and accurately to size. The novel feature of the machine is that the grinding is done on a steel disk wheel which has its sides covered with Helmet spiral abrasive disks, made by the builders. The machine will grind rings from the smallest diameter up to 10 inches diameter.

The machine as shown carries 18-inch disk wheels. The spindle is 1¾ inch in diameter, and is made from the crucible steel The bearing bushings are each 8 inches long and are carefully fitted into bored holes in the base casting, thus assuring perfect alignment, as well as making it easy to replace them when worn out. The bushings are split, have removable caps, which are fitted over the bushings, making it easy to remove the spindle if necessary. The end adjustment of the spindle is accomplished by means of a threaded collar, which is mounted on the spindle just under the flange of the spindle pulley. The end thrust is taken on hardened and ground steel thrust collars of large area. The bearings are well protected from dirt and grit, and particular attention is given the lubricating of all bearing parts. The spindle pulley is 7 inches diameter by 6¼ inches face.

On the right-hand side of this machine and secured to the bed, is a dove-tailed bed plate. On this bed plate is mounted a platen or carriage, which has a reciprocating motion, and is moved back and forth parallel to the face of the disk wheel. This motion is attained through a gear and rack underneath the bed, the gear receiving its movement through a crank and lever, the crank being attached to a lower shaft, which is driven by a spur gear meshing with a gear on the worm-gear shaft. This shaft, in turn, projects on the rear side of the machine, and is driven direct from the counter-shaft by a quarter turn belt. On the worm-gear shaft is mounted a clutch, which, upon being thrown in, lets this shaft make four revolutions, and then releases automatically, the four revolutions of this shaft moving the platen ahead and back to its original starting point.

Upon the platen is mounted a compound slide, also having a reciprocating motion, this motion being to and from the face of the disk wheel. The slide receives its motion from a cam which is secured to the outer edge of the bed

plate. Upon this slide is mounted the head or bearings of the spindle which carries the chuck for holding the work to be ground. This head can be moved back and forth at will by means of a screw and hand-wheel, the screw being equipped with a micrometer dial graduated to read in thousandths of an inch. The chuck is of the magnetic rotating type, and receives its rotary motion through bevel and spur gears from the lower shaft in the base of the machine. A sliding gear is provided in the base of the machine, by means of which a rapid or slow motion can be obtained across the face of the disk.



Besly Piston Ring Grinder.

The action of the machine is as follows: The work is placed on the chuck and the lever tripped, the platen moves forward, and the chuck carrying the work moves towards the face of the grinding disk, the work rotating and its entire surface coming in contact with the grinding disk. Thus, instead of grinding in one place only, the whole face is ground at once. As soon as the platen gets to its full forward stroke it recedes, and near the end of the stroke the chuck carrying the work also recedes from the face of the grinding disk. As soon as a full backward stroke is reached, the platen and chuck stop automatically. The principal dimensions are as follows: height from floor to center of spindle, 42 inches; space occupied by base on floor, 30 x 48 inches; weight of machine complete, 3,000 pounds.

GARDNER DOUBLE DISK GRINDER.

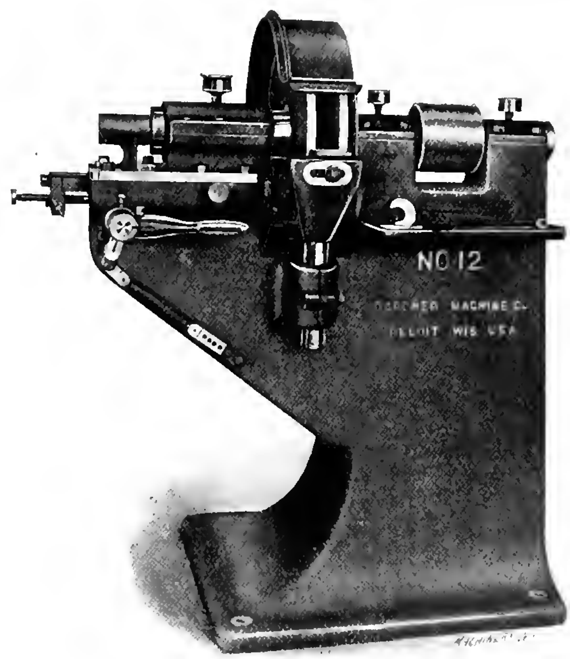
The double disk grinder shown herewith, made by the Gardner Machine Co., Beloit, Wis., embodies what is, so far as we know, a distinctly original idea in its construction—namely, that of having both wheels driven by one pulley and one belt. To accomplish this, the outer disk is carried on a sleeve supported in the adjustable bearing, and is driven by a drive shaft, forming an extension of the spindle on which the other disk and driving pulley are mounted, the sleeve being splined to the drive shaft.

This arrangement, it will be seen, makes possible a very neat design of frame, it being in the form of a column for carrying the fixed spindle, and provided with a knee extending outward to furnish a bearing surface for the slide of the adjustable spindle. The sliding head is equipped with micrometer stop screws and a back stop. The importance of the back stop is not always realized by the purchaser. It comes into play in finishing very thin work, say from 1/8 inch down to 1/32 inch in thickness. It is adjusted so as to allow the disks to be separated just enough to introduce the work, and not enough to allow room for the work to be caught between the work rest and the wheel. The sliding head is operated by means of a hand lever which is directly connected with a steel cut pinion meshing with a steel cut rack fastened to the under side of the sliding head.

To remove the disk from the machine, the driving shaft of the left-hand head is uncoupled from the main spindle. The end of this drive shaft is made with a left-hand thread and a taper shank, the main spindle being bored and threaded to receive it. When this has been removed, the sliding head can be taken off for re-covering the wheels, or the main spindle disk may be used with the machine in this condition, with special work table and fixtures for ordinary flat surface grinding. The disk wheels are fastened to the spindles by the usual countersunk screws.

The machine, as may be seen from the engraving, is rigidly constructed throughout, and great care has been taken in providing lubrication and excluding dust from the wearing surfaces, the hollow spindle being provided with dust-proof collars for this purpose, as well as the main bearings. Disk wheels of either 15 or 18 inches diameter may be used. The maximum distance between the wheels is 4¼ inches, which is enough for the great majority of cases, though this may be increased to suit special work. The weight of the machine in the condition shown in the engraving is 1,000 pounds, and when crated for domestic shipment weighs 1,800 pounds. It is furnished with all the necessary accessories, such as setting-up press for the disks, counter-shaft, wrenches, and other supplies.

This machine will be furnished in two other forms besides that shown. In one case, provided with an additional single disk at the right-hand end of the main spindle, having the usual tilting table and standard work holding arrangements. This machine will be known as the "No. 12 combination" grinder. The other style, the "No. 12 duplex," will have the same form of double disks, sliding heads, etc., duplicated on the right-hand side of the column, the whole machine being driven by one belt. This arrangement can be used either as a roughing and finishing machine, or, if desired, two men may be employed on the same or different work.



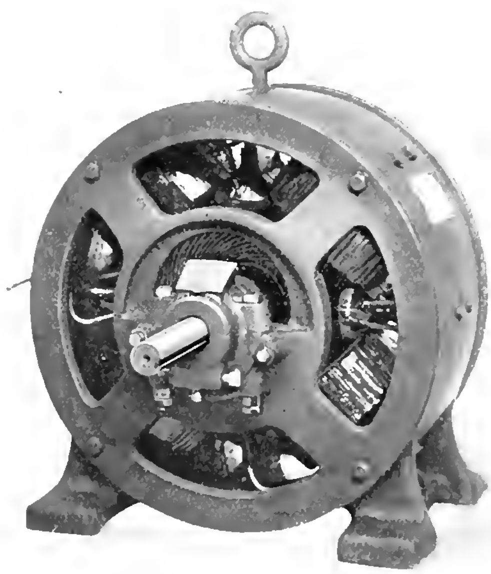
Double Disk Grinder driven from Single Pulley.

WESTINGHOUSE TYPE "SA" MACHINE TOOL MOTORS.

In order to operate a machine tool with the greatest economy, the speed must be adjusted in each case for the work in hand. The new type SA motor, brought out by the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., permits a quick, easy and accurate speed adjustment, and the advantage of the motor drive in this respect as compared with the slow and cumbersome method of shifting belts is apparent. The controller and the motor can be mounted convenient for the operator, and the desired speed can be obtained without stopping the work. It is stated that in one large American manufacturing establishment, where this type of motor was substituted for the older form of power, tests made before and after installing the motors indicated a saving in favor

of the motor of 30 per cent of the cost, as well as considerable improvement in the quality of the product. The speed of these motors can be adjusted within wide limits, simply by moving the controller handle, and the speed, once adjusted, remains practically constant at all loads until further adjustment is made. The number of different speeds obtainable between the minimum and maximum is limited only by the number of notches on the controller. The standard type of SA motors is built in capacities of from ½ to 23 H.P. for speed ratios of 1 to 4, and in capacities of from 1½ to 50 H.P., for speed ratios of 1 to 3.

In all type SA motors, the coils on the auxiliary poles are in series with the armature circuit, so that the strength of these poles depends on the load of the motor, and is always proportional to the armature reaction. This is true no matter which way the armature is rotating. The result is that under the brushes is a fixed magnetic field of exactly the right strength to cause sparkless commutation at all loads and at all speeds within the limits of the motor rating, and heavy



Westinghouse Type SA Machine Tool Motor.

overloads can be carried for short periods. The open type SA motor will carry its full rated load at any rated speed for 12 hours or 2 hours, according to its rated time of operation, with a temperature rise not exceeding 72 degrees F. It will carry an overload of 25 per cent for one hour or of 50 per cent momentarily without injurious heating or sparking. The two-hour ratings are satisfactory for intermittent machine tool service, and will give excellent results when applied for such purposes.

WALCOTT & WOOD 20-INCH CRANK SHAPER.

The crank shaper shown in the accompanying half-tones and line engravings is the first of a new line brought out by the Walcott & Wood Machine Tool Co., Jackson, Mich. The details of this line of shapers have been worked out along original lines throughout, and differ in many points from the standard construction with which most shaper users are familiar. The changes are quite largely along the line of increased stiffness and durability, and give evidence of careful attention to small details.

Driving Mechanism.

The machine is of the crank type with the quick return obtained by elliptical gearing. Except for the difficulty of making accurate gearing of this kind, this movement is especially adapted for the quick return motion of a shaper. The action is simple and direct, requiring very few parts, and is exceedingly durable. The methods of manufacture developed by the makers for these gears insure accurate work at reasonable cost, so that the only objection to their use is in a measure removed. The driving connections will best be understood by referring to Figs. 3 and 4 in connection with the half-tone engravings. The 4-step driving cone is mounted on the sleeve *A* which takes the pull of the belt. It drives shaft *B* which has mounted on it double sliding gears which may be made to engage at will, by the operation of lever *C*, with either of gears *D* and *E*. By this means the four speeds given by the cone pulley are doubled, giving

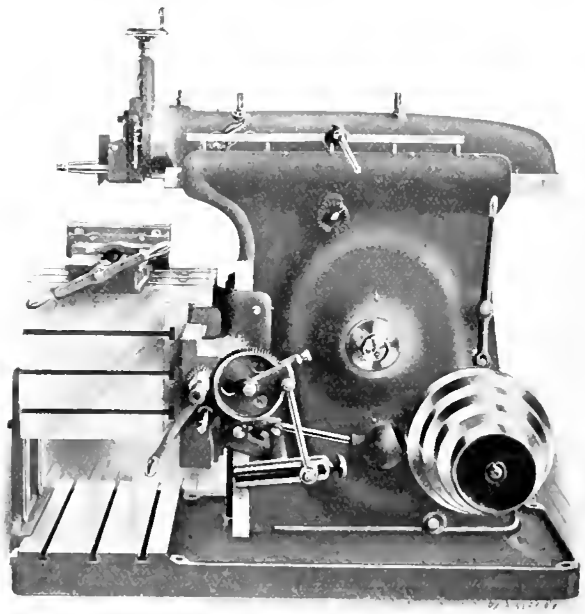


Fig. 1. Walcott & Wood 20-inch Crank Shaper.

eight in all. Pinion teeth are cut in the sleeve on which gears *D* and *E* are mounted, meshing with the bull-wheel *F*. This is keyed to a shaft, the other end of which carries one of the elliptical gears *G* whose mate *H* is attached to and drives the crank *U*.

The slotted link *J* which drives the ram *K* is of unusual length, as may be seen, being pivoted near the base of the machine to link *L*. The upper end is pivoted to block *M*,

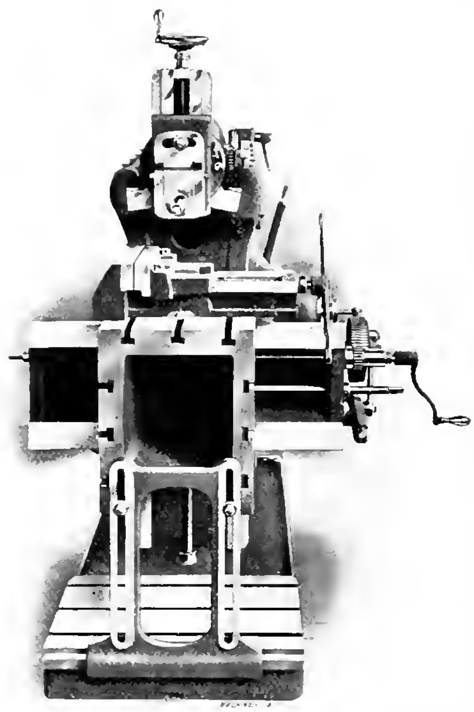

Fig. 2. Front View of Walcott & Wood 20-inch Crank Shaper.

which is supported on ways on the inside of the ram on which it is adjusted by screw *N* which is connected by bevel gearing with squared shaft *O*, by means of which the position of the ram is adjusted. The handle *P* operates a stud with a pinion on the lower end meshing with a rack having a wedge surface which tightens a binding lever, bringing the loose section of the adjusting block *M* simultaneously up against the under side of the ways on the ram and against the adjusting screw, clamping them all tightly. The length of

stroke is adjusted by squared shaft Q which is connected by spur and bevel gearing with screw R which shifts the position of a crank-pin in the slotted crank. The length of stroke is read from a dial S whose pointer is connected by spur gearing and rocks with the ram.

Tool Head and Down Feed.

The tool head is, in the main, of familiar construction, although a number of conveniences and improvements have been made in details. It swivels to any angle through an arc of 90 degrees, and its feed-screw has an adjustably graduated collar reading to thousandths of an inch. A graduated scale and adjustable pointer are provided for indicating the depth of the cut. A strap tool-post is used. The clapper box is strengthened by a tie-rib which connects the two sides, materially strengthening it against side thrust.

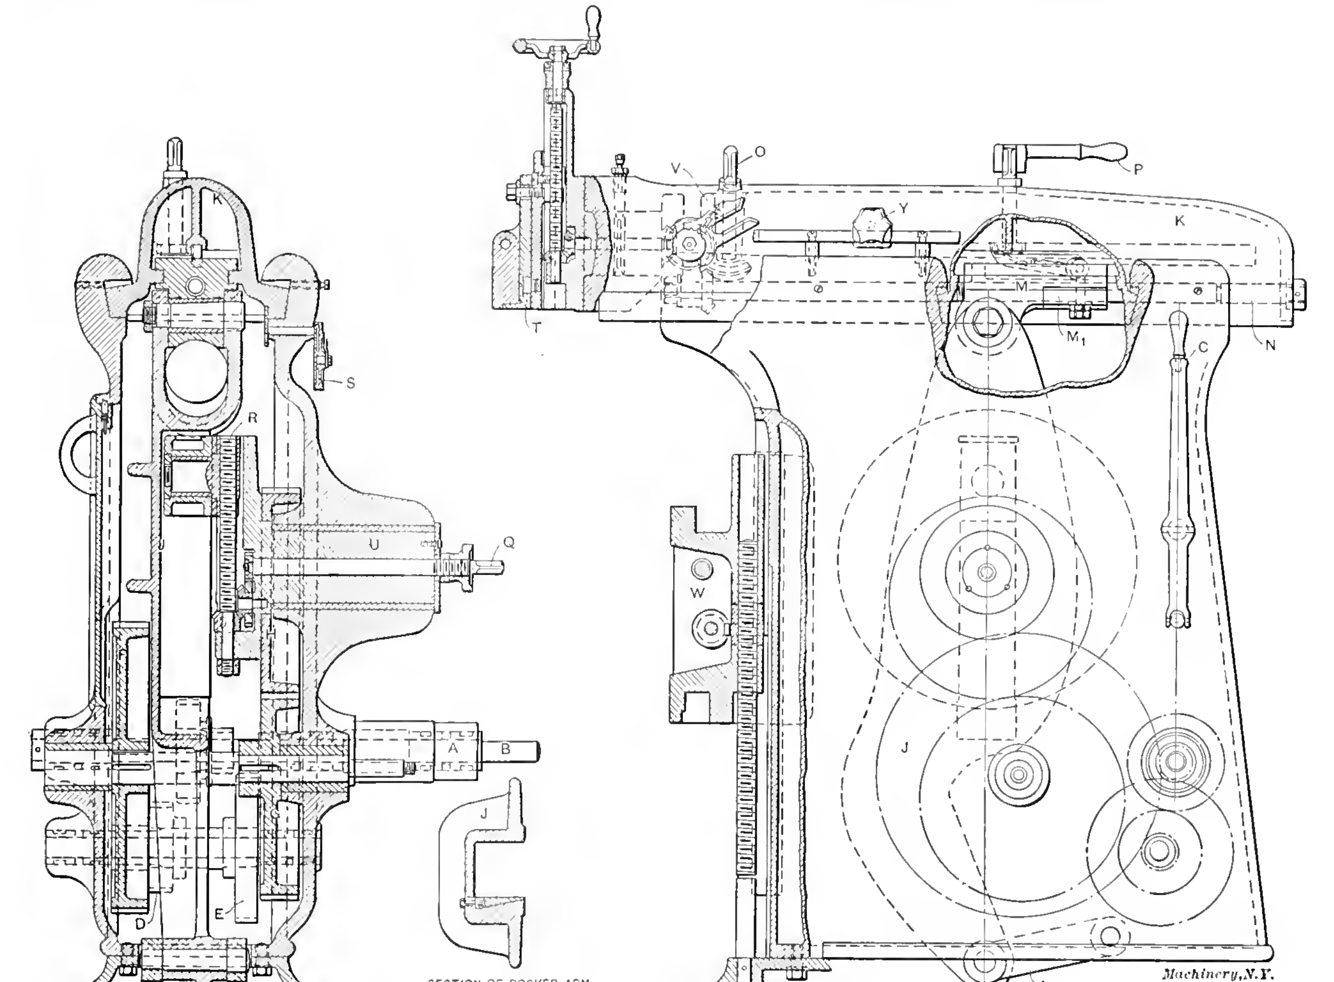
The power down feed is accomplished by positive mechanism acting without the use of springs. It is operated by an adjustable dog Y supported on a rail mounted on top of the column. This dog enters the slotted arm V at the end of the back stroke, rocking it forward and bringing it back again as the ram reverses. This rocking movement, by means of a ratchet and pawl, is transmitted, through the bevel gearing shown, to the down feed screw. The ratchet is used for connecting or disconnecting the motion. The amount of feed is varied by altering the position of Y.

Construction of the Sliding Bearings.

A particular feature of this machine is the method of gibbing used throughout. This is best seen in the case of the ram in Fig. 3. Instead of the ordinary square form of ram bearing with caps screwed on to hold the ram to its work, the construction shown is used, in which the bearing practically surrounds the ram slide on three sides with the solid metal of the column. The ram has flat bearings underneath and a flat wide side bearing tapering slightly outward and upward. The wide top bearing is tapered slightly upward and inward. The lower and side bearings fit the ram surfaces, being planed and scraped to receive them. The space between the tapered upper bearing surface of the ram and the over-hanging lip of the column is filled on each side with a tapered wedge gib set up by screws acting on its edge, thus adjusting them in the direction of their greatest stiffness, producing a uniform contact instead of localizing it under the points of the set-screws as is the case with the usual form of flat gib.

In order to insure the permanent maintenance of the sidewise alignment of the ram, the side bearing, so the builders claim, is 60 per cent greater on this machine than on any other regularly manufactured. The ratio of the lower bearing to the side bearing is calculated to be such that the ram will wear outward so that the wear will be continually taken up on the sides without requiring special provisions for this. By making the upward bearing substantially flat, the wedging tendency that results from the use of 45-degree top bearings, as sometimes used, is eliminated, while the abolishing of screwing on caps goes far toward removing the possibility of the "fan-tail" cut which results from the give of such caps under heavy cuts.

The same principle, so far as possible, is carried out in other bearings. In the case of the rocker arm J, a detailed cross-section of which is shown at the right of Fig. 3, a taper gib of the same type has been produced provided with screws for both forcing it out and drawing it in, so that its position can be accurately located. This, in combination with the slight angular displacement of the ram, resulting from its unusual length, as previously described, reduces the wear of the block and the slot to a minimum, and makes it possible to take up whatever wear may occur. The pin about which the arm is pivoted to the adjusting block of the ram, is tapered so that this may be adjusted for wear. The journal of the hub of the slotted crank U in the main frame is



Figs. 3 and 4. Section and Elevation showing Design of Shaper.

unusually long, and its bearing is cast solid with the column. All of this tends to make a strong and durable driving mechanism.

Cross-Rail and Table.

The cross-rail W, Fig. 5, is of box form designed to withstand the strain of heavy cuts. The bearings on the front of the column are made with the outside surfaces at a slight angle to provide means for automatically taking up wear in

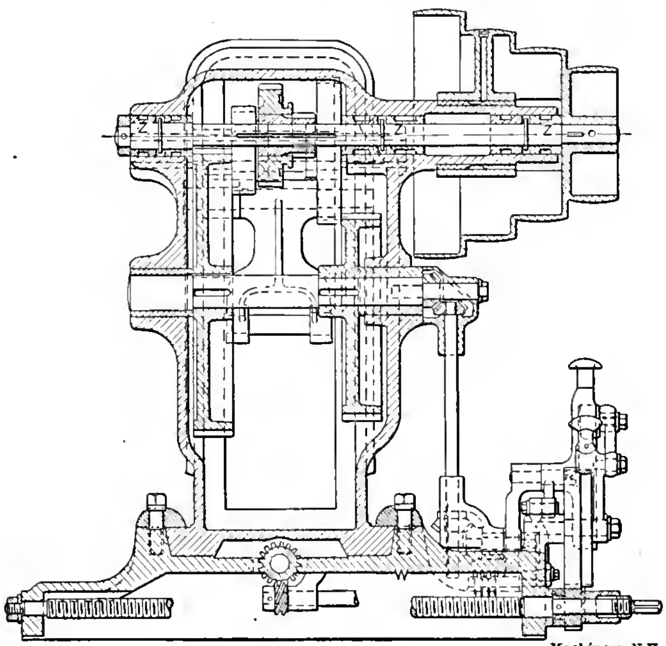


Fig. 5. Transverse Section through Apron, and Column of Shaper.

the same way as is done with the ram bearings. This makes it unnecessary to rely on the pressure of a few gib screws to maintain the alignment. The apron is provided with a gib of the same kind as used in the ram and rocker arm, for taking up the wear. The table is of box form, and can be readily detached. It is locked to the apron in a simple and effective way. An outer support of the practical form shown in Figs. 1 and 2 is supplied with the machine.

Feed Mechanism.

To avoid the necessity for adjusting the feed for various heights of the table, an original feed mechanism has been employed. At the right side of the cross-rail is mounted a bracket which contains a crank connected by bevel gearing and telescopic shaft with the bull-wheel shaft. The crank is connected with a slotted link which is thus vibrated in the proper relation with the ram for the feeding movement. An adjusting screw and knob shifts the position of a trunnion nut in this slotted link to vary the rate and the diameter of the feed. The trunnion nut is connected by a link with the ratchet arm of the feed gear wheel, which, in turn, meshes with the pinion on the cross-feed shaft in the usual way. The pinion driving the cross-feed screw is connected to it by clutch teeth kept in engagement by a spring. This furnishes a safety device so that if the table is accidentally fed to the extreme end of its travel, the resistance of this movement stopping the screw will cause the clutch teeth to be forced out against the pressure of the spring, thus stopping the feed and preventing the breaking of any part.

Details of Construction and Equipment.

In describing the means for adjusting the position of the ram by means of crank-shaft O, screw N and clamping handle P, mention should have been made of the reason for following this plan in place of the usual one in which M is clamped by a bolt through a vertical slot in the ram with a handle similar to P at the top. The arrangement here used does away with this elongated slot, and thus allows the ram to be ribbed through from side to side above block M throughout its whole length. This greatly increases the stiffness of the ram, and its capability for doing heavy and accurate work.

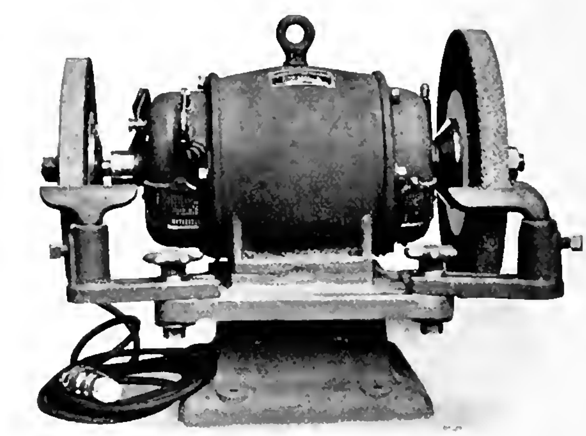
As to the general character of the design and workmanship of the machine, aside from what has already been explained, it may be mentioned that all bearings are bushed with bronze, and all rapid running bearings are provided with ring oilers. The ring oilers for the driving shaft are seen plainly in Fig. 5 at Z, Z, Z. The driving cone is provided with bushings with an oil chamber between, arranged so that a splasher attached to the pulley throws the oil over the stem and keeps the bearings thoroughly lubricated. Suitable oiling facilities are provided for all the other running and sliding bearings.

The vise, as shown in the half-tone, is designed to lie down flat on top of the table, giving it a rigid support. It is graduated and provided with a swivel base. All the shafting is of the best quality steel ground to size. The gears are all cut from the solid, and are of coarse pitch and wide face, driven by steel pinions. The maximum stroke of the machine is 20 inches; the horizontal travel, 27 inches; the length of the ram bearing in the column, 36 inches; the down feed of the head, 7 inches. The width of the belt used is 3 inches. The counter-shaft is run at about 350 revolutions per minute. The maximum ratio of the gearing is 32 to 1. The net weight of the machine and counter-shaft is 4,100 pounds.

The line of shapers to which this 20-inch belongs will later include a 16-inch and a 24-inch size, as well, with probably is 4,100 pounds.

U. S. ELECTRICAL TOOL CO.'S BENCH GRINDER.

The electric bench grinder illustrated in the accompanying half-tone is manufactured by the United States Electrical Tool Co., Cincinnati, Ohio. The motor of this bench grinder is of the air-cooled type of 2 H.P. capacity, and made for 110 or 220 volts direct current. It is operated by connecting it directly to an ordinary incandescent lamp socket. The



Bench Grinder built by the United States Electrical Tool Company.

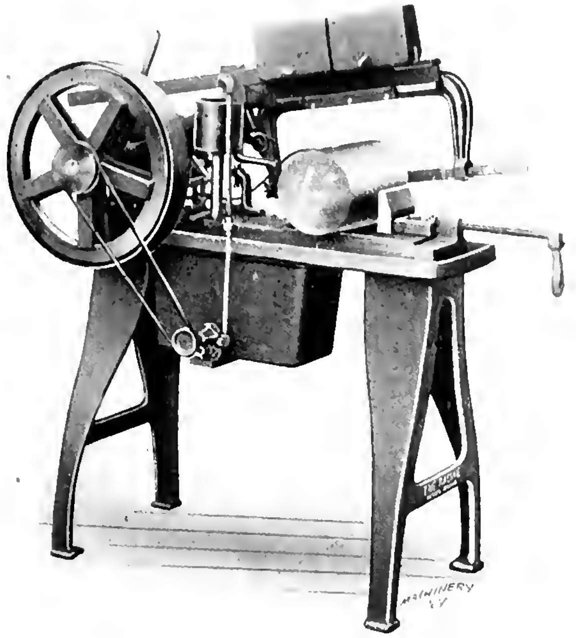
emery wheels used are 12 x 1¼ inch and 10 x 1 inch, respectively. The bearings are conical, dust-proof, and adjustable for wear. The tool rests are adjustable and can be taken off, if required, or swung out of the way. Besides being used for regular grinding work, this grinder is also suitable for buffing or polishing work.

RACINE HIGH-SPEED AUTOMATIC HACK-SAW MACHINE.

The hack-saw manufactured by the Racine Gas Engine Co., Racine Junction, Wis., which was described in "New Machinery and Tools" department in the January, 1908, issue of MACHINERY, has been brought out in an improved form, as shown in the accompanying engraving. As will be remembered, an important feature of the machine is the means provided for positively arresting the saw from contact with the work on the back stroke, thus lengthening the life of the saw, increasing the rapidity of the cutting, and squaring off the end of the work more accurately.

The improved design shown herewith has been especially planned for increasing the rate of production. With this end in view, a tank and pump for a lubricant has been pro-

vided. A cutting compound costing less than 2 cents per gallon is recommended, which is pumped from the tank through a pipe into a reservoir, and thence onto the work, whence it falls into the trough provided around the base of the machine, and then returns to the tank again to be used over continuously as in screw machines and other machine tools.



Racine High-speed Automatic Hack-saw Machine.

The raising of the saw on the return has proved to be of great value in increasing the rate of production. It is also impossible to break the saw by applying too much pressure to it. As much as 80 pounds pressure has been used for a saw blade 14 inches long, 1 inch wide, and 0.032 inch thick, without injury, a 6-inch round bar having been cut off under these conditions in 32 minutes. It is possible, also, to use a thin blade, thus effecting a saving of material.

The use of the cutting compound has made possible a doubling of the speed on a machine of this type, while the length of time that a saw blade can be used is increased from 10 to 40 per cent. according to the size and kind of material to be cut. The blade is also less liable to break.

ANGLE MEASURING INSTRUMENT MADE BY SCHELLENBACH-HUNT TOOL CO.

The Schellenbach-Hunt Tool Co., Cincinnati, Ohio, is making the unique angle measuring device shown herewith in Figs. 1 and 2. This instrument is arranged with suitable multiplying gearing to indicate the position of an adjustable

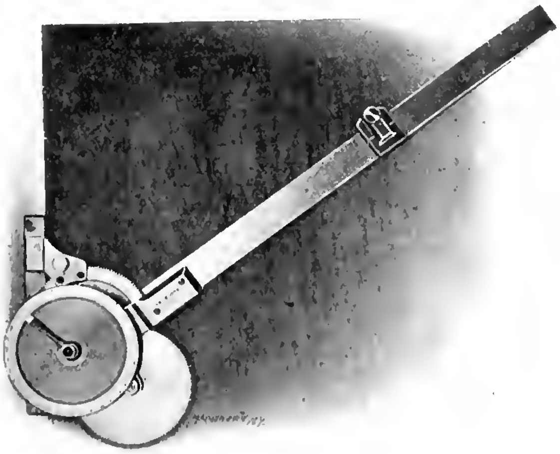


Fig. 1. Schellenbach-Hunt Angle Measuring Device used on the Drawing Board

straight-edge sector to within one minute in easily read graduations. It may be used for accurate work on the drawing board or for laying out angles for templets on sheet metal and similar work.

The device when used on the drawing board is arranged as shown in Fig. 1. To the straight-edge at the left, which lines the device with the edge of the drawing board, is fastened a stationary gear of 144 teeth about whose center is pivoted the radial arm used for taking off or scribing the angles. The working edge of this arm passes through the center of the pivot. The plate to which this arm is fastened carries a pinion of 18 teeth meshing with a stationary gear and attached to the end of the spindle of a large revolving gear of 135 teeth shown at the right. This gear, in turn, meshes with a pinion of 18 teeth on the spindle which carries the pointer shown, which thus makes 60 revolutions for each full revolution of the arm. The stationary dial around which the pointer travels, is, accordingly, graduated into 360 degrees, each degree corresponding with a minute of movement of the arm. Arranged thus, the arm can be swung around through a half circle.

In the position shown in Fig. 2, the guiding straight-edge has been removed from the fixed gear, and the latter is held to the drawing board by thumb tacks passing through holes in the web of the gear provided for the purpose. In this position the blade is free to move around the whole circle. A sliding block for a scriber or pencil is shown attached to the blade. This can be locked in any desired position on the blade as a stop for the graduations produced. The indicating hand can be set to any desired position in relation to the

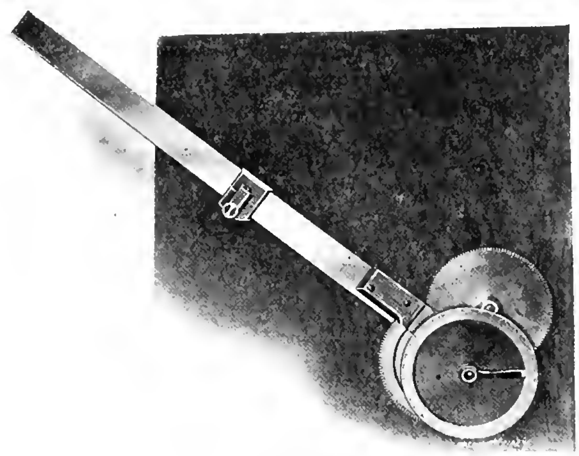

Fig. 2. The Instrument so arranged that the Straight-edge can be moved through 360 Degrees.

dial, and is clamped by means of the knurled thumb-screw shown. It may easily be seen that the device can be used for dividing circles into minutes or in even multiples of minutes. For odd spacing, a vernier is provided which reads to 5 seconds. With this, odd spacings can be effected. For an uneven number, such as 47, for instance, the fractional parts of the minute would be estimated on the dial. The blade of the instrument is 12 inches long. The screws are made of German silver, and the spindles and bearings are of steel, hardened and ground. The weight of the instrument complete, as shown in Fig. 1, is 20 ounces.

KEMPSMITH HORIZONTAL CIRCULAR MILLING AND INDEXING ATTACHMENT.

The Kempsmith Mfg. Co., Milwaukee, Wis., is building a circular milling attachment of the type shown in operation, Figs. 1 and 2. The operations for which it is adapted include circular milling of all kinds, indexing, cutting the teeth of gears, etc., and other operations in which successive portions of the periphery of a piece of work have to be presented to a milling cutter. It should be especially useful in connection with a vertical milling attachment.

The device consists of a circular table, either 11 or 18 inches in diameter as required by the customer, mounted on a base on which it has a solid bearing for almost its whole area. The table may be rotated on its base by means of a worm and worm-wheel, being set at the desired locations either by means of the graduations for degrees marked on its periphery, or by means of the index plate and crank shown in Fig. 2. The plate and crank are the same as used with the regular

spiral head furnished with the universal milling machine, which may be taken off and used with this attachment. Since the ratio of the worm and gearing is the same as that in the spiral head, the index tables are the same for each case. For continuous power rotation, feed connection is made with

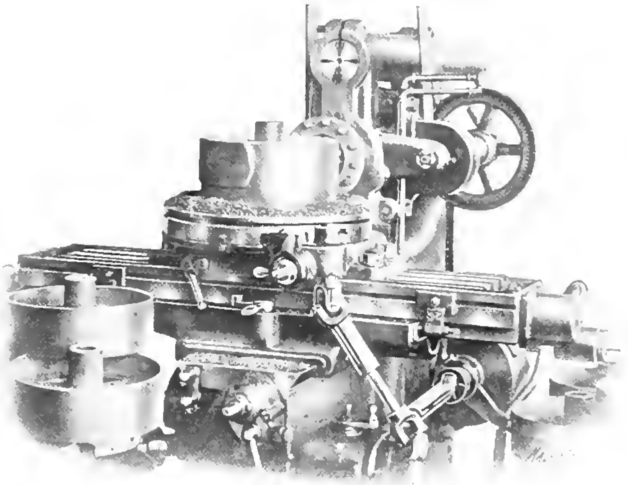

Fig. 1. Kempsmith Horizontal Circular Milling and Indexing Attachment being used for Pulley Crowning.

the feed box on the knee by the telescopic shaft and gearing shown in Fig. 1. A special bevel gear connection encased in a suitable containing bracket is provided for driving the telescopic shaft from the gear box. A clutch provided with an automatic throw-out is used for disconnecting this power feed when required.

The application of the device shown in Fig. 1 relates to the milling of a crowned pulley face. This is done, as shown, by using a round cutter head with inserted blades in its face to finish the face of the pulley, setting the latter with its center slightly off from the center line of the machine spindle. This produces the desired crowning effect which may be varied by altering the longitudinal adjustment of the table. In this case, of course, the power circular feed is employed. In Fig. 2 this power feed is disconnected, and the index plate and crank are being used for dividing a large spur gear. This is of a diameter much too great to be swung on the usual index centers of the machine. Of course, the centers could be mounted on blocks high enough to swing the work, but in that case the cut would be taken so far from the bearing sur-

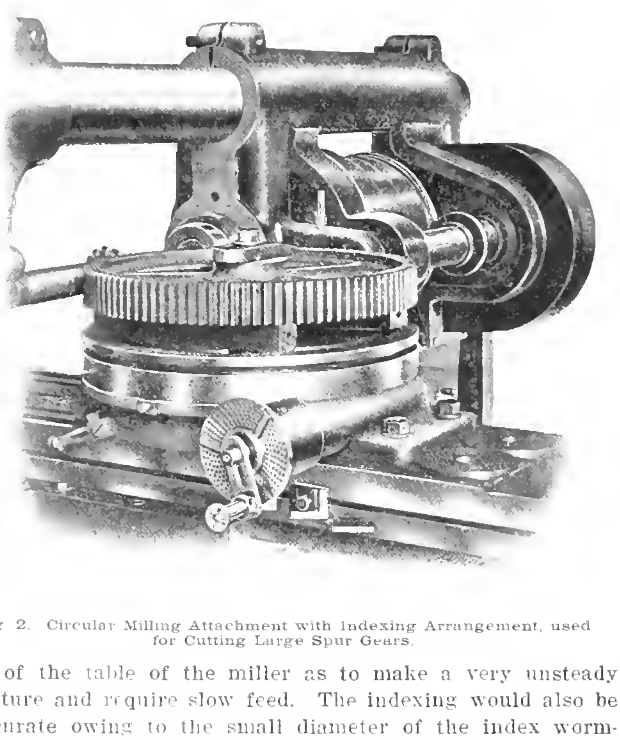

Fig 2. Circular Milling Attachment with Indexing Arrangement, used for Cutting Large Spur Gears.

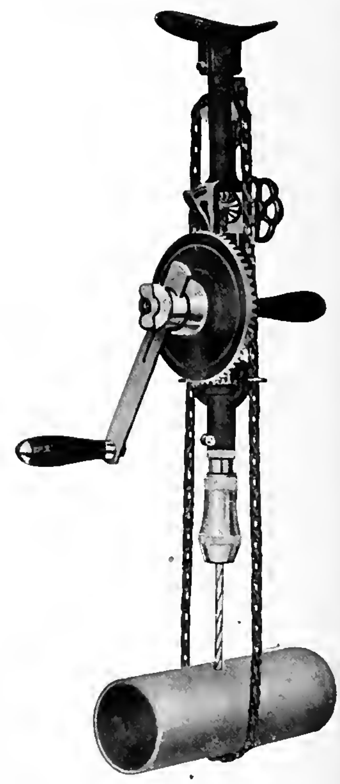
face of the table of the miller as to make a very unsteady structure and require slow feed. The indexing would also be inaccurate owing to the small diameter of the index worm-wheel as compared with the diameter of the work. In the present case the index wheel nearly approaches the work in diameter. The automatic vertical feed of the machine is used in this case. It will be seen that the strain of cutting is taken vertically downward against the knee which is well able to resist the stress, so that a heavy cut may be taken without chatter or vibration. The gear in this case was 6 pitch, 18 inches in diameter.

The attachment, as stated, is built in two sizes, giving either a 14-inch or 18-inch table. The table can be clamped at any angle throughout the full circle by a patent clamping ring, such as used on the universal millers. The table, if desired, can be released from the worm-wheel for quick adjustment.

UNIVERSAL BREAST DRILL MADE BY THE LANCASTER MACHINE & KNIFE WORKS.

The Lancaster Machine & Knife Works, of Lancaster, N. Y., is placing on the market the breast drill shown herewith which combines a number of useful features. It will be noted that it has a chain feed attachment. This attachment, which is automatic in its operation, and is operated by the supporting handle, allows pipes, beams and similar articles to be drilled with the greatest ease, it not being necessary for the workman to force the tool in by main strength. The machine can be adjusted to any angle, making it useful in working between girders and ceiling joists, and in the interior of machinery where space is limited. Where there is not enough room for a full turn of the handle, the ratchet attachment provided may be used. The tool is provided with two speeds for drills of different sizes, and the radius of the handle is also adjustable. The gears are machine cut. The head and socket have ball bearings, and the handles are cocobolo. The chuck is fitted with four steel alligator jaws which will firmly hold both round and square shank drills. If desired, however, the drill will be fitted with a 3-jaw chuck.



Universal Breast Drill made by the Lancaster Machine and Knife Works.

ECLIPSE POWER HACK-SAW.

The accompanying half-tone engraving, Fig. 1, illustrates a new power hack-saw brought out by the Eclipse Machine Co., Elmira, New York, and known as the Eclipse power hack-saw. An inspection of the general design of the machine plainly indicates that it is a radical departure in its field. The design of the machine makes it possible to cut off stock with greater accuracy than is usually possible with a power hack-saw, it being possible to cut off stock within limits of variation of not more than 0.002 inch for a 4-inch bar; at the same time the machine permits unusually rapid operation. The particular value of the accuracy obtainable is evident, as it saves expense in truing up the faces of the stock, which is usually necessary when stock has been cut off by a hack-saw.

As will be noticed in the half-tone, Fig. 1, the machine is provided with a stop device for setting the stock at any length desired to be cut off. This stop is automatic in its action, and requires a minimum amount of attention. An ordinary 20-inch hack-saw blade is used in the machine, and the stock is turned so as to always present to the saw an easy cutting surface, whereby the saw is saved, and therefore lasts longer than is ordinarily the case. In the line engraving, Fig. 2, the construction of the patented chuck

used in this machine for holding the material is illustrated. It is constructed on a rather novel principle, and will hold any size of round steel from ⅜ inch up to 6 inches in diameter, and square stock up to 4 inches in size. It is quickly operated with a single screw actuating device.

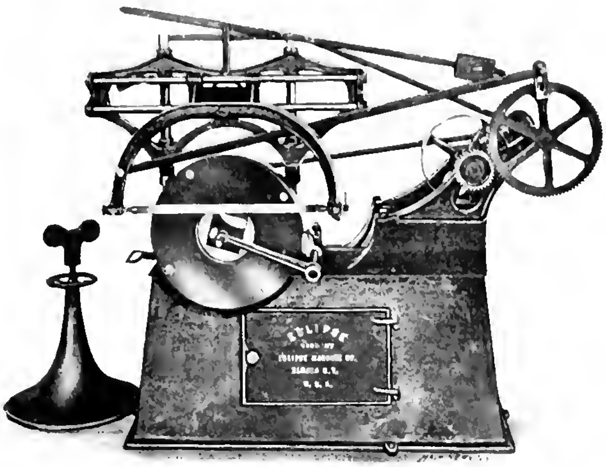


Fig. 1. The Eclipse Mechine Co.'s Power Hack-saw.

The power required to run this machine does not exceed one-half H.P. The weight of the machine is 650 pounds, and the floor space required is 4 x 2 feet. The selling agents are Manning, Maxwell & Moore, Inc., 85-87-89 Liberty St., New York.

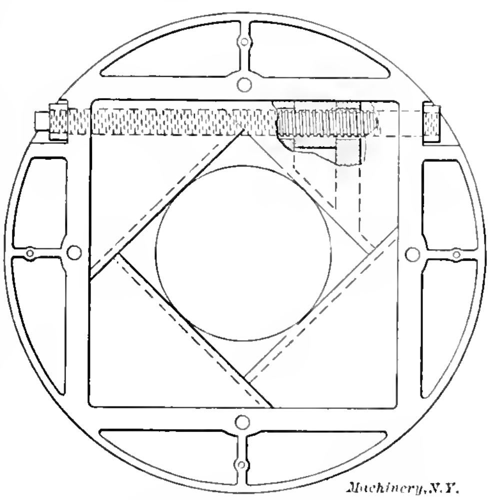

Fig. 2. Chuck of Simple and Ingenious Design used in the Eclipse Power Hack-saw.

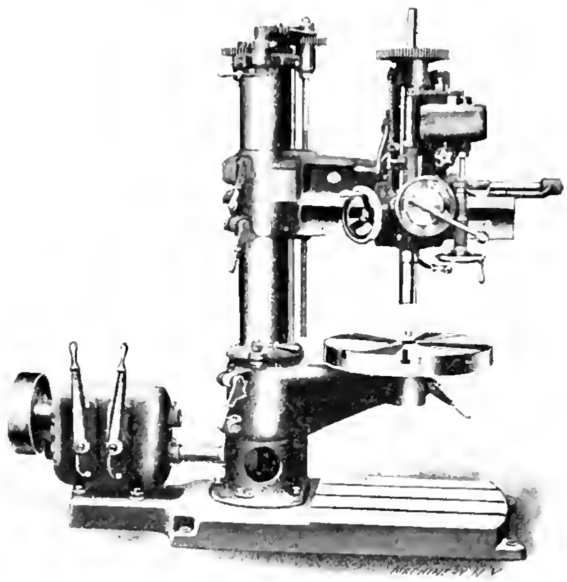
AMERICAN TOOL WORKS 2-FOOT RADIAL DRILL.

The American Tool Works Co., 300-350 Culvert St., Cincinnati, Ohio, is building the 2-foot radial drill shown herewith. This neat looking tool is an evidence of the inherent adaptability of the radial drill press, which is evidently proving itself useful in sizes which nearly come into competition with the old standard form of upright drill press. Of course, it goes without saying that any tool of this kind placed on the market in these days is designed with special reference to the use of high-speed steel tools. This would be plainly seen in the weight and massiveness of the parts even if no special mention were made of the fact.

The base is strongly ribbed at the point where the column is attached to it. This latter part is of the double tubular form. The sleeve or outer column revolves on conical roller bearings, hardened and ground, and may be clamped in any position by the builders' patented clamping ring which may be moved by the column to suit the convenience of the operator. The clamping of this makes the outer column practically integral with the inner one, which latter extends almost to the top of the outer column, having full bearings both at top and bottom. The arm is of combined parabolic beam and tube sections, giving greatest resistance to both bending and torsional strains. This design leaves the lower line parallel with the base, and thus permits work being operated on in close proximity to the column without the necessity of an extreme reach of spindle. The arm is raised and lowered rapidly by a double thread coarse pitch screw controlled by a conveniently placed lever. Arrow points provided, located on the column cap, indicate the direction of the movements obtained.

The spindle has 16 changes of speed obtained from a 2-speed counter-shaft, a 4-speed gear box, and a back-geared head. These changes being instantly obtainable and in small increments, give the workman the fullest facilities for driving his tool, whether a drill, tap, or counterbore, at the proper speed. The gear box is very powerful, of the geared friction type. The four speeds provided are instantly available through the operation of the two levers shown. This form of box makes it possible to change the speed with absolutely no shock, even under the most severe conditions. The back-gears are located on the head so that all the connecting shafting and gearing between the driving belt and the head operate at high speed and low torque. These gears may also be engaged and disengaged without shock while the machine is in operation, by a lever convenient to the operator, the high-speed movement being engaged by a friction clutch.



American Tool Works 2-foot Radial Drill.

TWO-FOOT ARM BACK-GEARED HIGH-SPEED RADIAL DRILLING TEST IN CAST IRON TWO INCHES THICK.

Size-Drill.	Speeds.		Feeds		Back Gears				
	Revolutions.	Cutting Speed.	Per Revolution	Inches per min.	Ratio.	Position.	Actual H. P.	Amperes.	Volts.

1 15/32" H.S.	207	79 5	.007"	1.4	1.5	Top	5.25	17	230
1 15/32" H.S.	207	79.5	.020"	4.14	1.5	Top	12 4	40	230

The head is adjusted on the arm by a hand-wheel through an angular rack and spiral pinion. It may be clamped to the arm in any position. The feeding mechanism in the head provides for four distinct rates in geometrical progression, carefully chosen, ranging from 0.007 to 0.020 inch. They are obtained by turning the knob shown just below the feed box until the feed desired, on the dial, comes opposite a fixed pointer. This obviates the necessity of referring to index plates in connection with the handling of levers. Positive-geared feeds of this type insure greatly increased productive

capacity, especially when using drills which can be pushed as hard as those made of modern high-speed steel. A friction member is provided in the drive, which allows the drill to be crowded to its limit without danger of breaking any of the mechanism. The feeds can be automatically tripped at any position of the spindle by an adjustable dog. Depth graduations are provided on the spindle, and all depths can be read from a datum point. The safety stop acts automatically at the full depth of the cut in preventing breakage of the feed mechanism. The tapping mechanism is carried on the head between the back-gears and the speed box, thus giving the friction clutches, though powerful in themselves, the added benefit of the back-gear ratio. This makes unusually heavy tapping operations possible, and also permits taps to be backed out at an accelerated speed. A lever for starting, stopping and reversing the spindle is controlled from the head at the front of the machine.

TWO-FOOT ARM BACK-GEARED HIGH-SPEED RADIAL DRILLING TEST IN STEEL THREE INCHES THICK.

Size Drill.	Speeds. Revolutions.	Speeds. Cutting Speed.	Feeds. Per Revolution.	Feeds. Inches per min.	Back Gears. Ratio.	Back Gears. Position.	Actual H. P.	Amperes.	Volts.
3/4" H.S.	406	79.7	.007"	2.84	1.5	Top	5.25	17	230
3/4" H.S.	406	79.7	.011"	4.46	1.5	Top	12.4	40	230
3/4" H.S.	290	56.9	.020"	5.8	1.5	Top	5.9	20	220
1 1/32" H.S.	290	78.3	.011"	3.2	1.5	Top	5.9	20	220

1 27/32" H.S.	76	36.6	.020"	1.52	5.72	Btm.	8.3	28	220

The accompanying tables give the results of tests made on one of these machines. The builders believe that these records are quite remarkable in the amount of power the machine will permit from the drive to the point of the tool.

TWO-FOOT ARM BACK-GEARED HIGH-SPEED RADIAL TAPPING TEST WITH PIPE TAPS IN CAST STEEL ONE AND ONE-EIGHTH INCH THICK.

Diameter Tap.	Speeds. Revolutions.	Speeds. Cutting Speed.	Feeds. Per Revolution.	Feeds. Inches per min.	Back Gears. Ratio.	Back Gears. Position.	Actual H. P.	Amperes.	Volts.
2 1/2"	38.5	28.9	1/8"	4.8	5.72	Btm.	9.14	31	220
3"	38.5	35.2	1/8"	4.8	5.72	Btm.	9.7	33	220
TEST IN CAST IRON ONE AND ONE-EIGHTH INCH THICK.									
2"	40	24.8	1/11.5"	3.4"	5.72	Btm.	4.24	14	226
2 1/2"	40	30.1	1/8"	5"	5.72	Btm.	5.15	17	226
3"	40	36.6	1/8"	5"	5.72	Btm.	5.75	19	226

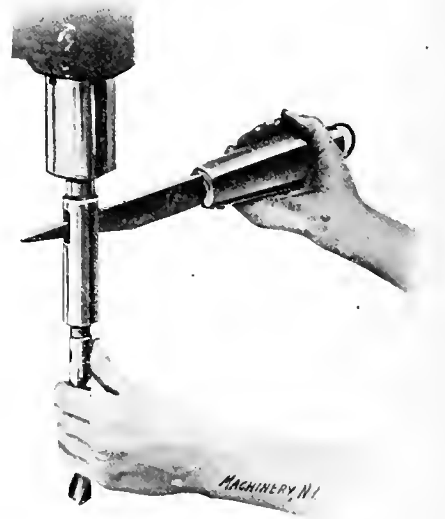
They call especial attention to the rate at which the 3-inch tap was operated in steet and cast iron, which was at the rate of 35.2 and 36.6 feet per minute, respectively.

Although the machine is shown arranged for single pulley drive through a speed box, it will also be provided with a cone pulley, if desired by the purchaser. The speed box arrangement is easily adapted to direct motor connection which may be made in a number of ways, though the builders recommend that the motor be mounted on the base beside the speed box and be connected to it by gearing.

AUTOMATIC DRILL DRIFT.

The drill drift illustrated in the accompanying half-tone is a practical appliance which undoubtedly will be appreciated in modernly equipped machine shops. It is known as the "automatic drill drift," and is manufactured and marketed by the Automatic Drill Drift Co., of Springfield, Ill. When in operation, the drift or blade is inserted in the slot in the drill socket and the drill is removed simply by sliding the heavy handle over the blade, until the base of the blade strikes against the bottom of its socket in the handle, this impact being sufficient to remove any drill. The tool consists of a hardened, polished steel blade, mounted in the heavy handle, as shown, in combination with a low tension coil spring placed behind the base of the blade in the handle. This spring serves to keep the blade permanently in its extended position, excepting when in operation.

The most pronounced advantage of the tool is that the drift and the driving mechanism are self-contained, requiring only one hand to operate the device, the other being free to hold the drill and prevent it from falling, as it invariably does when the operator is compelled to use one hand to hold the drift, while he drives it home with the other hand, by means of any object in sight. The size of the tool makes it practically universal for all ordinary purposes, as it will fit Morse sockets from No. 1 to No. 3 inclusive. A ring is provided at the end of the handle, by which it may be attached by a chain to the drill press, so as to always keep it in place, handy and ready for use. This tool, being so simple and inexpensive, should prove very useful in the machine shop, where it should cure the practice of driving drills out of their sockets by unsuitable appliances.



A Tool which combines Drill Drift and Hammer.

ARMSTRONG-BLUM MFG. CO., 113 N. Francisco Ave., Chicago, Ill. Hack-saw designed so that a drawing cut is produced, thereby doing away with the common tendency of buckling the saw blades. The blade is automatically raised on the return stroke by the action of a spring, which latter is so placed as to give the required pressure on the cutting stroke.

FERRACUTE MACHINE CO., Bridgeton, N. J. Foot press provided with a gang of one hundred 5/8-inch punches and dies for cutting paper blanks. The punches are hollow, each punch containing an ejector pushing the blanks through the lower die into brass tubes provided for their reception. The stroke of the press is 4 inches, and the total weight of press and dies, 2,750 pounds.

TECHNICAL SUPPLY CO., New York City. Duplex blue-printing machine for the continuous printing of blue-print, VanDyke, or other papers. Two Cooper-Hewitt lamps are used and two strips may be printed at once, at speeds varying from a very slow rate for black process papers, up to 4 or 5 feet per minute for fast printing papers. The rate of printing for the two sides of the machine is independent.

BUFFALO SPECIALTY CO., Buffalo, N. Y. Tandem hack-saw of original design, providing for two complete hack-saws in one frame, the object being to use the minimum amount of power, one saw cutting while the other saw is reversing. The saws are held out of contact with the work on the return stroke. Each saw has a capacity for cutting 5x5-inch stock with a stroke of 6 inches. The saws run at from 85 to 110 strokes per minute.

BUFFALO FOUNDRY & MACHINE CO., Buffalo, N. Y. Steam hammer, differing from the usual construction in that the anvil block is cast solid with the main frame, enabling the hammer to be used for small drop forging as well as for ordinary steam hammer forging work. The hammers are rated by the

actual scale weight of the falling parts, without counting the force of the blow from the pressure, and run from 100 to 300 pounds. The hammers can be run either by steam or compressed air without change.

Westinghouse Electric & Manufacturing Co., E. Pittsburg, Pa., after consulting prominent steel engineers, has placed on the market a motor especially designed for rolling mill service. It is thoroughly protected against dust, is provided with ample wearing surfaces, with plenty of clearance between the running and stationary parts, so that the machine will run indefinitely before they come in contact. The insulation used throughout is strictly incombustible, and will stand very high operating temperatures without deterioration.

Strong, Carlisle & Hammond Co., Cleveland, Ohio—Oil tempering furnace constructed so that the path of the flames strike the baffle wall under the oil tank, and are then deflected to the outer walls of the combustion chamber and to the sides of the oil tank. The furnace is equipped with a thermometer registering up to 760 degrees F., and with a chain hoist for raising and lowering the material which is contained in a heavy iron basket. The gas consumption per hour is 70 cubic feet; the floor space occupied is 36 x 37 inches; the capacity of the basket is 200 pounds.

Corbin Church Co., Plainville, Conn., is building a manufacturer's drill of single or multiple spindle type for drills up to ¾ inch diameter. The feed is 4½ inches. Each spindle has an automatic feed control which disconnects the feed when the drill has reached the proper depth, and returns the spindle, again re-engaging it when the operator is ready with a new piece of work, thus saving time in duplicate manufacturing. Combined with this feature is a device for automatically disengaging the feed when the drill point strikes a hard spot or other obstruction to its normal progress.

C. J. Toerring Co., 2121 Toronto Street, Philadelphia, Pa.—Machine for drying blue-prints. The machine consists of a series of small rollers revolved by friction contact with a larger heat roller revolving around a heat coil. The prints pass through a washing tank on the end of which the machine is mounted, and are fed into the dryer directly from the tank. This machine enables from 1,000 to 1,500 blue-prints of ordinary size to be handled in a day. It is run by a 1/20 H. P. motor; it runs at a speed of approximately 8 feet per minute, and requires 1½ K. W. per hour for heating.

G. W. Fleming Co., Bradford, Pa. A sensitive drill press of which the most original feature is a provision by which the spindle speed is changed by the lever for feeding the drill. Swinging this lever downward around the horizontal axis feeds the drill, as with the usual construction. Swinging the lever sideways shifts the friction roll in or out across the face of the driven disk on the spindle, changing the spindle speed. The speed can thus be altered while drilling is in progress, if it is found that a change is necessary, without removing the hands from the feed lever or the work.

Edwin Harrington, Son & Co., Inc., Philadelphia, Pa. Four-spindle locomotive frame drill built specially for the American Locomotive Works. Each of the heads is independently driven by a 6-horse-power variable speed motor. The minimum center distance between the drills is 28 inches, and the maximum center distance between the two outside drill heads is 34 feet 8 inches. The spindles can be brought within 16 inches of the top of the table, the maximum distance being 36 inches. The speed range is from 50 to 120 revolutions with, and from 100 to 300 without, the back gears. The feeds vary from 0.005 to 0.015 inch per revolution. The machine has a capacity of drilling four 2¼-inch holes simultaneously in steel, and weighs 46,600 pounds.

Our present educational system requires that a boy or girl leave school to learn to make a living.—*Common Sense.*

AN AMERICAN MECHANIC IN EUROPE—4.

THE FOURTH OF A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

Paris, France, June 17, 1908.

During the time which has elapsed since my last letter from Turin, Italy, the writer has visited the western part of Germany, following the Rhine Valley from Mülhausen, Elsass, to Düsseldorf, and has had an opportunity to meet most of the prominent machine tool builders and a large number of dealers in the cities along this route. It is difficult to give an exact statement of the present conditions of business. Dealers who have a large territory, and who sell a great variety of machinery and tools, and who, therefore, ought to be the ones best informed, say that the machine tool trade is dull throughout the country and that no improvement worth mentioning has taken place. Many dealers carrying on a smaller business, however, are reporting a fair amount of trade, and also that some improvement is noticeable. The machine tool shops are working with full, or nearly full, force and on full time, in this part of Germany. Some machinery, especially of the common types and sizes, is made for stock, but not to any large extent. Messrs. de Fries & Co., Düsseldorf, who are prominent both as dealers and manufacturers of machine tools, said that business is not good, but that there is no real cause for complaint. In their shops, where they usually employ about 800 men, the force was reduced about ten per cent, but the men remaining worked full time.

The railroad equipment shops here have, at the present time, large orders on hand from the various German state railways. This, of course, influences the machine industry throughout the country. In general, it can be said that Germany is carrying the industrial depression with less effect than America. The different business methods in vogue, the longer time of delivery for machines ordered, etc., are, of course, important factors; but one factor which greatly influences trade conditions is the German policy of government ownership of railroads. The state railways do not take into consideration a temporary industrial depression in ordering the material needed. Private roads, on the other hand, when a country is afflicted with a trade depression, refuse to buy and to equip themselves for future demands, and wait until times become better. This, of course, makes a trade depression still more pronounced, at the same time as it makes the crowded business in good times still more crowded. The machine tool industry, which depends to so great an extent directly or indirectly on the demands of the railroads, is thus benefited by the public ownership of the German railroads.

Wages in Germany.

In the letter in the June issue, the writer gave some figures relating to the wages paid in the machine tool industry in Italy and Switzerland. In Germany the wages paid depend upon the location of the shop, differing with the cost of living, the highest wages being paid in Berlin and its vicinity. In the northern part of Germany wages are generally higher than farther south. The Locomotivefabrik Krauss & Co., Munich, gave the following figures representing the average earnings of the men employed in their shops: Boiler makers, M. 5.50 ($1.32); blacksmiths, M. 5.70 ($1.37); machinists, M. 5.00 ($1.20); and unskilled laborers, M. 3.80 ($0.91), all based on a ten-hour day. Generally speaking, the wages in Saxony and along the Rhine are about 10 to 15 per cent higher than those quoted, and in Berlin from 20 to 40 per cent higher.

In a letter from the firm of R. Wolf, Magdeburg-Buckau, received recently in reply to an inquiry on this subject, the following information as to wages was given: Skilled machinists, 60 pfennigs (14.4 cents) per hour; pattern makers, 58 pfennigs (13.9 cents); unskilled laborers, 35 to 42 pfennigs (8.4 to 10.1 cents). Shop foremen receive on an average M. 200 ($48.00) per month, and draftsmen who have no technical school training, M. 150 ($36.00) per month. The workingmen in the shop are kept until the age of about sixty to sixty-five years, and old-age pensions are paid, amounting to from one-third to one-half of the wages of the last year in service, according to the length of time the employe has been in the firm's employ. This firm has a regularly installed apprentice-

ship system, the time of serving the apprenticeship being four years. The apprentices get, during these years small pay, increasing from year to year. There is no special trade school in this factory, but the apprentices are bound by contract to attend the artisans' and manual training schools of the city. Besides, the apprentices, like all boys without high-school education, attend the public evening schools up to the age of 17.

As remarked in a previous letter, the European wages are, when directly compared with those paid in America, very low; but it is not proper to make a direct comparison, because there are some other factors which count, besides the one of 4.17, the ratio between the American dollar and the German mark. These other factors must be taken into consideration in order to get a fair comparison. Living expenses here are somewhat cheaper, the work is more steady, and the workman who is carrying out his duties faithfully, does not live in such a fear of being laid off or thrown out of work as soon as business becomes ever so little "slack," which is so common in America; neither does he fear being laid off because of old age as early as is the case in America. The most important of all the factors to be considered, however, is the old-age pension paid by most—probably all—the State governments in Germany, and in some instances by the manufacturing concerns themselves. Two-thirds of the premium for the state pension is paid by the employer, and one-third by the employe himself. Having his old age thus reasonably well cared for, the working man can afford to expend a larger percentage of his earnings on his current living expenses.

Some Things Seen in the Shops.

When visiting the shops of Messrs. de Fries & Co., Düsseldorf, the writer took special interest in their screw-cutting practice. According to the works manager, screws of all descriptions—with few exceptions—are milled. For executing the common screw-cutting work by milling, ordinary screw-cutting lathes are rigged up with a milling attachment, which takes the place of the tool-post. The milling attachment is driven by belt or rope from an overhead drum. It is provided with a graduated scale by means of which the depth of the thread can easily be read off and adjusted. The rotative speed of the cone pulley is, of course, very much slower than that used for cutting the screws in the ordinary way. It is claimed that the greatest advantage of this practice of milling screws, over that of cutting them in the regular way is that unskilled labor can be employed, and that time is saved by this method because of the fact that one man is able to run more than one machine, the machine practically taking care of itself as soon as it is well started and the milling cutter is fed to the proper depth of thread.

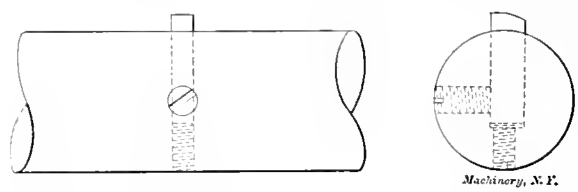
Because the lead of a screw being cut always depends upon the lead of a thread that has been previously cut, any incorrectness in the master thread (as in a lathe, in the thread of the lead-screw) will be reproduced in the screw. For ordinary purposes, the errors in the lead of lead-screws of lathes of good manufacture is insignificant, but occasions arise when these errors must be taken into consideration. In order to avoid the duplication of errors of this character, Messrs. de Fries & Co. have designed a new screw-cutting lathe, working on the principle of producing a thread independently of a previously cut lead-screw. The lathe employed for this purpose is of common design, the feature of extraordinary interest being the arrangement for feeding the carriage; a flexible steel band is used for this purpose instead of the lead-screw. This band is located centrally between the two ways of the bed, and one end of the band is fastened to the front end of the carriage, while the other end extends under the head-stock and is fastened to a drum, turned accurately to a definite diameter. When this drum is revolving, the steel band is wound up on it, and thus feeds the carriage. The drum, of course, must be large enough so that the steel band when winding up does not reach fully one complete turn around the drum, because if it reached more than one turn around, the band in winding up on itself, would be wound up on a larger diameter than that of the drum, thus causing incorrect results. The drum is driven from the cone pulley by means of a worm and worm-wheel.

For the return, another steel band is fastened to the rear end of the carriage, this band extending to the rear end of the lathe, and running over an idle pulley. A counterweight is suspended from this band heavy enough to pull the carriage back, when released from the pull at its front end. This lathe is not used for cutting the whole screw from start to finish, but simply for finishing the thread. The arrangement is by its construction too weak to stand up for the heavy cuts necessary for rough threading. The thread is therefore cut in an ordinary screw-cutting lathe, somewhat over size, and then placed in this special lathe mentioned, and there finished. The inventor of the device, the works manager of the company, claimed that by this machine it was possible to cut the most correct thread as yet produced for commercial purposes.

Threading Large Holes in Cast Iron Press Stands.

While visiting the shops of the firm of L. Schuler, Goeppingen, Germany, the writer took some interest in the method employed for threading large holes in the stands for the presses made by this company for sheet metal work. These presses are friction- and screw-driven, and a hole located at the top of the stand has to be threaded to take the screw which is to execute the whole actual pressing action, this screw varying for different sizes of presses from about 3 to 5 inches in diameter. As no inserted bushing is used, the thread is cut into the stand itself.

For the carrying out of this operation the stand of the press is put up in a heavy lathe, so that the center of the hole comes in line with the lathe centers. A heavy boring-bar is then used, one end of which is clamped in a chuck, mounted on the lathe spindle, and the other end extending on the other side of the hole to be threaded, supported only by a heavy steady-rest. The thread to be cut is of square cross section, and the cutting tool used is shown in the accompanying engraving. A square thread cutting tool is inserted in the boring-bar, being clamped on one side by a small headless set-screw, and fed into the work from the other side by a screw



Section of Boring-bar with Inserted Square Threading Tool.

at the rear end of the tool. In order to save the edge of the tool, it is taken out each time after passing through the work, before the work is returned to the original position; then the tool is inserted again at the front end of the hole, the tool being, at the same time, fed forward by means of the screw at the rear end of the tool, and a new cut started. A complete set of different sized boring-bars and tools for different diameters is, of course, necessary to meet the different requirements of the different sizes of holes to be threaded.

Machining Change Gears.

"Racquet's" article of the above title, in the April issue of MACHINERY, reminded me of a way of finishing change gears which I saw used in another German machine tool building shop. The first operation was to bore the hole in the blank. This was done in a vertical boring mill, and in this machine, also, both ends of the boss were finished by an ordinary facing tool. When the blank was finished so far, it was put on an arbor in a vertical milling machine, and the three surfaces on the rim, that is, the two sides and the outside cylindrical surface were here milled to the finished size in one cut by a gang milling cutter, consisting of one cylindrical cutter for the cylindrical surface of the blank, and two side milling cutters for milling the sides of the blank.

In another German shop the outside cylindrical surface of a gear blank was not finished at all by turning, only the sides of the rim being finished. In order to finish the cylindrical surface, the cutters for milling the teeth were so made that the teeth were finished on the top at the same time that the flanks and bottoms of the teeth were milled and finished. It seems as if this method would represent some saving in the cost of manufacturing the change gears, al-

though it might, to some extent, be done at the cost of the accuracy of the product obtained. The increased cost of milling cutters must also not be lost sight of.

Pickling Castings.

Great attention is paid to the proper pickling of castings. It is fully realized that the pickling process is not merely of advantage as a cleaning process, but that the greatest advantage of it is to be found in the softening effect upon the scale or skin of the castings, the tool not becoming dull as soon as if the casting had not been subjected to a proper pickling process. The most common solution used in Germany appears to be one of 20 per cent sulphuric acid, diluted in water. The solution is applied to the castings, not merely by putting the castings in the solution, but by forcing the solution against the castings through a large jet.

Cutting Metals by Oxygen.

In my letter in the May issue of MACHINERY reference was made to some work done by the oxy-hydrogen, or, more correctly, perhaps, the oxygen blow-pipe method of cutting iron at the Borsig Works, at Tegel, near Berlin. Some more detailed information about the use of this method may be of interest. As is well known, the principle involved in this method of cutting iron is the use made of the oxidizing effect on the metal, or, in other words, the iron is burned away. In order, however, to cause rapid combustion of the iron when the oxygen is applied to it, it must be heated to a temperature of 1,300 to 1,500 degrees F. before applying the oxygen. This pre-heating of the iron is accomplished by a burning jet of hydrogen and oxygen. The apparatus for cutting the iron consists of two nozzles, arranged to follow each other, the first nozzle pre-heating the iron, and followed by the second nozzle for the application of the oxygen, this causing combustion of the iron, and executing the cutting. The two nozzles are arranged so that the oxygen will always strike exactly the same spot which has been pre-heated by the preceding flame. It is important that the cutting nozzles be moved at a certain correct speed. If the cutting nozzles are moved too slowly, the continuous cutting will be interrupted, because the iron will get time to cool off before being struck by the stream of oxygen from the second jet. If, again, the nozzles are moved too quickly, the oxidizing effect will not be complete, and the cutting will not reach through the piece to be cut. With some practice, however, it is not difficult to learn by experience the correct speed for any particular work. When properly done, a cut made by this method is very smooth and equals a sheared cut.

It might be assumed that the material would be severely attacked on the surface by the influence of the oxygen, but this, however, is claimed not to be the case. With the exception of a layer of 0.01 inch, at the most, next to the cutting edge, the material keeps its original chemical composition, and the physical qualities remain the same. It is claimed that pieces of iron up to a thickness of twelve inches may be cut by this process. Of course, the exactness of the cut changes with the different thicknesses. At a thickness up to 2 inches, the process may be carried out within limits of 3/64 inch, while at thicknesses of from 2 to 4 inches, the limit attainable is 3/32 inch, and above 4 inches it is still less. The width of the cut, of course, also increases with the thickness of the material.

The blow-pipes are connected with flexible piping to the tanks filled with the respective gases. As the pressure in the tanks is high, being about 150 atmospheres when filled, the gas passes through a pressure reducing valve before being used. The pressure of the oxygen, when used for cutting, varies, depending upon the thickness of the material, from about 1½ to 5 atmospheres.

As a matter of curiosity, some work done by the assistance of the hydro-oxygen jet may be mentioned: when visiting the Deutsche Oxhydric Co., the writer saw a large bunch of grapes with leaves and branch of the vine, which, by the aid of the hydro-oxygen flame had been made from ordinary thin sheet iron. The imitation was good and, although the piece was of iron, it was very light. There was also a branch of a pear tree, with a large, nice-looking pear, and two leaves, and also a lily of the valley made in the same way. As a souvenir, the writer received a cup made, during his visit, from welded pipe, by the aid of the same process. The pipe was chucked in a lathe and then heated by the gas jet, and at the same time pressed to shape by hand by a plane tool.

The Geared Head vs. the Cone Pulley Drive.

The following interview with Mr. Louis Montigny of the Werkstätte für Maschinenbau, Mülhausen, is interesting because of illustrating European views on this important subject. Mr. Louis Montigny is an expert on the design of machine tools, and has been employed as such in several shops both in England and Germany, and his views are therefore not only important as giving his personal opinions, but also because they, in a measure, embody the general opinions in this regard abroad.

"During the last few years," says Mr. Montigny, "it has been quite the fashion here in Europe to equip lathes with geared head drives, but it doesn't seem to be the fashion quite as much now as it has been, and we are now again building a great many lathes with cone pulley drives."

When asked whether he considered the geared head drive preferable for modern lathes, Mr. Montigny replied: "That depends on several conditions. The advantage of the geared head, as compared with the cone pulley drive, is, of course, the easier control of the speed changing device. By means of the levers provided it is much easier to change the speed, according to the size and the material of the work to be done than is possible to do with belts on cone pulleys. If an experienced man is running the lathe, the geared head is preferable, but if an inexperienced and unskilled man is working at the machine, it is likely to cause trouble, because of breaking the teeth in the gears or by otherwise getting out of order. A mistake with a change lever may cause considerable damage, and the machine has to be laid up for repairs for at least a few hours. This, however, won't happen as easily with machines driven from cone pulleys, because there are not as many parts to break, and besides the belt will slip easier and act as a safety device. The greatest advantage of the geared head is to be found when the lathe is used for heavy duty work, as for instance, when taking a heavy roughing cut. With the geared head the belt speed is usually higher, and therefore more power can be transmitted without the liability of the belt slipping. This also means more power at the cutting point, and consequently a heavier cut. For very smooth finish turning, however, it is my opinion that as good results are not obtainable by the geared head lathe as with one having a cone pulley drive, because, for this kind of work, it is of advantage to have the belt drive the work directly. Transmitting the power through a long train of gears, as is the case in the geared head drive, always means, with the ordinary accuracy obtainable in commercial gear-cutting, some little jars and jerks, caused by the play of the teeth between the gears, and the consequence of this jarring will be noticeable on the turned surface."

Trade Conditions in Belgium.

The machine tool industry, as well as the machine industry in general, seems to be in a less prosperous state in Belgium than in Germany. Some of the machine tool works are running with the force reduced 30 to 40 per cent. Times are, however, reported to be improving, and manufacturers are optimistic in their views of the future. Belgium, being a small country, and consequently having a more limited home market, has not got any large machine tool works, the largest shops for manufacturing machine tools being equipped for about 150 to 175 men. It is interesting, however, to notice to what an extent some of these concerns are specializing their manufacture. There are two concerns making lathes as a specialty, the Ateliers Demoor, Brussels, and Le Progres Industriel, Société Anonym, Loth, near Brussels, both employing about 150 to 175 men. These shops are equipped throughout in a modern manner for manufacturing lathes. The machines are usually built in lots of ten to twenty. The detailed parts, after each operation, are brought into the inspection department and inspected so as to prevent any further working on a piece that has been spoiled.

The system of paying is according to the straight piece-work system, but the manager of the Ateliers Demoor seemed

to think a great deal of the bonus or premium system, and he is, at this time, working on the future application of this in the works. In fact, he already had this system applied in the erecting department, and stated that it had worked out so favorably as to save 30 per cent of the labor cost.

Another interesting shop in Brussels is that of the firm of Despaigne, a concern employing about eighty men. The specialties manufactured are bolt, nut, and thread rolling machines, and kindred kinds of machinery. The strong feature of this concern is some of their original designs, and of specially great interest is an automatic thread rolling machine in which a remarkably high speed is used.

Extended Use of Limit Gages.

It has been said about the German machine manufacturers that they have not as yet learned the extensive use of fine measuring instruments of which America boasts, especially of the micrometer. This is true, to a certain extent, but instead of going into the question itself regarding this, the writer wants to point out some interesting practice noticed in some shops on the European continent, and, in particular, in the two concerns in Belgium just referred to, who specialize in the manufacture of lathes. Generally speaking, the concerns in Europe have not as yet learned the full importance of specializing, but where this principle has been applied, the methods of manufacture are also modernized.

The two firms mentioned do not employ micrometers in their manufacturing to any large extent. For roughing work they use an ordinary pair of calipers. For the finishing work they use limit gages, not only for inspecting, but directly in the shop work. This, of course, is possible only when there is a specialization on a certain class of machines which are built in large numbers. The limit gages are of the double-ended type, where one end will pass over, while the other end must not pass over the work. For internal diameters limit gages of the double-ended plug gage type are used. These limit gages are all made in duplicates, and one is used in the shop and one in the inspection department, so that the machinist and the inspector are always working with exactly the same kind of an instrument. Any opportunity for disputes, differences, or misunderstandings, is thus entirely precluded. For all work made in large quantities, all the measuring instruments are kept in sets, and are used for this particular work only, so that mistakes because of using wrong gages are eliminated. It is claimed by these firms that the constant use of limit gages in the shop is superior to that of using micrometers. It is also cheaper, because the cost of the gages, is, in the long run, not as high as the time lost by setting and adjusting micrometers. There is also a great advantage in the fact that the machinist always knows the limits of accuracy required on the piece of work he is finishing, and no time is wasted on finishing the work to closer size than necessary.

Machine Tool Business in France.

The conditions in the machine tool trade in France are improving, and dealers and manufacturers alike are optimistic about the future. This is partly due to the improvement in the automobile trade. The automobile factories in the vicinity of Paris, which the writer has visited, have a fairly large amount of work on hand, and the machine tool factories are also busy. The machine tool industry in France has not as yet, as far as the quantity is concerned, reached the same height as in Germany. Comparatively few machine tools are made here, and France is, to a large extent, depending upon American, English, and German imports for supplying the demand. Regarding the quality of the machine tools made in France, however, judging from the products of a few concerns, this can be put on a level with the German makers' products. One of the most important machine tool factories in the country is the firm of H. Ernault, Paris, employing about three hundred men. This factory is equipped with high-class machine tools, among which is a large number of the best American makes, especially in the gear-cutting department; the firm specializes in lathes, milling machines, and gear-cutting machines.

The Société Francaise de Machines-Outils, about which considerable has been written, occupies at present only a small plant employing about one hundred men. The building of the main works has progressed so far that some machines are being put in, and a few are already running there. The buildings are fully up to date in construction, and are to be equipped with several electric traveling cranes with a railroad track running through the building. Among the machines in operation were several American, English, French and German, all of high class. Mr. Nardin, the manager, is a very capable engineer, and said they intended to employ about seven hundred men when everything was running. All the castings are made outside, as they do not have any foundry of their own, and all the power running the machines and for lighting is brought from a large electric central station. At present the company is making lathes of a few types only, a gear head and cone head, and a turret lathe which they claim is an improvement over the Potter & Johnston machine; an automatic dowel pin machine, and a spur gear planer of Mr. Nardin's own design; but they intend also to take up the making of planers and vertical boring and turning mills.

American Manufacturers must Keep in Close Touch with the Foreign Trade.

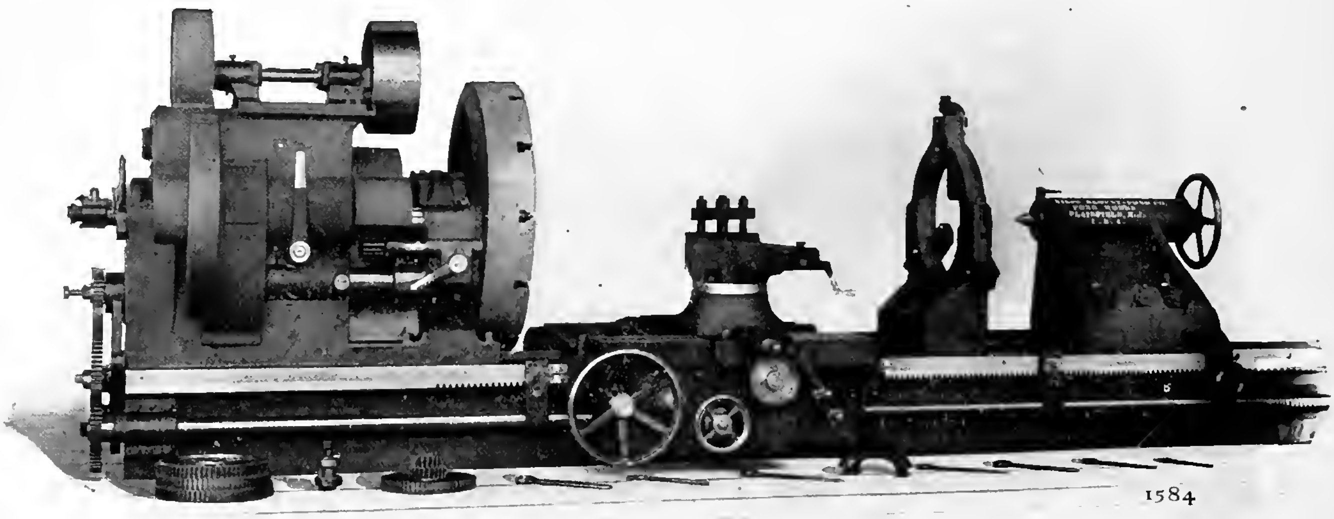
In Germany the criticism in connection with American machine tools was more or less limited to the criticism of a few points of the design and the workmanship, although something was said, especially in Berlin, in criticism of the way in which the American machinery in general is introduced abroad. This point of criticism is put forth with much more force and emphasis in Paris. Because of the competition between American machines on the one hand, and German machines on the other, the French dealers and users have a splendid chance to compare the different methods employed. The dealers in Paris seem to think that the American manufacturers neglect the duties they owe to their European trade. Not only are conditions in Europe different from those in America, but those in one European country different from those in another, and it is of great importance that American manufacturers should study the local conditions, and conduct their business in each country according to these, and not according to the conditions in America. It is emphasized that American manufacturers who really want trade in Europe should either go over themselves or send some one, preferably one familiar with the language, to study conditions, and while there, to devote himself to business, and not to sightseeing and pleasure. One dealer pointed out the great success of two American concerns in introducing their products in France. One of these concerns represents the very highest class of machinery, while the other has not as yet attained for itself so high a reputation, but both concerns have from time to time studied the conditions, and conducted the business with due regard to local requirements. The success of the smaller firm mentioned proves that it is not only the very highest grades and classes of machinery that can be sold here, but also the medium grade, if sold at a corresponding price, provided it is properly introduced. As an instance of an American manufacturer neglecting his foreign trade, it may be mentioned that one dealer stated that about half a year ago he had signed a contract of agency for an American concern, but he has not as yet received any price list of the machines he is to sell.

A comparison has been made between the American and German ways of introducing their machinery in France, and the Germans are said to employ superior methods. Of course, they are nearer the territory, and are in possession of more first-hand local knowledge, and can therefore attend to their business better. France gives, however, the impression of being a better territory for American machinery than does Germany. The competition with the home manufacturers would not be keen here. It would, therefore, be deplorable if American manufacturers lost this opportunity as a consequence of neglecting to obtain sufficient local knowledge about the requirements to carry on business with the highest possible efficiency. If American manufacturers do not take advantage of the opportunity presented, there is no doubt that the German manufacturers will use this to their advantage, and gain thereby.

POND HEAVY LATHES

GEARED HEAD

Driven by single pulley with wide belt or direct connected motor.



48-inch Pond Geared Head Engine Lathe.

A heavy powerful machine for use with high-power steel tools.

The face plate spindle is driven by a single pulley of large diameter and a wide belt through gearing, which, in connection with the two-speed counter, gives twelve spindle speeds.

Machine swings 49 inches over the bed and 39 inches over the carriage—with 16 foot bed will turn 7 feet between centers.

All shafts in headstock run in bronze bearings, which are self-oiling with large oil wells.

When motor driven a variable speed motor is mounted on headstock and is direct connected through gearing, giving a wide range of speeds.

Drive may be readily changed from belt to motor after machine is installed.

Photographs and full description furnished on request.

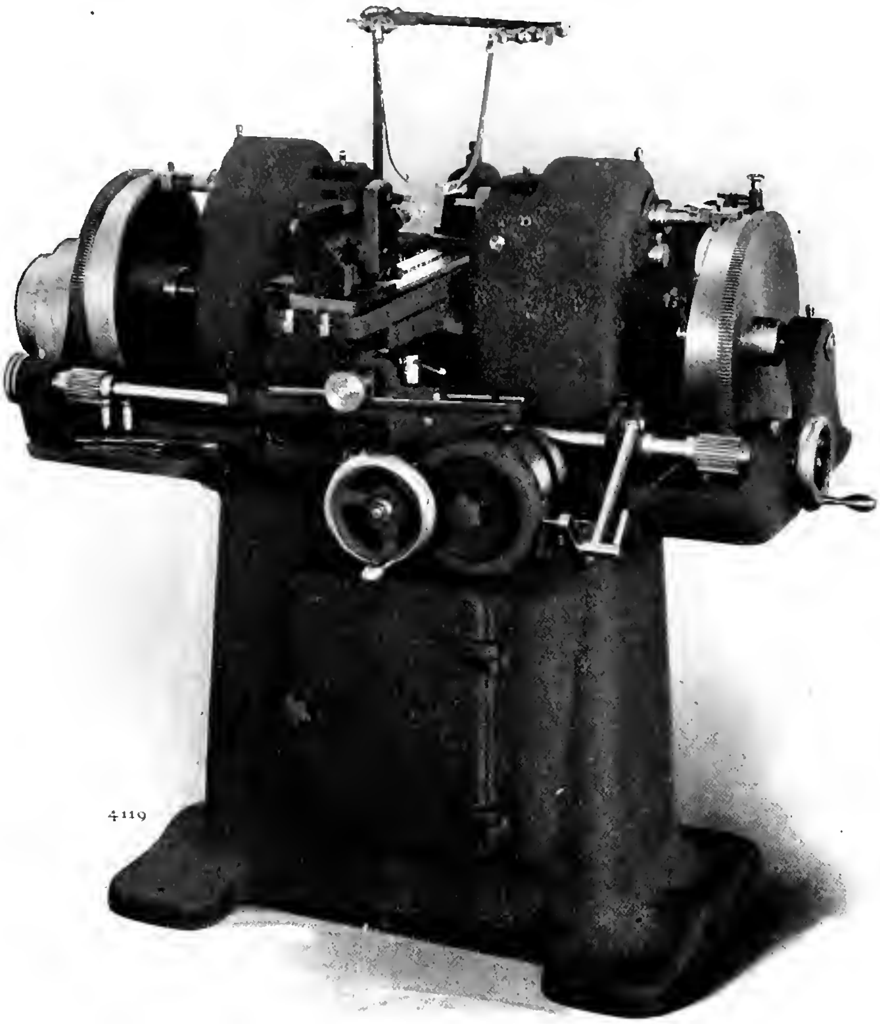
SPLINE Milling Machine

An Entirely New Machine for Milling Slots with Closed Ends, Keyways, and an Endless Variety of Other Work.



The New Spline Milling Machine.

This machine, embodying new principles, takes care of work for which heretofore there has been no suitable machinery.

Considering its use the designer may take advantage of the use of slots—which many times would simplify his designs, but which have in the past been avoided owing to the high manufacturing cost.

The great advantage of this tool will appeal to the manufacturer who has formerly been compelled to resort to expensive broaching operations or to hand milling for cutting keyways with closed ends, and tang slots which owing to their depth require extreme care in manipulation of tools as well as the continuous services of a skilled operator.

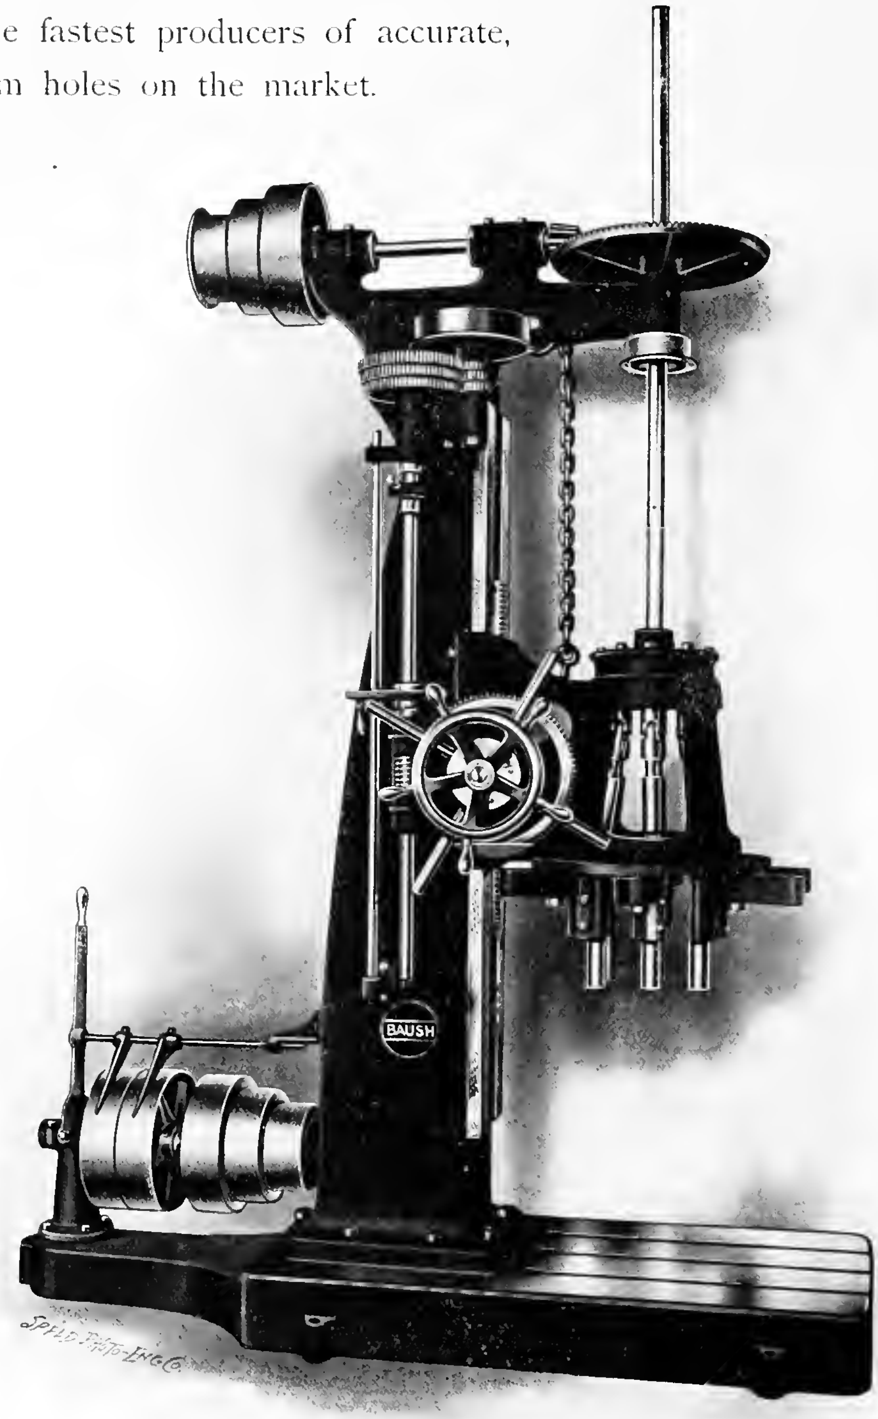
The Baush Adjustable Multiple Drills

are the fastest producers of accurate, uniform holes on the market.



They are made in 20 different sizes and several styles; carrying spindles which are adjustable to cover any layout and all holes are drilled simultaneously. Let us show you the drill for your work.

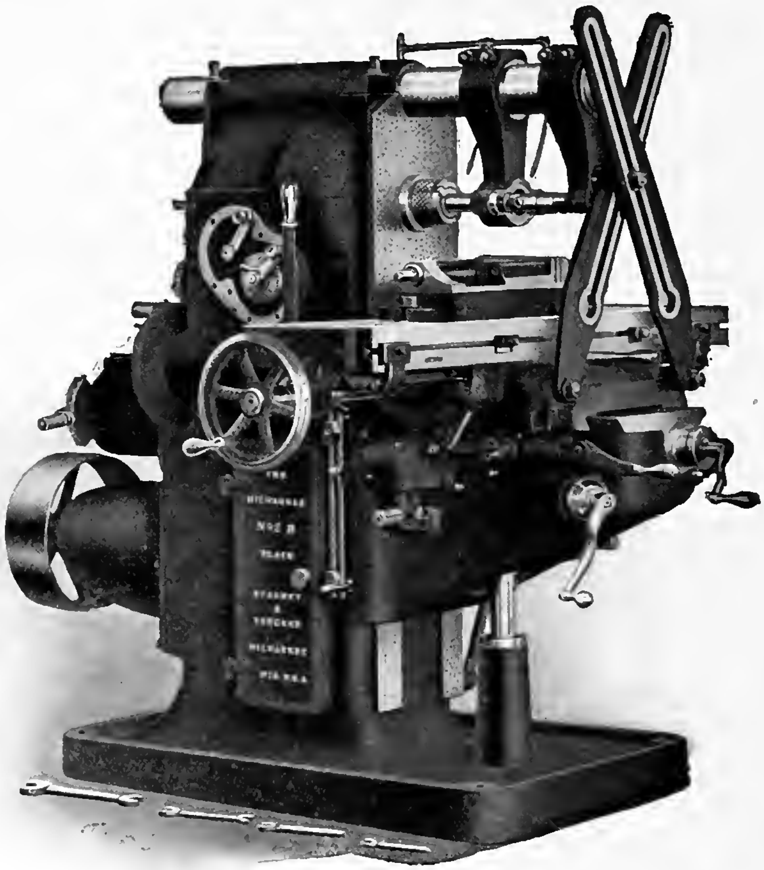
Cut shows our No. 16 Multiple, for six 1″ drills. Ask for bulletins.

Baush Machine Tool Company

200 Wason Avenue, Springfield, Mass., U. S. A.

AGENTS—Manning, Maxwell & Moore, Boston, Cleveland, New York, Philadelphia, Pittsburg, Chicago, Detroit, Syracuse and Birmingham. Selig, Sonnenthal & Co., London, England. DeFries & Cie, Akt. Ges Dusseldorf, Germany. Fenwick Freres & Co., France, Holland, Switzerland and Italy. Hugo Tilquist, Stockholm. Takata & Co., Japan.

ONE OILING FOR THE SEASON'S WORK



Is the treatment required by **Milwaukee Millers** and no stuck or cut bearings interfere with the steady employment of the machines at their maximum capacity. All gears and bearings are automatically flooded with oil, preventing noise and reducing friction and wear to a minimum.

Every machine is equipped with a pump for supplying a flood of lubricant to the cutters and ample means are provided for its return to the reservoir in the base of the machine. Wide tables on both Plain and Universal Machines, a great advantage in clamping work. Single pulley drive without countershaft or overhead belts and electric motor can be attached at any time.

Full particulars on request.

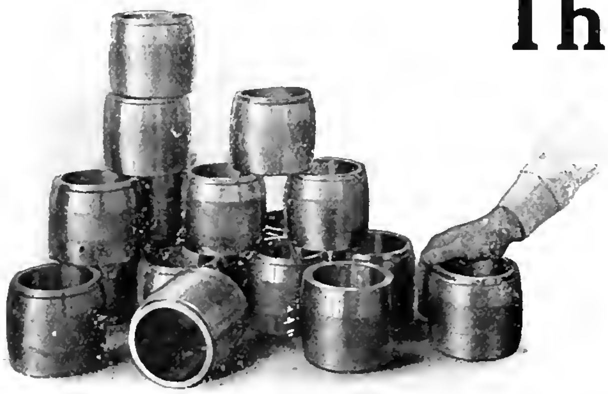
There's an all around Shop using



Samples of chuck work.

The operator is *Satisfied* he can do a good day's work, the superintendent is *Satisfied* with the quality of work produced and the manufacturer is *Satisfied* that he will reap a *Satisfactory* profit.

Reasons for it, of course—the very best of reasons. You'll find them in the sterling qualities of the machine itself. Its strength, convenience, the rigid control of work and tools; wide range of usefulness; ability to handle chuck or bar work with equal facility; rapid change from one class of product to another; universal equipment of tools, and in the special Flat Turret features such as Cross-sliding Head, Single Drive, Variable Speed device and unusual system of lubrication.

Work from the bar turned out on the Flat Turret Lathe.

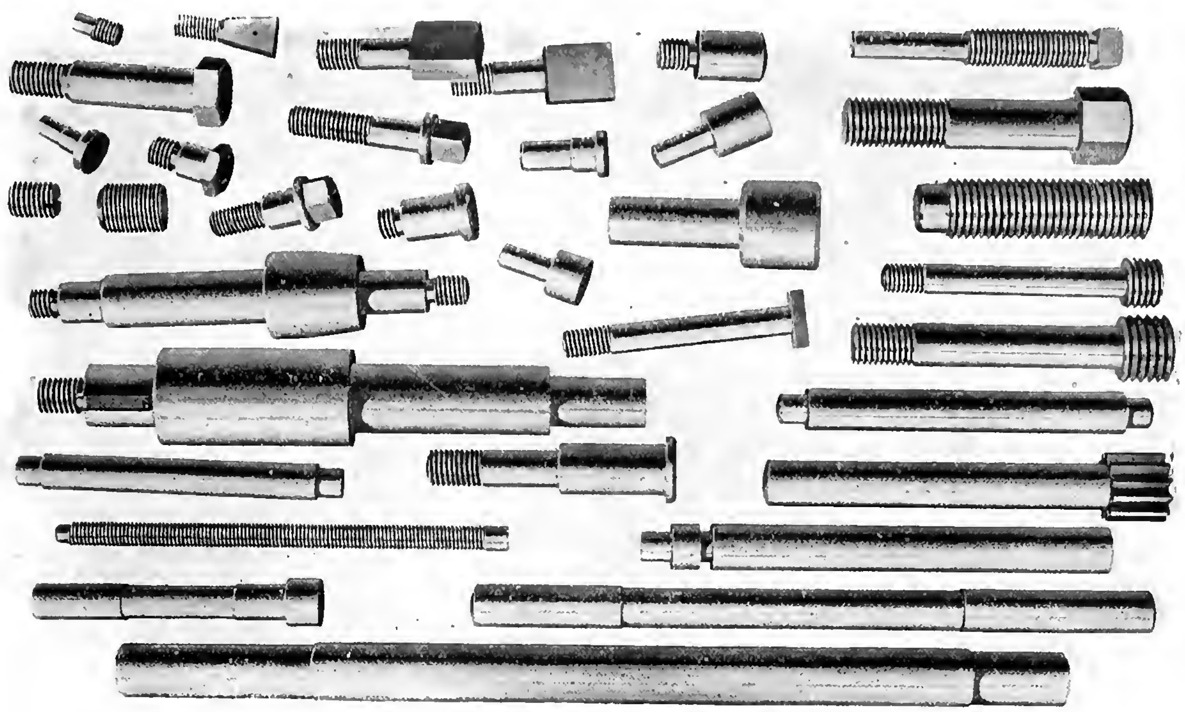
Sense of Satisfaction Pervading the FLAT TURRET LATHES



Work from the bar turned out on the Flat Turret Lathe.

We just mention a few of the reasons to give you a line on its up-to-dateness, but we will be glad to explain fully if you are interested. We make a guarantee as to the percentage of saving the Flat Turret Lathe will effect—and an individual estimate is at your service if you will permit us to send a representative to your plant.

More than 5000 Flat Turret Lathes are in use in this country and abroad. Two sizes, 2 x 24 and 3 x 36.

Examples of chuck work.

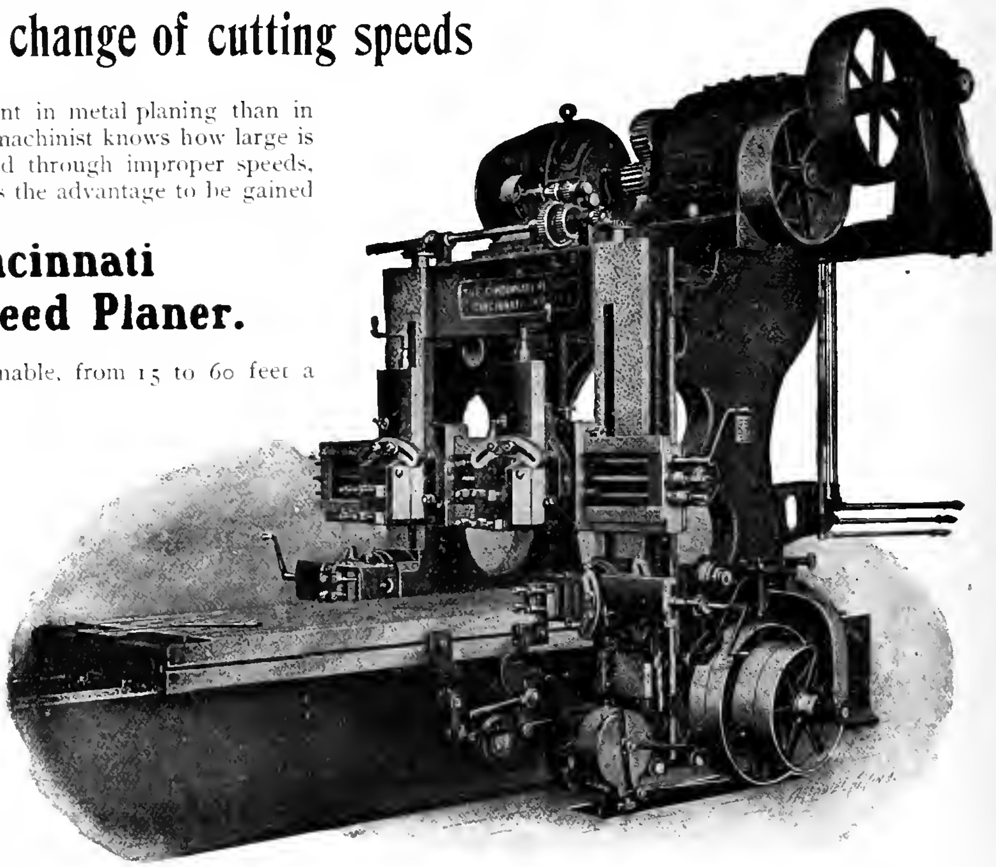
CINCINNATI, OHIO, U. S. A.

The Best Results from High Speed Steels cannot be obtained without ready access to a change of cutting speeds

This is perhaps more important in metal planing than in any other operation. Every machinist knows how large is the percentage of time wasted through improper speeds, and by the same token knows the advantage to be gained through using

The Cincinnati Variable Speed Planer.



Four changes instantly obtainable, from 15 to 60 feet a minute. Massive, powerful and saves 25 to 50 per cent. in time over the one-speed machine.

Write us for more points.

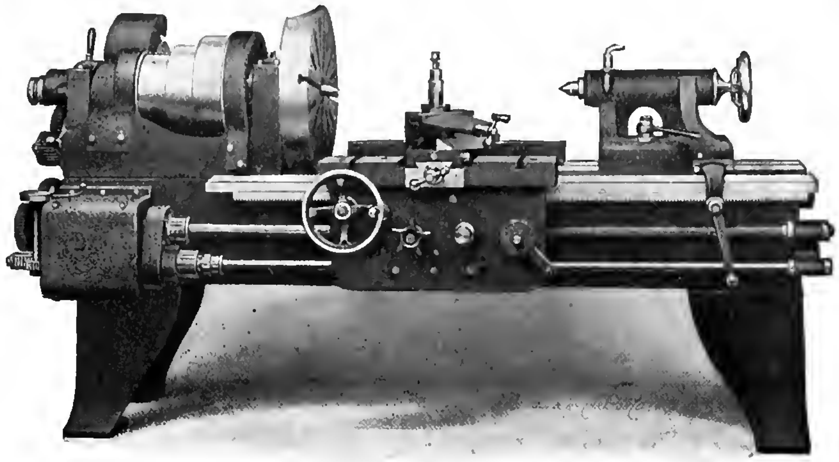
WHITCOMB

Engine Lathes



Increased Facilities for Operation

Rigid design and unusual power are distinguishing features of our new line of Engine Lathes. The beds are of improved box pattern, deep, heavy and very stiff. Power is obtained through double back gears and a three step cone carrying a wide belt. Changes of speed may be obtained even more easily than in the ordinary lathe. The range of feeds is very wide, and at all times five changes of feed can be instantly obtained by the simple movement of a conveniently placed lever. The capacity of these lathes for high class work, their convenience, durability and economic use of high speed steels, put them in the front rank among manufacturing tools.

Ask for new Engine Lathe Catalogue.
We also build a full line of Second Belt Planers.

The National New Wedge Grip Bolt and Rivet Header

has exceeded even our fondest expectations, and is worthy of the careful investigation of all bolt machine users.

The wedge prevents any "rocking" or springing open of the grip dies, and it is unnecessary to overgrip (hence batter) the dies to secure the required amount of gripping pressure. *As a result the dies will last from three to four times as long as in the regular toggle headers.*

Fins, also, are practically eliminated, and this combined with the die saving makes the installation of this machine a plain business proposition.

One customer has ordered twenty-four.

We build complete equipment for Bolt and Nut Plants.

Our aim is to build our machines better, if anything, than need be.

Hence, we are in position to furnish only the best.

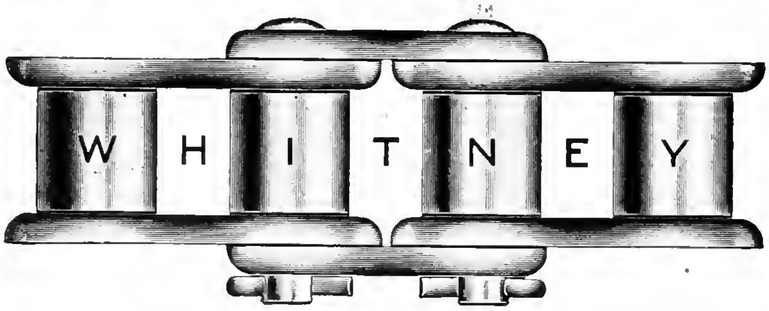
If you are not taking advantage of the Woodruff Patent System of Keying it will pay you to investigate.

Better results and a great saving in cost.

We carry 95 regular sizes of Keys and Cutters in stock for immediate delivery.



"Whitney" Patent Cotter Detachable Roller Chains

Made a fine record in the Briarcliff Road Race.

THE WHITNEY MFG. COMPANY, New York City, May 2, 1908.
Hartford, Conn.

Gentlemen—The uniform strength of an automobile driving chain is one of the important requisites in a speed contest.

The "Whitney" Chains which formed a part of the equipment on our three "Stearns" Cars in the recent Briarcliff Stock Car Road Race, showed their superiority by coming through this exceptionally difficult contest without the sightest evidence of the terrific strain which they had undergone. Our "Stearns" Cars made an exceptional showing in this race, and we attribute our success in no small degree to the entire absence of chain trouble.

Our experience in previous contests has taught us that a faulty chain can cause a lot of trouble.

We therefore take this opportunity to express the satisfaction which we feel at the manner in which "Whitney" Chains demonstrated their worth.

Your very truly,

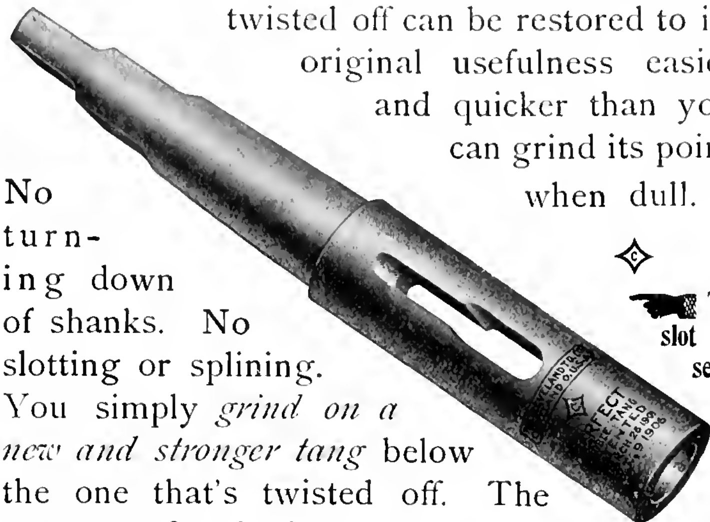
WYCKOFF, CHURCH & PARTRIDGE,
By C. F. Wyckoff, President.

The Whitney Mfg. Company, Hartford, Conn.

Ready for the scrap-heap.

From the Scrap Heap to the Drill Press

Any taper shank drill with its tang twisted off can be restored to its original usefulness easier and quicker than you can grind its point when dull.



The lower slot drives the second tang.

No turning down of shanks. No slotting or splining. You simply *grind on a new and stronger tang* below the one that's twisted off. The new tang fits the lower slot in

"PERFECT Double Tang" SOCKETS

(PATENTED)

Made as Rough, Fitted and Shell Sockets. They are simple, "fool-proof," and inexpensive; have no parts to get out of order, and will *fit any spindle* having a regular taper hole. With them you can

The Change from Belt to Motor Drive can be so easily made on the

"Libby" Full Swing Side Carriage Turret Lathe

that it is *accomplished* in less time than it takes to arrange preliminaries in the ordinary machine and at a very small cost. No need to change the head-stock, any 2 to 1 type of motor can be used. This new lathe will reduce production costs on a wide range of duplicate machined parts and is especially adapted for heavy service.

Ask for Bulletin giving special "Libby" advantages.

Do you want the "Real Thing" or a Substitute?

THE GRAHAM OR DETROIT CHUCK

is the Original Chuck for holding drills, taps, reamers, etc., with grooved shanks. The very merit of the device was bound to breed imitators—a good thing is never long without them—but the *Original Chuck* has advantages its followers lack.

It is at once simple, durable and practical. It holds the tools so that all danger of turning, slipping or drawing out of the chuck is eliminated. It fits the spindle of any drill-press or lathe. It saves drill breakage; saves 10 per cent. in time; assures accurate work and is adjusted by a single turn of the sleeve without the aid of wrench, set screw or hammer.

One Chuck, with reducers, will hold a complete range of tool sizes from 3-32" to 2 1-2"

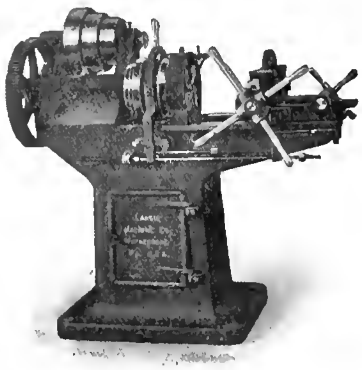
Threads to Cut?



Bolt threading, small pipe, special work of any kind? Do it on the "Landis." The improved Die in the Landis Bolt Cutter has solved the thread cutting problem. It increases production, insures accuracy, outwears any other die ten times over, has positive lead, correct clearance, a permanent throat, requires neither hobbing, annealing or retempering, covers a wide range of special work, and the same chasers will cut right or left hand threads.

Let us send our latest booklet.

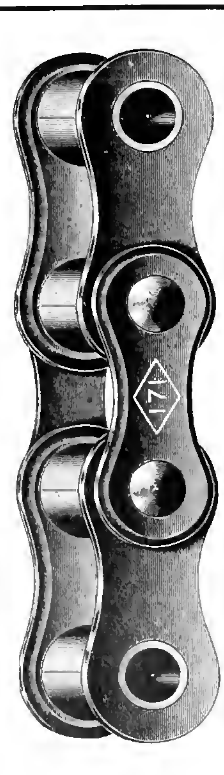
Office, 1125 Hamilton Street.



You Can't Beat Diamond Chain

If you want efficient short drives,

If you haven't time or money to waste on belt dressing, or can't afford power loss through slippage,

If you don't want noise and wasted power as with gears,

If you DO want your machines to run at exactly the right speed all the time,

If space is an object,

The one good solution is

DIAMOND MACHINERY CHAIN

with which you can run the driven shaft always at a speed proportional to that of the driver, and do it without expense for labor or repairs.

Diamond Chain is light, will go into a much smaller space than belting, and will far outlast the best belt made. Try a Diamond Chain, on one machine.

Write for Book "Chain Transmission of Power."

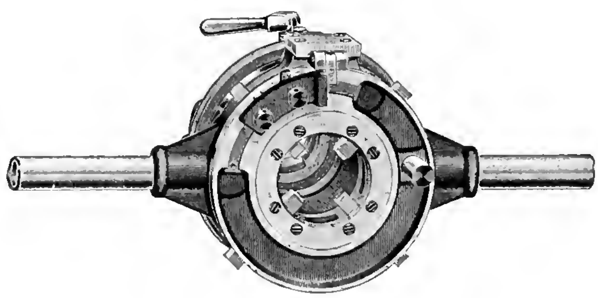
CLEVELAND, O.

In threading pipe with a

"BUCKEYE" DIE STOCK

One man does all the work on 2-inch pipe, for instance, with ease.



The operator simply continues the easy turning-around, until he feels the dies release themselves automatically,—that means the thread is finished; there is no turning back to be done then. Several other good points.

The Uniformity of Work Produced by the Grant Riveting Machine

is an advantage that would alone be sufficient to put the Grant machine in the lead; but beyond this the work is superior to other methods of riveting, can be done in a fraction of the time, and the process is absolutely noiseless. No blow is struck, plates are not cracked or bruised, and a smooth, perfect head can be swedged on any rivet in one second.

There is a profit bearing side to the Grant Riveting that will interest every manufacturer.

LAUNCHING A GREAT LAKES FREIGHTER.

RALPH E. FLANDERS *

THE work of the engineer, for the most part, has a dull and uninspiring aspect. Years of experience may have been brought to bear on the design and manufacture of a 90-pound rail, but the traveler who is whirled madly over it in the eighteen-hour train, knows little of the care and skill expended in perfecting this one of the many details which have to be perfected, if his journey is to be reasonably safe and comfortable. The planning and construction of the water system of a great city requires engineering ability of the highest kind, and on the successful solution of the problems involved, depend the health and happiness of thousands of human beings; but, aside from an incidental spectacular undertaking, like the Croton Dam, or the long intake tunnels of the cities bordering on the Great Lakes, there is nothing beyond the occasional frozen pipe or too industrious meter, to draw the attention of the householder to any point more distant than the faucet from which he obtains his supply.

When it comes to the building of a vessel, however, the engineer has his turn, particularly in the act by which the completed hull is transferred from the solid ground on which it was built, to the water which is thenceforth to bear it throughout its useful life. The launching of a vessel is spectacular in the extreme, and has excited the imagination of poets and moralists for generations; and there is no purely engineering event which has such a fascination for the common, everyday, unimaginative citizen who is fortunate enough to witness it.

From what has just been said, the reader may perceive (even if the thought would not occur to him naturally) that Mr. Pessano, president of the Great Lakes Engineering Works, provided a most satisfactory spectacle when he arranged for the launching of a large freighter during the time of the convention of the American Society of Mechanical Engineers, at Detroit, last June. Not only was the event spectacular, as intimated, but the means provided for supporting the hull on land and launching it into the water, are of such an interesting nature, mechanically, that quite possibly a brief description of them will be appreciated by the reader.

In the first place, we will have to understand a little something of the way in which the hull of a vessel is erected. In the shipyard in question, the work is carried on in a very systematic fashion. The various plates and beams which go to make up the keelson, frames, sides, etc., are all cut, drilled, and formed in the shops, to patterns carefully prepared in the mold loft, from drawings furnished by the designers. As these parts are completed, they are taken to the berth in which the vessel is to be constructed, where they are assembled into place in their proper order, it being taken for granted that no further drilling or fitting will be required. The keel plates and keelson are laid, the frames erected, and the side and bottom plates temporarily bolted in place, all with astonishing rapidity.

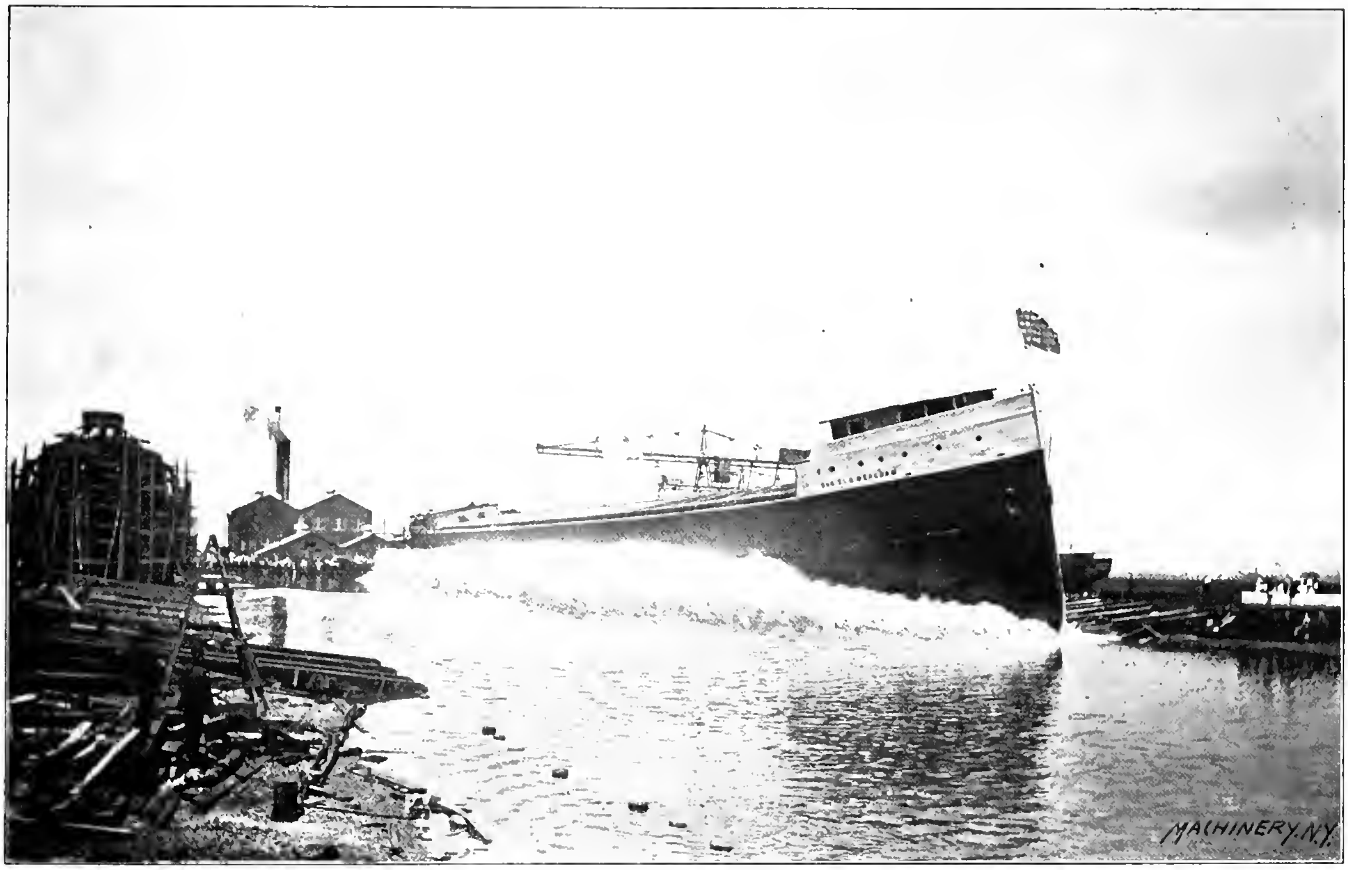

Fig. 1. The Launching of the 10,500-ton Lake Steamer, the Daniel B. Meacham, an Event of the Detroit Meeting of the A. S. M. E.

The whole structure is supported, with the flat bottom five or six feet from the ground, on piles of heavy blocking, placed under the various frames, where the great weight of the hull can be borne without damage to it. These piles of blocking will be seen in Figs. 2, 3 and 4, where they are shown resting on the ground, being thus distinguished from those to be described later, resting on the sloping beams or "ways."

It will be seen that each of these piles is capped by a block set on wedges, by means of which the support given the hull may be increased or relieved. The necessity for this will be understood when it is remembered that each of these many supports has to be removed during the progress of the work,

* Associate Editor of MACHINERY.

to permit rivetting the holes in that portion of the hull which it conceals. As the rivetting proceeds, and these piles of blocking are from time to time removed, the weight reposing on each is transferred (by means of the wedges) to new piles, placed in adjacent positions under completed areas of the hull. It will thus be seen that when the dry land work is finished, every one of the original supports has been removed, and the whole weight transferred to a new foundation.

As the hull approaches completion, preparations are made for the launching. It should be understood that these flat-bottomed, cargo-carrying vessels are, in the Great Lakes district, launched sideways into the water. This can be done into a narrow slip, without obstructing navigation in the channel. No cradle is required for supporting the sliding hull, as is necessary with sharper built, high-speed vessels.

Before the time set for launching, the sloping beams known as the "ways," and shown in all the illustrations, are solidly laid beneath the vessel, with their smooth upper surfaces lined up in the same plane with each other. New piles of blocking (shown in Figs. 2, 3 and 4) are then erected on the ways, with top blocks supported by wooden wedges whose ends are barely entered, as shown best at *A* in Fig. 3. Before laying this blocking, the surface of the way beneath the pile is greased, and a dog is driven in to prevent the blocking from slipping, until the hour arrives for the launching.

When everything is ready, all the wedges *A* in all the piles are driven in, and the whole ship is thus lifted onto the ways. The stationary piles, such as *B* in Fig. 3, are then loosened and

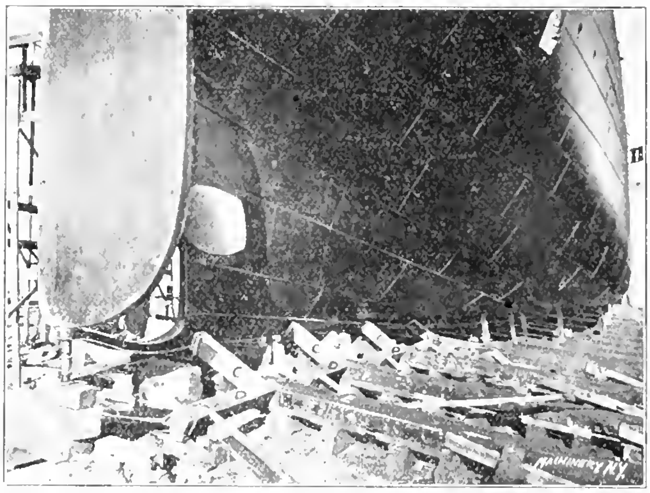

Fig 2. View of Stern showing the Launching Ways, and the Three Triggers which retain the Vessel at this End.

knocked out of the way. To facilitate this, it will be noticed that in pile *B* is a double wedge block, held together by a steel plate with cross pins at each end. If the hull is not entirely lifted from the blocking, the removal of the pin in the plate permits the upper wedge block to slide off the lower one as soon as the vessel begins to move.

Provision has to be made to keep the vessel from sliding off into the water after it has been raised onto the ways by the driving of the wedges, and before the moment for launching arrives.

To effect this, struts or "dog shores" *C* (as shown in Figs. 2, 3 and 4) are set against the seam of the keel-plate of the vessel, with their lower ends bearing on triggers *D*, which, in turn, are supported at the inner ends against abutments *F* on the sides of the ways *E*. The dog shore and the abutment are so located as to make each trigger a lever of high ratio, and the force with which the vessel tends to slide down the ways is transferred (in diminished degree) to the wire ropes looped around the outer end of each. As may be seen in Fig. 4, these wire ropes are carried to the upper side of the berth, where they are attached to posts in the ground by ropes and tackle blocks, by which the triggers and dog shores are strained up against the keel-plate. It is the chopping of these ropes, where they are looped around the posts, that finally releases the vessel.

In this case there were eight triggers—three each at the bow and stern, and two amidships. In Fig. 4 a workman is shown in pantomime in the act of cutting one of the trigger ropes. If he had done it in reality at the time the picture was taken, it is well within the bounds of possibility that he might have been "fired."

The order of procedure in launching is something like this: First, the exposed portion of the upper side of the ways is greased, the area under the blocking having been already treated, as explained. Then a small army of men is set at work driving the wedges (see *A* in Fig. 3), which raise the

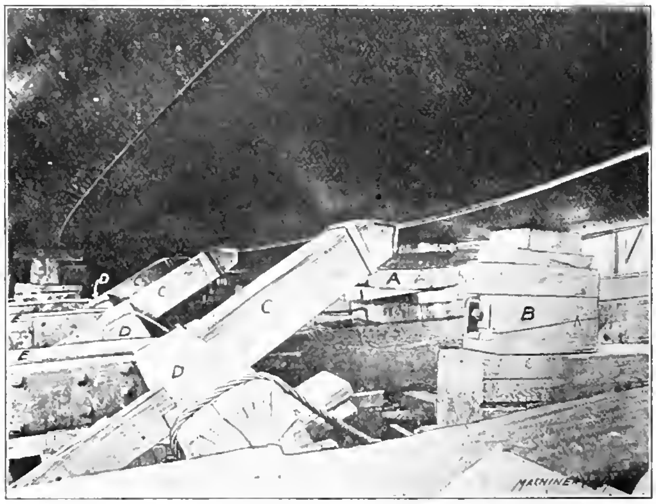

Fig. 3. Details of the Trigger, and the Stationary and Sliding Blocking under the Bow.

vessel onto the ways. After a few minutes of driving, a period of rest follows, to allow the blocking to settle as it receives the weight. Then a second period of driving, another of rest, and the final drive, which leaves most or all of the ground blocking free, the vessel being now held from sliding only by the triggers and the dogs driven into the ways.

As the blocking and the dogs are removed from each section, the foreman of that section, assured by careful inspection that everything is free, removes from the ground a white stake, previously set outside of his section. In addition, there are three stakes at each end of the line, representing the three piles of keel blocking at the stem and the stern. As the clearing away of each section proceeds, the superintendent is informed of the progress of the work by the successive removal of the stakes, and the final removal of the keel block stakes at the ends. When all is thus known to be ready, the time for launching has arrived, and the workmen come out from under.

Now the speeches are made, and the girl with the champagne bottle takes her place on the stand at the prow. Then

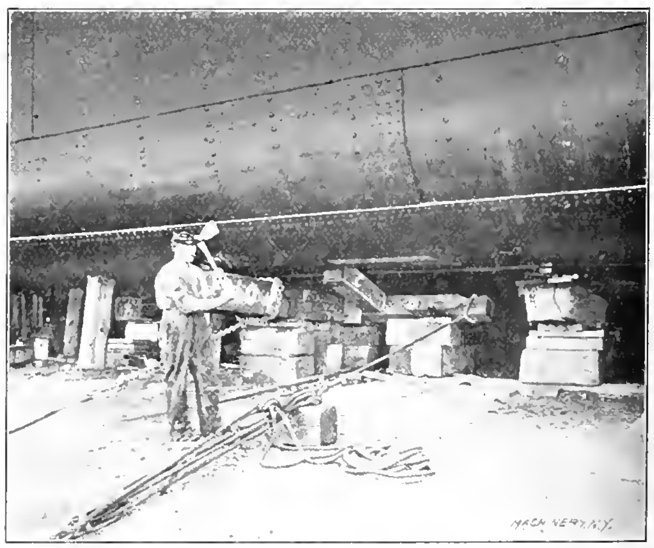

Fig. 4. The Man that wields the Axe that cuts the Rope that binds the Trigger that holds the Ship.

the superintendent gives the order, and the two amidship trigger ropes are cut. The ship is flexible enough to spring down the ways several inches when this is done, being still held at the stem and stern. A fixed gage is generally set in the ground amidships, just touching the side of the vessel before the triggers are released. The deflection is measured by the resulting gap, to get some idea of the ridigity of the

structure. Finally the order is given to cut the stem and stern trigger ropes, and the vessel is thereby released.

This whole mechanism, it will be seen, is of the simplest. In its essentials, it has been changed little in generations, though it has been modified somewhat for the sidewise launching. The carefulness of the axmen in cutting the trigger ropes at the moment of the signal, is relied on to release both ends simultaneously.

The launching at Detroit was witnessed by the members and guests from the decks of the steamer *Brittania*, which lay out in the stream two hundred feet or so from the entrance to the slip. It was a gala day for the assembled employes and their families, as well as for the engineers. The army of workmen beneath the vessel had made their first and second drives before we arrived, and were engaged in their third as our boat took its position. The innumerable hammer blows, whose aggregate force bodily raised the great mass, sounded like the rattle of a battery of rapid-fire guns. We were too far away to hear the orders, or the speech-making, but we could see the white stakes disappearing, one after the other, and knew that the sharp eyes of the superintendent were watching them also. Finally, after what seemed an interminable wait, the stern started slowly down the ways, with the bow following a fraction of a second later. It slid thus, slightly canted, gathering

Fig. 5. General View of the Vessel on the Launching Ways.

speed as it went, and finally shot off the ways into the water, gracefully clearing their dangerous-looking lower ends.

There may have been some in the party who saw the girl in white, smash the beribboned bottle on the prow as the vessel slipped away. It is impossible to see everything at once. The writer's clearest recollection is that of watching the great broadside wave kicked up by the hull, pour over the further edge of the slip, and up onto the land, mixing lumber piles, spectators, and relics of the blocking in one long, confused windrow. None of the unfortunates were drowned, but they were all badly "mussed."

The movement of the vessel was arrested before it struck the other bank, partly by the tremendous resistance offered by the hull against the confined water of the slip, and partly by the numerous cables by which it was connected with the shore. The launching was said to have been one of the most successful on record.

The *Daniel B. Meacham*, for thus the vessel was christened, is to add one more to the wonderful navy of freighters which ply the waters of the Great Lakes. It is one of the sights of the world to watch, from the meadows about this shipyard, the vessels of this great navy as they pass up and down between the grassy banks of the beautiful Detroit River. Long and low, with texas and pilot-house at the prow, and engines, boilers, and crews' quarters at the extreme stern, they are built for "strictly business"—but the builders are proud of them. It is difficult to believe it, but the total tonnage passing through the Detroit River in the eight or nine months the channel is open, exceeds the combined annual tonnage of the harbors of New York, London, Liverpool, and Hamburg. One of these stately freighters passes the city, on an average, every seven minutes, weighted with its cargo of ore, coal, or wheat. Perhaps some time we will build a canal which will release this fleet from its narrow bounds, and permit it to carry our produce and our flag to countries across the sea.

* * *

A certain wealthy man living in New Jersey, not many miles from New York City, maintains a large estate. It is stocked with fine horses and cattle, and has a modern dairy. The surplus milk from this dairy is sold to customers at a price slightly above that received by neighboring dairymen whose dairies are not kept in as scrupulously clean and hygienic condition. Certain captious critics found fault with their wealthy neighbor's enterprise and asked why this man who possesses so much of the material things of life should so demean himself as to "peddle milk." They and others suggested that the eminently proper thing to do with his surplus milk was to give it away to the deserving poor, to charitable institutions, hospitals, etc. It seemed to them to be the only course a wealthy man could follow without doing an injustice to his dairymen neighbors and lowering his position. This mistake, for mistake it certainly is, arises from two causes; the first is pure snobbery, and the second cause, with which this note is concerned, is a mistaken idea of the source of wealth. Wherein is this man wealthy? In his possession of ways and means that enable him to command the labor of others? He has title to land, houses, barns, stock in transportation lines, mines and other wealth-producing enterprises. He, in one way or another, directs the energies of many thousand persons, but he cannot waste their energies without causing economic loss. If he chose to give away the milk produced on his dairy farm it would simply mean in the last analysis that he orders certain laborers or servants to work for other individuals for no compensation. The fact that his personally employed servants receive payment from him does not matter. The persons benefiting by his charity would give no recompense, and such practices would be ruinous if followed on a large scale. Because a man is wealthy, it does not give him the right to waste the work of others. The law of supply and demand hinges on the principle of compensation, and is as immutable as the law of conservation of energy.

* * *

The daily press, and even some technical journals, have published a statement to the effect that a "wireless" truck has been in operation in the yards of the Union Pacific's Omaha shops, this being the latest development in wireless transmission of electrical power. It was stated that this truck was used to haul a string of smaller trucks, loaded with material, from one point in the shops to another, the source of power being a wireless station in the center of the shop plant. It has been stated that the inventors of this wireless power transmission scheme are Dr. Frederick H. Millener and W. R. McKeen, Jr., the latter superintendent of motive power of the Union Pacific Railroad Co. We have been informed by Mr. McKeen, however, that the newspaper articles printed in regard to the operation of the "wireless" truck at the Omaha shops have been considerably exaggerated. The facts in the case are that for experimental purposes a storage battery truck has been equipped with necessary receiving wires, and wireless waves have been used in connection with a wireless telegraph outfit for connecting and breaking the circuit between the batteries and the motor on the car, thereby starting and stopping the latter.

Engineers, at the outset of their professional careers, are taught to give honest work for their money, and being absorbed in the study of truths of nature, are forced to forego the cunning whereby to possess themselves of money and power which they have not earned.—*W. D. Marks, in Engineering News.*

THE DESIGNING OF MACHINE FRAMES.

E. A. FESSENDEN.*

For men of limited experience, a machine frame of the common C-type, such as is used in punching and shearing machines, in some kinds of riveters, and, in a modified form, in slotters, drill presses, steam hammers, and many other tools, is always more or less difficult to design. The stresses are rather complex, and the means for securing the best distribution of metal for bearing these stresses is not easy. Much has been written on the subject, and the author of this article does not claim any originality in the ideas involved in the discussion. It is believed, however, that the method of presenting the solution of the problem has some points that may merit consideration. A common punching and shearing machine frame will be used for illustration, because the form and proportions of these frames are so well known. The method employed, however, is perfectly general and may be used for many other machine frames.

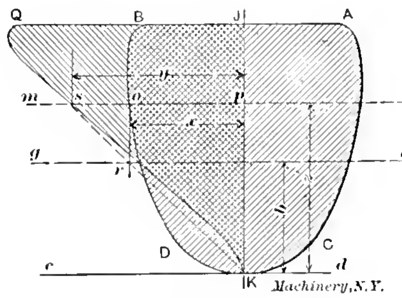

Fig. 1. Graphical Method for Finding the Center of Gravity.

In the discussion which will follow, it will be necessary to use the moment of inertia and center of gravity of an irregular section. The method of finding these quantities, which is outlined below, is not original with the author, but he has not seen it previously published, and it is presented here in the hope that its use may become more general.

The following graphical method for finding the center of gravity and moment of inertia of an irregular figure, will be found to offer an advantage over the ordinary method by calculation, in the matter of time saved.

Let $ABDC$, Fig. 1, represent any irregular section. In the figure, a section symmetrical about a vertical axis is shown, and the construction carried out for half of the figure. For an unsymmetrical section, both sides would have to be considered, as well as a construction for the gravity axis parallel to two base lines. A case of this sort will rarely arise in practice.

Lay off the line gh at any distance b from the edge of the section. The line gh is perpendicular to the center line JK. Then lay off another line mn, parallel to gh, at any distance z from cd. Let the distance op be called x. From o drop a perpendicular on gh cutting at r. Join K and r and extend the line until it cuts mn at s, and let $sp = y$. After determining several points s in the same way, connect them by a smooth curve, giving the figure KQJ.

Then by our construction, we have,

$$\frac{y}{x} = \frac{z}{b}; \qquad y = \frac{xz}{b}$$

The area of KQJ is

$$G = \int y dz = \frac{1}{b} \int xz dz$$

But $\int xz dz$ is the "static moment" of the original figure $KDBJ$, and therefore bG is the static moment of $KDBJ$ about cd. If A is the area of $KDBJ$

$$\frac{bG}{A} = \frac{\text{static moment of } KDBJ}{\text{area of } KDBJ}$$

$$= \text{distance from } cd \text{ to center of gravity} = e.$$

If the areas A and G and the distance b are measured, the distance to the center of gravity is readily found from this last equation. A planimeter offers the best means of measuring the areas, but if this is not possible, sufficient accuracy may be attained by dividing the areas to be measured into rectangles and triangles, computing their separate areas and taking the sum of the areas of all the subdivisions as the area of the original figure.

* Address: University of Missouri, Columbia, Mo.

There is a similar construction for finding the moment of inertia, that should be carried out on the same figure as was used for finding the center of gravity. The two constructions are separated here in order to avoid confusion in explaining them.

In Fig. 2 the lines gh and mn are laid off as before so that pq is x, and pw is y. Then we is drawn from w perpendicular to gh; join K and e and extend Ke to f, making $pf = y_1$. Several points f will give the figure KSJ, and we have, as before

$$\frac{y}{x} = \frac{z}{b}; \qquad y = \frac{xz}{b}$$

and also,

$$\frac{y_1}{y} = \frac{z}{b}; \qquad y_1 = \frac{yz}{b} = \frac{xz^2}{b^2}$$

Then the area of KSJ is

$$J = \int y_1 dz = \frac{1}{b^2} \int xz^2 dz$$

but the moment of inertia

$$I = \int xz^2 dz$$

from which

$$J = \frac{1}{b^2} I; \text{ and } I = b^2 J.$$

In this equation we know b, and can measure J as before.

This construction gives the moment of inerita about the line cd, whereas it is generally required about the gravity axis. It might have been so found if the base line had been the gravity axis instead of the line cd. However, the mathematical computation for the transformation of axes is easily made. The following formula should be used:

$$I_o = I_{cd} - e^2 A,$$

where I_o = moment of inertia about gravity axis,

I_{cd} = moment of inertia about cd,

e = distance from cd to center of gravity,

A = area of $KDBJ$.

It is to be clearly understood that the values of e and I found above refer only to the figure actually drawn on the drawing

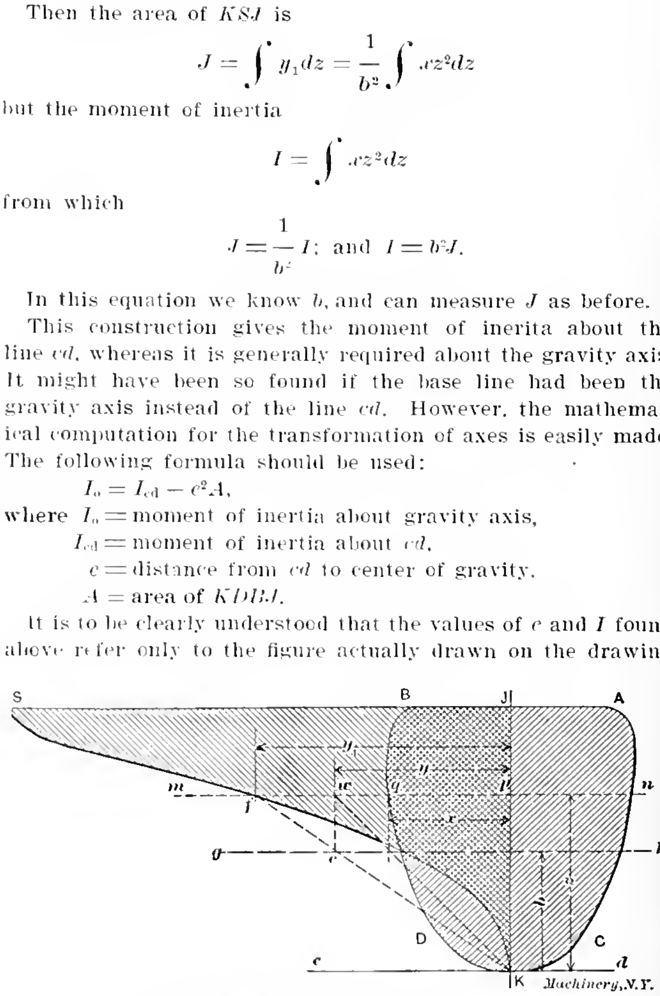

Fig. 2. Graphical Method for Finding the Moment of Inertia.

board and not to the full-sized section. For the actual values we have

$$I_{\text{actual}} = X^4 I_{\text{drawing}}$$
$$e_{\text{actual}} = X e_{\text{drawing}}$$

where X is the scale of the drawing.

Fig. 8 shows the construction applied to a punch frame section.

The Stresses Involved in a Punch Frame.

Let Fig. 3 represent the side view of a punch frame. It will be sufficient to investigate the stresses at four different sections, testing at other points later if it appears necessary. The preliminary calculations will be made on sections indicated at AB, CD, EF, and GH or JK.

For determining the stresses on the section AB, consider the upper portion of the punch a "free body" as shown in Fig. 4. It is subjected to an external force P, acting upwards, arising from the resistance of the material being punched. In the actual punch this force tends to separate the jaws. To balance P there is an internal stress acting over the section AB. The following discussion will show that this internal stress is a compound stress.

Conditions of equilibrium require that the algebraic sum of all forces, external and internal, acting on a body, must be zero; and also that the sum of all couples, or forces tending

to produce rotation, must be zero. It is then evident that to balance P there must be downward forces equal to P. Such downward forces exist in what may be considered as a uniform tensile stress of t_1 pounds per square inch over the section AB. The resultant of all these small downward forces making up the uniform tensile stress, can be considered as a single force P_1, equal to P, acting at the center of gravity of the section AB. The algebraic sum of all the forces on the free body is now zero, but P and P_1 together form a couple of value $Pl_1 = P_1l_1$, tending to rotate the portion of the punch under consideration in a clockwise direction, so that an equal and opposite internal couple is necessary to balance it. This

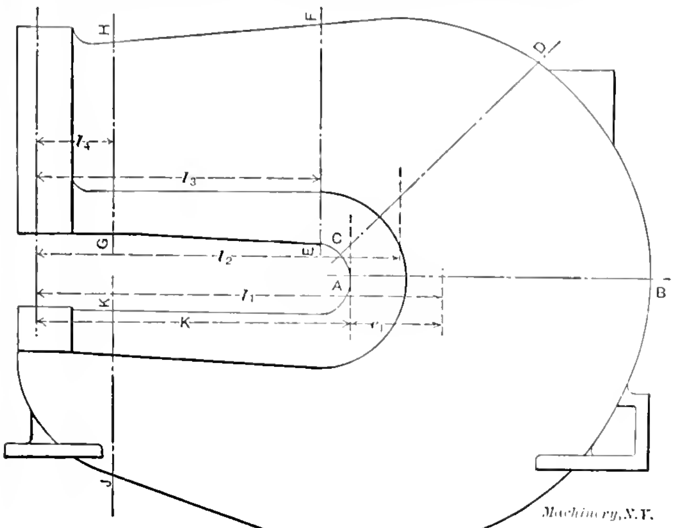

Fig. 3. Side View of Punch Frame.

internal couple acts over the entire surface of the section AB, and may be considered as being made up of an infinite number of small couples, each consisting of a tensile stress on the throat side of the frame sectien and an equal compressive stress on the outer part of the section. (See Fig. 4.) Then the total internal stress may be found by combining these elementary stresses as shown.

The following formulas are used to calculate the values of these internal stresses. Their derivation is comparatively simple, and may be found in any treatise on the mechanics of materials.

$$P = \pi dts, \tag{1}$$

where d = greatest diameter of hole to be punched on the machine considered,
t = thickness of plate punched,
s = shearing strength of material punched.

$$t_1 = \frac{P_1}{A_1} = \frac{P}{A_1}, \tag{2}$$

where t_1 = uniformly distributed tensile stress over section AB, in pounds per square inch.
A_1 = area of section AB, in square inches.

$$f_1 = \frac{P_1l_1}{N_1} = \frac{M_1e_1}{I_1} \tag{3}$$

where f_1 = tensile stress at point A, due to couple P_1l_1, in pounds per square inch.
l_1 = arm of couple in inches $= K + e_1$ (Fig. 4),
e_1 = distance from center of gravity of section to edge next to punch throat, in inches,
N_1 = section modulus, for tension, of section $AB = \frac{I_1}{e_1}$,
M_1 = bending moment in inch pounds,
I_1 = moment of inertia of AB about gravity axis.

$$c_1 = \frac{P_1l_1}{Z_1} = \frac{M_1z_1}{I_1} \tag{4}$$

where c_1 = compressive stress, in pounds per square inch, at point B, due to couple P_1l_1.
Z_1 = section modulus of section AB, for compression, $= \frac{I_1}{z_1}$

where z_1 is the distance from the center of gravity to the outer edge of the section.

The following equations may be written for the maximum stresses on the section AB

Maximum unit tension

$$= T_1 = t_1 + f_1 = \frac{M_1e_1}{I_1} + \frac{P_1}{A_1} = \frac{P_1l_1e_1}{I_1} + \frac{P_1}{A_1} \tag{5}$$

Maximum unit compression

$$= C_1 = c_1 - t_1 = \frac{M_1z_1}{I_1} - \frac{P_1}{A_1} = \frac{P_1l_1z_1}{I_1} - \frac{P_1}{A_1} \tag{6}$$

In equations (5) and (6) everything is known from the conditions that would be given in the problem, as it is received by the designer, except the quantities $\frac{e_1}{I_1}$, $\frac{z_1}{I_1}$ and A_1. It will be seen that these are all factors depending on the size and shape of the section AB under consideration, and these are for the designer to determine.

Method of Designing Frame.

After clearly understanding the stresses involved in the design, the next step will be to proportion the frame to withstand these stresses. This may be accomplished in the following manner:

1. Assume the shape of the section at AB, Fig. 3. In making this assumption the designer will have to be guided by experience, either his own or that of others as shown in machines already built, catalogues, textbooks, drawings, photographs, or any other means of gaining information that is available. The section shown in Fig. 8 will give a fairly good idea of the commonest form used for punches. In making the first drawing it is not necessary to make any assumption as to the *size* of the finished section; the *shape* is all that is necessary.

2. Lay out this section on a drawing board. Use any scale, and make the drawing rather large, say eight inches as the longest dimension. The *size* is of no particular importance, only be careful to get the figure drawn of the same proportions as desired in the final section.

3. Find the gravity axis and the moment of inertia of the figure drawn, by the graphical method explained above.

4. It is evident that the figure drawn will not be the correct *full sized* section of the punch, but it will be a drawing of that sectien to some scale. Let that unknown scale be such

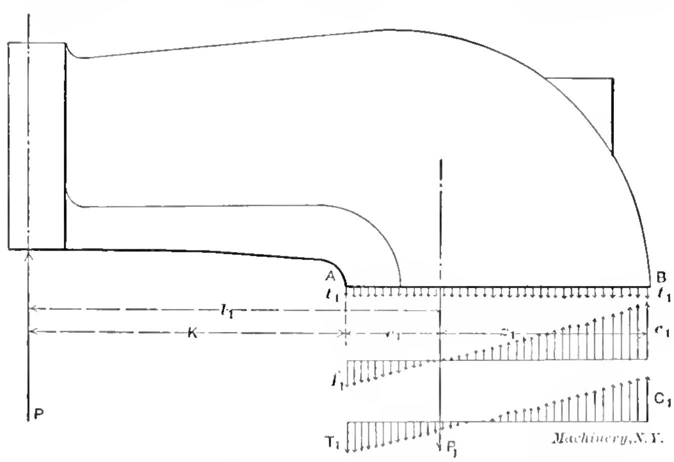

Fig. 4. Graphical Illustration of Stresses in Punch Frame.

that one inch on the drawing represents X inches on the actual section. If, then, quantities relating to the figure on the drawing board are represented by letters with the subscript d, and quantities relating to the actual section, by letters without additional subscripts, the following equations will hold true:

$$e_1 = X(e_1)_d \tag{7}$$
$$z_1 = X(z_1)_d \tag{8}$$
$$A_1 = X^2(A_1)_d \tag{9}$$
$$I_1 = X^4(I_1)_d \tag{10}$$

We can measure $(e_1)_d$, $(z_1)_d$, $(A_1)_d$, and $(I_1)_d$ directly from the drawing, and insert the values for e_1, z_1, A_1 and I_1 in equations (5) and (6). We then have

$$T_1 = \frac{P_1l_1X(e_1)_d}{X^4(I_1)_d} + \frac{P_1}{X^2(A_1)_d}$$

$$= \frac{P_1[K + X(e_1)_d]X(e_1)_d}{X^4(I_1)_d} + \frac{P_1}{X^2(A_1)_d} \quad (11)$$

$$C_1 = \frac{P_1 l_1 X(z_1)_d}{X^4(I_1)_d} - \frac{P_1}{X^2(A_1)_d}$$

$$= \frac{P_1[K + X(e_1)_d]X(z_1)_d}{X^4(I_1)_d} - \frac{P_1}{X^2(A_1)_d} \quad (12)$$

Equation (11) can now be used to solve for X, if the allowable value for T_1 is known. A machine of the punch or shear type is subject to severe shock at the moment the tool strikes the metal. For this reason a very low allowable safe stress should be taken. It is suggested that the maximum allowable tensile or shearing stress be not greater than 2,000 to 2,200 pounds per square inch for cast iron. Equation (11) is a

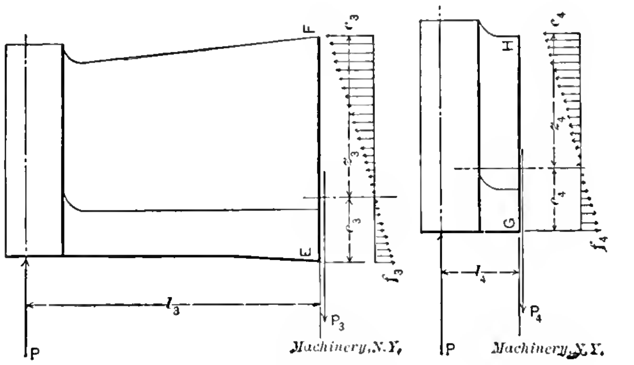

Fig. 5. Fig. 6.

Graphical Illustration of Stresses in Punch Frame.

4th power equation, and the quickest and easiest way to solve it is by trial. After finding the value of X from equation (11), it can be substituted in equation (12) to find the value of C_1. This should not exceed 8,000 to 10,000 pounds per square inch. It will usually be found much less than this, because mechanical difficulties are encountered in the manufacture of the punch if the outer part of the section is made thin enough to raise the compressive stress to the highest allowable value. These difficulties are mainly in the shape of extremely high cooling strains in the casting, so that the risk is too great to compensate for the comparatively small saving in iron. Take the value of X found, and apply it to the original drawing to find the actual size of section. All linear dimensions of the drawing will be multiplied by X to get the actual size. This will fully determine section AB.

Having section AB, there are two methods of determining other sections. They may be found in a manner exactly similar to that used for section AB, by assuming a *shape* of section and solving for the *size*, or the size and shape may both be assumed and then tested for safety. The latter method will undoubtedly give the most satisfactory results, because it would probably require a great many trials by the first method for the reason that while each section would be strong enough to bear the stresses upon it, there would be considerable difficulty in combining these independently found sections into a pleasing and harmonious whole.

After finding section AB, use it as a basis, together with all the other known data about the punch, from which to assume an outline of the side view. In this part of the work, as in the first assumption of the shape of section AB, reference must be made to the results of past experience, and here again books, drawings, and illustrations will be found helpful. Fig. 3 is a side view of the frame of a punch made by one of the largest manufacturers of machine tools in the United States; if nothing better is at hand, it may be used as a guide. The thickness of the outer part of the frame is kept the same as was found for the section AB, and the frame is a trifle narrower from side to side at the tool end than at the back end.

Now, consider a section along some plane EF, parallel to the line of action of the tool. The "free body" is shown in Fig. 5. The forces acting on the free body are found in a manner very similar to that used in discussing the stresses in the section AB. Let all quantities relating to this section be denoted by the subscript 3, and have the same meaning as the same letters had when used with subscript 1 in the discussion of section AB. The following equations may then be used to determine the stresses on the section.

P = the punching pressure.

P_3 = a force equal and opposite to P, causing shearing stress along EF.

P and P_3 with arm l_3 form a couple. This tends to produce bending in the frame and must be resisted by an internal moment of equal magnitude, M_3.

$$M_3 = P_3 l_3 = P l_3. \quad (13)$$

As before, we have the tensile stress in section EF at E due to the couple as

$$f_3 = \frac{M_3 e_3}{I_3} \quad (14)$$

and the compressive stress in the section at F, due to the couple as

$$c_3 = \frac{M_3 z_3}{I_3}. \quad (15)$$

The shearing stress is distributed uniformly over the entire section and its value is

$$s_3 = \frac{P_3}{A_3} = \frac{P}{A_3}. \quad (16)$$

The maximum tension, compression, and shearing effects are found by combining f_3, c_3, and s_3, according to the rules found in various works on the mechanics of materials. "Kent's Mechanical Engineer's Pocketbook" (7th edition, p. 283) gives the following rules, taken from Prof. Merriman's "Strength of Materials."

$$T_3 = \tfrac{1}{2} f_3 + \sqrt{s_3^2 + \tfrac{1}{4} f_3^2} \quad (17)$$

$$C_3 = \tfrac{1}{2} c_3 + \sqrt{s_3^2 + \tfrac{1}{4} c_3^2} \quad (18)$$

$$S_3 = \pm \sqrt{s_3^2 + \tfrac{1}{4} f_3^2} \text{ or } \pm \sqrt{s_3^2 + \tfrac{1}{4} c_3^2} \quad (19)$$

Since the value of s_3 is uniform over the entire section, while the stresses due to the couple are variable, it is evident that the maximum shearing effect will occur at that part of the section where the stresses due to the couple are a maximum, *i. e.*, probably at F.

The section must be designed strong enough to resist both tension and shear. In general, it is not possible to make it equally strong to resist both, when such a material as cast iron is used. At a section near the end, the shearing stress may be the one to fix proportions, but when taken near the back of the throat, the tensile stresses are more liable to require consideration.

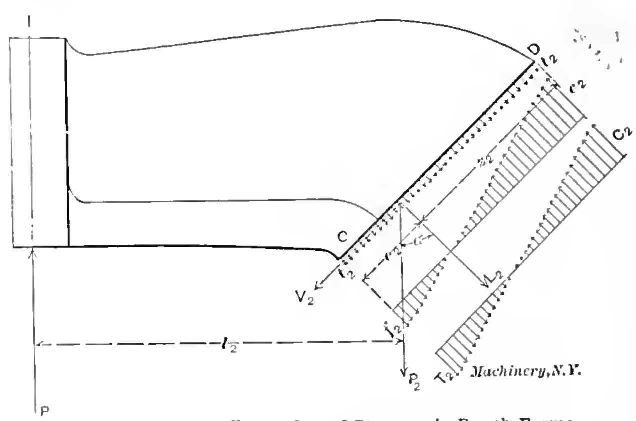

Fig. 7. Graphical Illustration of Stresses in Punch Frame.

Equations (17), (18), and (19) should be solved for T_3, C_3, and S_3, and the results should show values within the maxima stated above. If the section is well designed, the values of T_3 and S_3 will not be very different from those mentioned, and as before, the section will probably be excessively strong in compression.

A section taken at GH or JK would be investigated in a manner exactly similar to that used for the section EF. (See Fig. 6.) It may be expected that the section at GH will appear much stronger than necessary, but this is because it is necessary to provide a space for the main shaft to pass through, as well as for the sake of appearance. The head will need to be large to accommodate the moving parts within it, and the part of the frame immediately behind the head must not appear too small to support the head.

It is next necessary to consider a section taken at an angle, for example along the line CD. The free body is shown in Fig. 7. The forces will be denoted by the same letters as heretofore, but with the subscript 2.

P = the punching pressure,

P_2 = a force equal and opposite to P; P_2 is resolved into two components, L_2 and V_2,

$L_2 = P_2 \cos \alpha$ (produces uniform tension),

$V_2 = P_2 \sin \alpha$ (produces shearing stress).

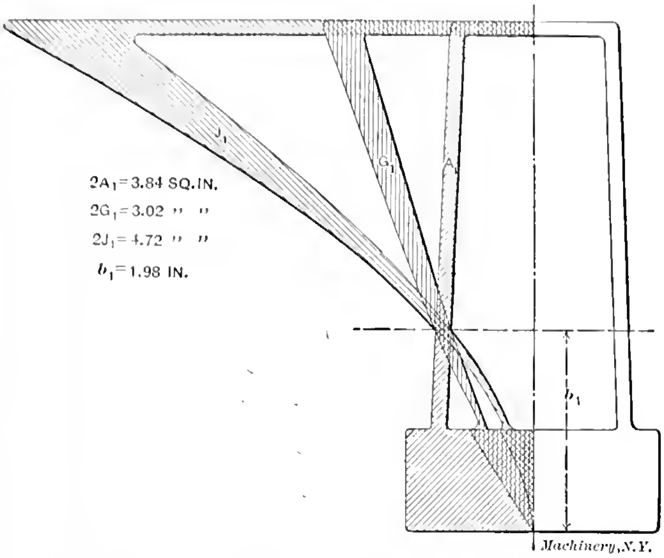

Fig. 8. Section of Punch Frame showing Method of Determining the Center of Gravity and the Moment of Inertia.

P and P_2 together form a couple which has a value $P_2 l_2 = P l_2$, which must be resisted by an internal moment, M_2.

$$M_2 = P_2 l_2 = P l_2, \qquad (20)$$

As before,

$$f_2 = \frac{M_2 e_2}{I_2} \quad (21) \qquad c_2 = \frac{M_2 z_2}{I_2} \quad (22)$$

$$t_2 = \frac{L_2}{A_2} \quad (23) \qquad s_2 = \frac{V_2}{A_2} \quad (24)$$

The maximum stresses per square inch will then be

$$T_2 = \frac{f_2 + t_2}{2} + \sqrt{s_2^2 + \left(\frac{f_2 + t_2}{2}\right)^2} \qquad (25)$$

$$C_2 = \frac{c_2 - t_2}{2} + \sqrt{s_2^2 + \left(\frac{c_2 - t_2}{2}\right)^2} \qquad (26)$$

$$S_2 = \pm \sqrt{s_2^2 + \left(\frac{f_2 + t_2}{2}\right)^2} \text{ or } \pm \sqrt{s_2^2 + \left(\frac{c_2 - t_2}{2}\right)^2} \qquad (27)$$

Take the greater of the two expressions in equation (27) for the subsequent work. This section will have dimensions between those of AB and EF.

Example of Calculation.

In order to illustrate the method of procedure outlined above, the following example is given. The machine in question is designed to punch a 1¼-inch hole in a 1-inch plate. The throat depth is 60 inches.

The punching force necessary may be found from equation (1).

$P = \pi d t s = \pi \times 1.25 \times 1 \times 50{,}000 = 196{,}350$ pounds.

The punch frame is to be of the same general form as that shown in Fig. 3, except that the section at JK is to be of the same size as that at GH. By reference to various drawings and photographs the shape of the section at AB is assumed to be that shown in Fig. 8. This is drawn, in this case, on a drawing board, making the longest dimension 5.01 inches (for general practice it would be well to make the drawing larger than this, say 8 inches high), and the figures denoted by G_1 and J_1 constructed for finding the gravity axis and the moment of inertia. In this case only half of the construction is carried out, because the section is symmetrical about the vertical center line, and it will be understood that the areas measured have to be doubled before they are used in the computations, i. e., the values of the areas A_1, G_1 and J_1 used in the following calculations are not the areas actually measured from the drawing as shown in Fig. 8, but twice these values, to account for the construction for the right hand side of the section which is not carried out on the drawing board. With a value of b_1 as 1.98 inch, the areas of A_1, G_1, and J_1 when measured with a planimeter are as follows:

$A_1 = 3.84$ square inches,

$G_1 = 3.02$ square inches,

$J_1 = 4.72$ square inches.

Then the values of the moment of inertia and the distance from the bottom of the figure to the gravity axis may be found through the use of equations given in the first part of this article, as follows:

$$(e_1)_a = \frac{bG_1}{A_1} = \frac{1.98 \times 3.02}{3.84} = 1.56$$

$$(z_1)_a = 5.01 - (e_1)_a = 5.01 - 1.56 = 3.45$$

$$(I_1)'_a = b^2 J_1 = (1.98)^2 \times 4.72 = 18.5$$

$$(I_1)_a = (I_1)'_a - (e_1)^2{}_a A_1 = 18.5 - (1.56)^2 \times 3.84 = 9.2$$

These values apply only to the figure which was drawn on the drawing board and not to the actual section. It is next necessary to find the size of the actual section. This is accomplished by assuming T_1 as 2,000 pounds per square inch and solving for X in equation (11).

$$T_1 = \frac{P_1 \left[K + X(e_1)_a\right] X(e_1)_a}{X^4 (I_1)_a} + \frac{P_1}{X_2 (A_1)_a} \qquad (11)$$

$$2000 = \frac{196{,}350\,[60 + 1.56X]\,1.56X}{X^4 \times 9.2} + \frac{196{,}350}{X^2 \times 3.84}$$

from which the value $X = 11.45$ is found by trial.

Therefore, to get the actual size of the section at AB, each dimension of the drawing is multiplied by 11.45. This gives the depth of the section as 57.36 inches, and also

$e_1 = 1.56 \times 11.45 = 17.86$ inches,

$z_1 = 3.45 \times 11.45 = 39.5$ inches,

and all other dimensions in the same proportions.

The value of C_1 is next calculated by equation (12) and found to be 3,420 pounds per square inch. It would seem that this is very low for a compressive stress, but the thickness of the outer part of the frame is only about 1⅝ inch, and it does not seem best to make it thinner.

After having determined the size and shape of the section AB, the outline of the punch is sketched in, the general shape being about as shown in Fig. 3, and care is taken to secure a form of pleasing appearance and conforming to general practice. Then drawings are made of sections at CD, EF, GH, and JK, as shown in Figs. 9, 10, and 11, using a scale $X = 12$. The constructions for finding e and z are completed as shown, and the results of the calculations for the sections are tabulated below:

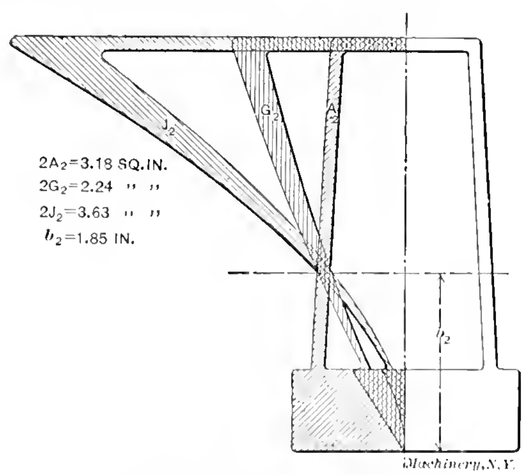

Fig. 9. Section in the Plane C—D, Fig. 3.

Section.	A	G	J	b	e	z	I'	I
CD	3.18	2.24	3.63	1.85	1.304	2.976	12.44	7.03
EF	2.74	1.83	2.58	1.56	1.04	2.51	6.47	3.51
GH } JK }	2.26	1.74	2.47	1.27	0.978	2.02	3.98	1.82

The next step in the design is to investigate the stresses in the sections at CD, EF, GH, and JK. The calculations are shown below. All calculations are conveniently made with a slide rule.

Section C—D.

This section is taken at an angle $a = 45°$. Then, from equations developed in the discussion of the section CD in the earlier part of the article, we have:

$P_2 = P = 196{,}350$ pounds.
$L_2 = P_2 \cos a = 196{,}350 \times 0.707 = 138{,}700$ pounds.
$V_2 = P_2 \sin a = 196{,}350 \times 0.707 = 138{,}700$ pounds.
$l_2 =$ (by measurement from drawing) 69.25 inches.
$M_2 = P_2 l_2 = 196{,}350 \times 69.25 = 13{,}600{,}000$ inch-pounds.

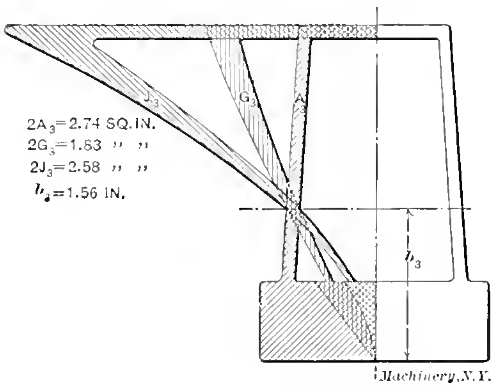

Fig. 10. Section in the Plane E—F, Fig. 3.

$$f_2 = \frac{M_2 e_2}{I_2} = \frac{13{,}600{,}000 \times 12 \times 1.304}{12^4 \times 7.03} = 1460 \text{ pounds.}$$

$$c_2 = \frac{M_2 z_2}{I_2} = \frac{13{,}600{,}000 \times 12 \times 2.976}{12^4 \times 7.03} = 3326 \text{ pounds.}$$

$$t_2 = \frac{L_2}{A_2} = \frac{138{,}700}{12^2 \times 3.18} = 303 \text{ pounds.}$$

$$s_2 = \frac{V_2}{A_2} = \frac{138{,}700}{12^2 \times 3.18} = 303 \text{ pounds.}$$

$$T_2 = \frac{1460 + 303}{2} + \sqrt{303^2 + \left(\frac{1460 + 303}{2}\right)^2} = 1811 \text{ pounds.}$$

$$C_2 = \frac{3326 - 303}{2} + \sqrt{303^2 + \left(\frac{3326 - 303}{2}\right)^2} = 3056 \text{ pounds.}$$

$$S_2 = \sqrt{303^2 + \left(\frac{3326 - 303}{2}\right)^2} = 1544 \text{ pounds.}$$

It will be noted that the tensile stress is somewhat smaller than the maximum value of 2,000 pounds per square inch which was to be allowed. However, the strength of the casting is likely to be least at this point for two reasons: first, because the section is taken at the center of a rather sharp bend for so massive a casting, and second, because of the necessity of introducing a bearing on the upper side near this section, thus requiring the frame to support the reaction from the bearing. For these reasons a lower value for the tension is not out of place.

Section E—F.

If the tabulated values of the properties of the section EF are substituted in the equations developed for that section, the following values of the stresses result:

$P_3 = P = 196{,}350$ pounds.
$l_3 = 54$ inches (measured from drawing).
$M_3 = P_3 l_3 = 196{,}350 \times 54 = 10{,}600{,}000$ inch-pounds.

$$f_3 = \frac{M_3 e_3}{I_3} = \frac{10{,}600{,}000 \times 12 \times 1.04}{12^4 \times 3.51} = 1815 \text{ pounds.}$$

$$c_3 = \frac{M_3 z_3}{I_3} = \frac{10{,}600{,}000 \times 12 \times 2.51}{12^4 \times 3.51} = 4380 \text{ pounds.}$$

$$s_3 = \frac{P_3}{A_3} = \frac{196{,}350}{12^2 \times 2.74} = 498 \text{ pounds.}$$

$$T_3 = \frac{1815}{2} + \sqrt{498^2 + \left(\frac{1815}{2}\right)^2} = 1944 \text{ pounds.}$$

$$C_3 = \frac{4380}{2} + \sqrt{498^2 + \left(\frac{4380}{2}\right)^2} = 4438 \text{ pounds.}$$

$$S_3 = \sqrt{498^2 + \left(\frac{4380}{2}\right)^2} = 2248 \text{ pounds.}$$

These results are all fairly near the requirements, and the section may be said to be satisfactory. The value of S_3 is a trifle higher than was originally specified; this could be reduced by increasing the area of the section slightly. The excess is, however, hardly enough to warrant this.

Sections G—H and J—K.

Sections GH and JK are practically alike in the punch under discussion, although they are not so drawn in Fig. 3. The section as shown in Fig. 3 at GH is nearer the size to be investigated than that at JK. The stresses will result as follows:

$P_4 = P = 196{,}350$ pounds.
$l_4 = 14.5$ inches (measured from drawing).
$M_4 = P_4 l_4 = 196{,}350 \times 14.5 = 2{,}850{,}000$ inch-pounds.

$$f_4 = \frac{M_4 e_4}{I_4} = \frac{2{,}850{,}000 \times 12 \times 0.978}{12^4 \times 1.82} = 885 \text{ pounds.}$$

$$c_4 = \frac{M_4 z_4}{I_4} = \frac{2{,}850{,}000 \times 12 \times 2.02}{12_4 \times 1.82} = 1830 \text{ pounds.}$$

$$s_4 = \frac{P_4}{A_4} = \frac{196{,}350}{12^2 \times 2.26} = 603 \text{ pounds.}$$

$$T_4 = \frac{885}{2} + \sqrt{603^2 + \left(\frac{885}{2}\right)^2} = 1189 \text{ pounds.}$$

$$C_4 = \frac{1830}{2} + \sqrt{603^2 + \left(\frac{1830}{2}\right)^2} = 2011 \text{ pounds.}$$

$$S_4 = \sqrt{603^2 + \left(\frac{1830}{2}\right)^2} = 1096 \text{ pounds.}$$

It is to be noted that in the case of these sections all the stresses are decidedly small. This is caused by the large section required at GH to provide room for the passage of the main shaft and also because a smaller section at this point would present a weak appearance as a support for the massive head. In the case of the section at JK, however, these reasons do not hold, and the frame in question would have been better proportioned had the section at JK been smaller, thus

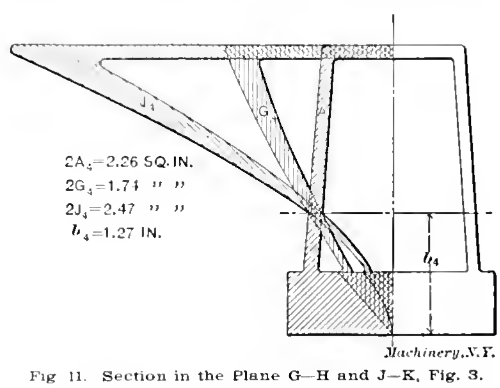

Fig. 11. Section in the Plane G—H and J—K, Fig. 3.

making the stresses more nearly equal over the entire frame. The punch frame illustrated in Fig. 3 is better proportioned in this respect.

The system of design here presented may be applied to frames of many other forms of machines besides punching and shearing machines. It offers the following advantages:

1. It is mathematically correct in principle.
2. The sources of error are comparatively small and are of a kind easily detected.
3. The graphical constructions involved are not laborious, and are sufficiently exact for any ordinary work. The degree of accuracy can be increased at will by employing larger scales.
4. Considerable latitude is allowed for the judgment of the designer.

GEAR-CUTTING MACHINERY—8.

RALPH E. FLANDERS*

This installment of this series of articles continues the discussion of machines for cutting the teeth of bevel gears, the particular type under discussion being that operating on the templet principle.

Fig. 155 shows a machine of this type, built by the firm (Société Suisse pour la Construction de Machines-Outils

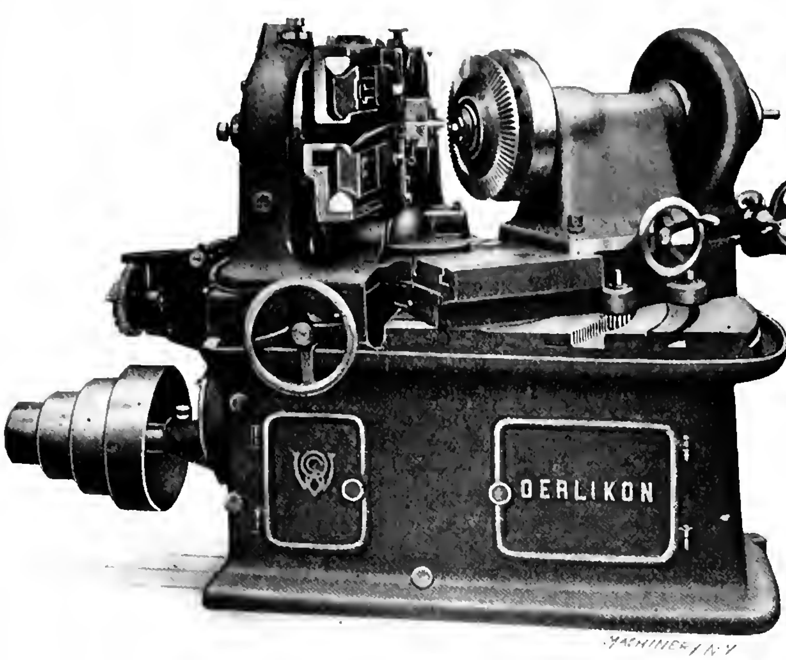

Fig. 155. Oerlikon Bevel Gear Cutter operating on the Templet Principle, and using Two Tools Simultaneously.

Oerlikon, Oerlikon près Zurich, Switzerland) which designed the one last described. The writer has little definite information in regard to this machine. The head carrying the slides is fed inward about a vertical axis, as in the Gleason machine. The swiveling movement of the tool slide about the horizontal axis is also similar to the Gleason machine, but the two are differentiated in their action by the provision of a second slide and tool-holder, both pivoting about the same horizontal axis. The movement which the templet imparts to the upper slide is duplicated on the lower one, though in the reverse direction, so that the outlines formed on each side of the tooth are symmetrical. Besides the use of the two tool slides, this machine also differs from the Gleason in having the head carrying the work spindle and the automatic indexing mechanism, swivel for adjusting to the angle of the work, about the same vertical axis around which the feeding movement of the cutter slide head takes place. This tool was designed by its builders to provide a maximum of accuracy and rapidity for work within its range.

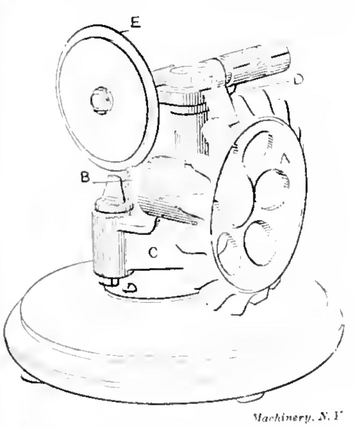

Fig. 156. Model showing the Principle of the Rice Machine shown in Fig 157.

In Fig. 156 is shown the principle of a templet bevel gear planing machine differing in many respects from any of those previously shown. This principle originated with Mr. Charles DeLos Rice, of Hartford, Conn., and the machine he designed, incorporating it, is much used for cutting chainless bicycle gears, though it is not now on the market. The differences consist principally in the form of templet used, and in the form of the follower and the cutting edge of the tool. In other templet machines the follower which makes contact with the templet is presumably a point, as should also be (to insure theoretical exactness) the cutting point of the tool. In reality, of course, the outlines of both these members are rounded, a roll being generally employed for making the contact with the templet, and a round-nose tool being used for doing the cutting. Theoretical accuracy could be obtained under these conditions if the shape of the templet were made to allow for the diameter of the roller which follows it (as is the case in making templets for the Gleason machine, at least) and if the shape of the point of the tool is also considered. The latter, however, should grow continuously smaller as it approaches the small end of the tooth, in the same scale with the decrease in size of the tooth itself, and similarly, it should grow larger as it approaches the large end. As it, of course, remains the same size all the time, a slight error is introduced—so slight, however, as not to introduce anything except a negligible inaccuracy.

In the Rice machine the copying of the former is done with theoretical precision. Both the guiding and the cutting edges are plane surfaces, and being such, obviate the necessity for a change of scale in cutting outlines at different points of the stroke. Fig. 156 shows a model of the movement employed, especially made for the purpose of illustration. The templet *A*, used, is a complete gear of the same proportions as the work to be cut, but on a larger scale. It is mounted on a spindle fast to the blanks *B*. This spindle is carried by a swinging bracket *C*, pivoted about an axis at right angles to that of the work, and passing through the apex of the pitch cone of the work and master gear. The sketch of the model shows a disk *E* mounted on a fixed horizontal spindle, entering one of the spaces which have been cut in the blank. The acting surface of the disk is in the plane of the vertical axis about which bracket *C* swings. In the same plane is the acting surface of a fixed stop or guide plate *D*, which, as shown, is mounted on the same pedestal as the spindle of the disk and enters the space cut in the master gear in the same way that the disk enters the space between the teeth of the work.

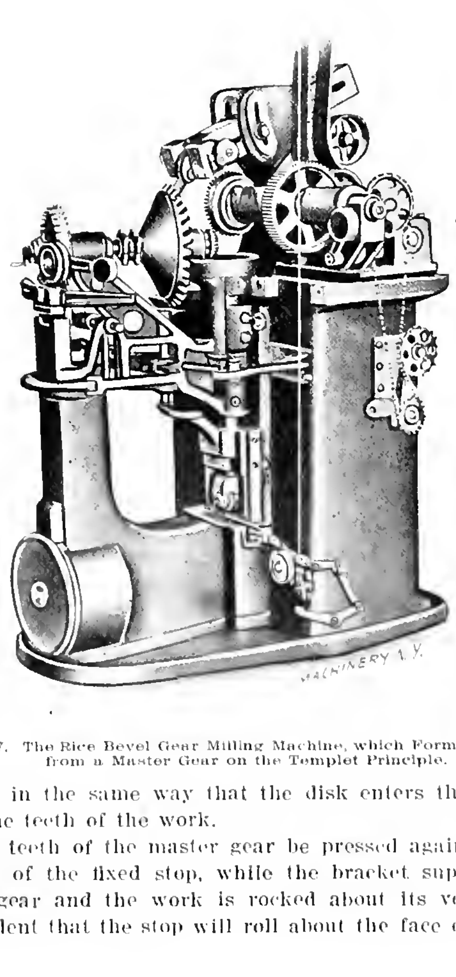

Fig. 157. The Rice Bevel Gear Milling Machine, which Forms the Teeth from a Master Gear on the Templet Principle.

If the teeth of the master gear be pressed against the acting side of the fixed stop, while the bracket supporting the master gear and the work is rocked about its vertical axis, it is evident that the stop will roll about the face of the tooth

* Associate Editor of MACHINERY.

of the master gear or templet, making line contact with it, while the face of the disk will act in an identical manner, though on a smaller scale, with relation to the tooth of the work. If the disk be replaced with a cutter of the same diameter, and with a cutting face in the same plane as that occupied by the acting face of the disk, the rocking of the bracket about its vertical axis will evidently cause the cutter to mill out a tooth face identical with that of the templet or master gear, but on a smaller scale. While this operation appears to have the ear marks of the generating process, it operates on the templet principle in reality, as is shown by the description we have just given. The cutter is made of large diameter, as compared with the work, in order to give as straight a bottom to the tooth space as possible. The deepening of the tooth space in the center does not, of course, affect the accuracy of the working portion of the outline.

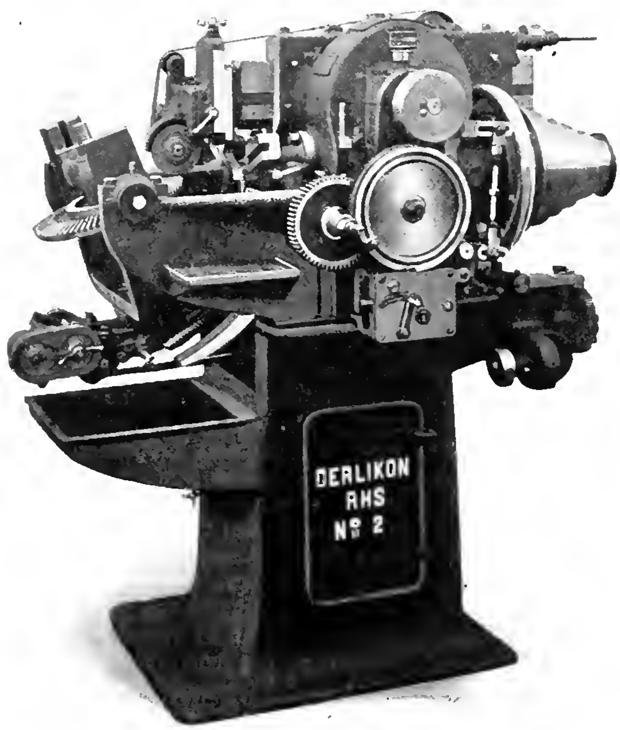

Fig. 158. The Oerlikon Templet Gear Shaper of Fig. 154, arranged with Grinding Wheel for Finishing Hardened Bevel Gears.

An automatic machine in which these principles are embodied is shown in Fig. 157. The mechanism is too intricate to be described without the use of a considerable number of line drawings and an extended description, so we will content ourselves with enumerating the movements which the mechanism effects. The master gear governs the tooth spacing, the tooth thickness and the tooth form. The master gear and a previously-gashed blank being mounted in position in the machine with the guide plate and cutter positions and other adjustments properly made, the mechanism is started. The cam movements provided first feed the master gear and work spindle upward until the cutter is in to depth and the stop bears against the face of the master gear. The bracket carrying them is then rotated about its vertical axis until one face of one tooth of the blank is completed. The work is now dropped down out of the way, and the spindle, with the blank and master wheel, are indexed one revolution, after which they are again raised, repeating the same operations as before. This is done repeatedly until the whole gear has been cut around on one side of all the teeth. When this has been done, the machine stops and the attendant rotates the segment of a hand-wheel rim seen encircling the front pillar of the machine. Through the link connections on this rim, the fixed gage and the cutter are each shifted axially a distance equal to their thickness, so as to bring them to positions to work on the other side of the tooth. The automatic mechanism for swinging the work spindle is also changed by the same movement, so that it swings in the other direction. The mechanism is then started up and the other sides of all the teeth are finished.

An interesting point in the product of this machine is that the gears produced are accurate copies of the master gear on a smaller scale. It is thus possible where bevel gears are to be made in large quantities, to make the master gear and pinion, and run them together under conditions severe enough to test their suitability for the work the smaller gears are to perform. Such corrections as may be required being made in these large gears, assurance is given that the smaller gears will behave in a satisfactory way. The principle of this machine could, of course, be adapted to a machine for general use, by using as a templet but a single tooth of the master gear, instead of employing an entire wheel, as here shown. It was at one time, we are informed, the intention of the inventor to develop such a machine, but so far this has not been done commercially. Obviously, this method of applying the templet principle cannot be applied to teeth having concave surfaces.

Machines Employing the Templet Principle for Grinding the Teeth of Bevel Gears.

The grinding operation has been used in a templet machine built by the Société Suisse pour la Construction de Machines-Outils Oerlikon, Oerlikon près Zurich, Switzerland and shown in Fig. 158. As may be seen, it is a modification of their regular templet planing machine, previously shown in Fig. 154. The change consists merely in replacing the cutting point of the tool with the edge of a grinding wheel, carried on the head of the ram, and provided with suitable means for driving it at the proper speed. Under these conditions, the edge of the wheel shapes the teeth of the gear to the form of the templet provided. The builders state that by the employment of special wheels which they have developed for the purpose, it is possible to cut clear around a large gear without a perceptible change in the condition of the cutting-edge, or a corresponding change in the profile of the tooth produced. If this is so, the greatest objection to the grinding process for gear cutting of any kind is largely obviated. The purpose of the machine is, of course, the finishing of the teeth of hardened gears to remove the inevitable inaccuracies due to distortion arising from the heat treatment. It has been found especially useful in automobile work.

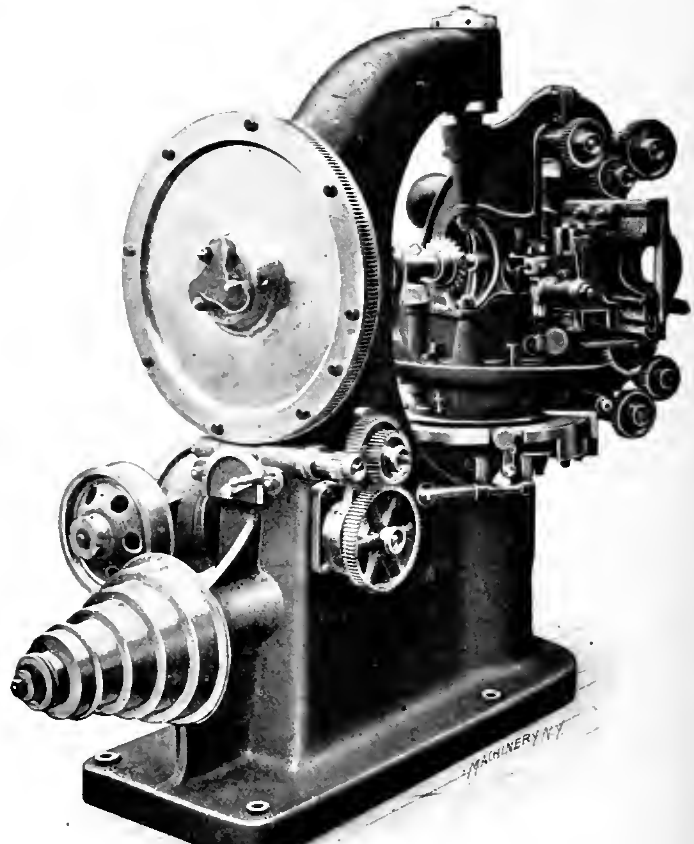

Fig. 159. The Duboec Bevel Gear Planing Machine, cutting Involute Teeth by the Odontographic Principle.

This Swiss firm has done especially noteworthy work in the building of machines for cutting bevel gears. The three we have illustrated, Figs. 154, 155 and 158, and one we will show later for milling bevel gears by the molding-generating principle, do not by any means exhaust their list of machines built for forming the teeth of gears of this type. Among other Oerlikon designs may be mentioned two of great interest, described in a paper by Mr. Fred. J. Miller, to be found in Vol. 22 of the Transactions of the American Society of Mechanical Engineers.

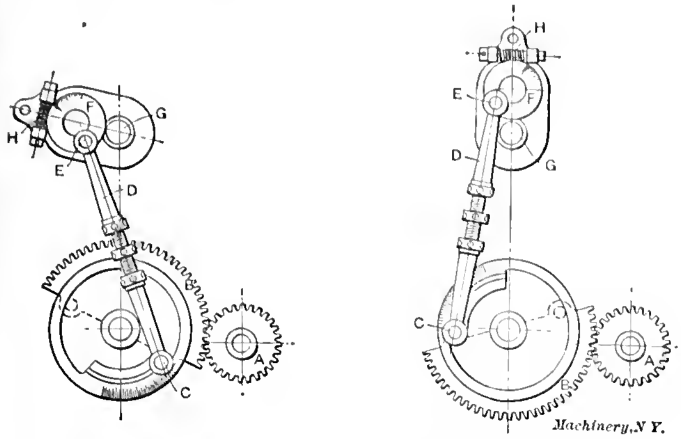

Fig. 160. The Odontographic Mechanism of the Dubosc Machine at the Beginning and End of the Cutting Action.

Machines Working on the Odontographic Principle for Cutting the Teeth of Bevel Gears.

A machine operating on the odontographic principle, in which the point of the tool is guided by mechanism which very nearly reproduces the theoretical shape, is shown in Fig. 159. It is built by Officina Meccanica Ing. E. Dubosc, Via Principi d'Acaia, 62, Turin, Italy. In this machine, as may be seen, the work spindle is horizontal and is indexed by a dividing wheel of large diameter. The work arbor is supported at the outer end in a stirrup held in the swinging tool frame, this support making it possible to do heavy and rapid cutting. The work is adjusted by means of suitable gages until the apex of its pitch cone lies in the center line of the journals provided at the top and bottom of the main casting of the machine for the trunnions of the frame which swings about the work in a vertical axis. This frame carries most of the mechanism of the machine, and is provided with pivots in a horizontal axis, in the same plane with the vertical axis, about which swings a counterbalanced arm having guides for the tool slide. A tool may thus be set to have a reciprocating movement in any plane, toward and away from a point coinciding with the apex of the pitch cone of the work. This being the case, if suitable mechanism for effecting it is provided, the tool may be made to plane a conical surface, vanishing at the center of the horizontal and vertical axes, and determined by any line drawn on the surface of a sphere having the same center. In this respect it resembles all templet and odontographic machines, which are distinguished from each other only in the means provided for guiding the tool, as shown in Figs. 136 and 137.

In the machine in question, the odontographic mechanism provided produces teeth of involute form. This mechanism (which is obscured in Fig. 159) is shown in diagrammatic form in Fig. 160, in two positions. We cannot take the space here to describe why the mechanism produces a curve of almost absolutely true involute form, nor can we enter into the details of the connections by which the movements effected by this mechanism are transferred to the point of the tool, as this would require an article in itself. It can only be said the pinion A is connected with a worm meshing with a segment of a worm-wheel fast to the base of the machine, by means of which the frame carrying the mechanism and the tool is rotated about its vertical axis. This pinion meshes with the segmental gear B, which carries a crank-pin C, angularly adjustable for a certain amount about the center of the gear. A connecting-rod D, adjustable for length, connects crank-pin C with a second pin E attached eccentrically to a disk F, eccentrically seated in turn in a crank whose center is G. Disk F, with crank-pin E, may be adjusted for various angular positions about the center of the disk by worm H. Crank G is connected with mechanism for swinging the tool slide in a vertical plane about its vertical axis, the whole mechanism thus serving to connect the movements of the tool about the horizontal and vertical axes. By setting C according to graduations at various angular positions with relation to B, and by setting E at various positions by the rotating of disk F, and by adjusting the length of connecting-rod D, the movements about the horizontal and vertical axes may be so connected as to produce tooth outlines of correct forms.

This apparatus, as described, determines the form of the tooth. Change gears provided between G and the vertical movement which it accomplishes, and A and the horizontal movement with which it is connected, alter the scale of the outline—that is, adapt it to a large tooth or a small tooth as may be required. Still other change gears are provided for the indexing, which is automatic, as are all the functions of the machine for completely forming one side of all the teeth of the gear. When this has been done, the machine is reversed for cutting the other sides of the teeth. The shape that can be given varies from the straight side of the rack tooth (which is used for all gears having more than 150 teeth), to small bevel pinions with undercut flanks in which a reverse motion has to be given to the movement about the horizontal axis. The tool is provided with mechanism for cutting on both the forward and back stroke on work that is large enough to admit this.

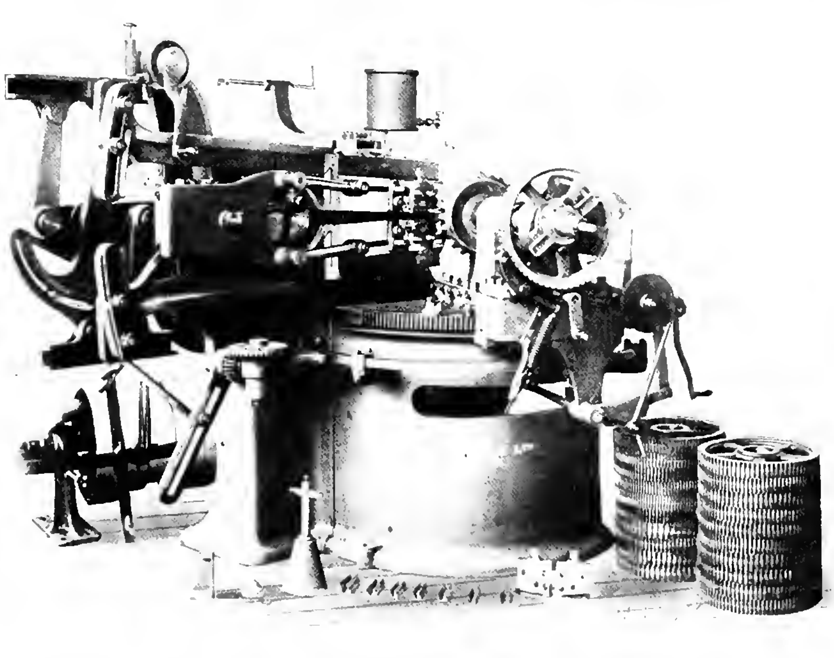

Fig. 161. The Smith & Coventry Odontographic Bevel Gear Planing Machine.

We are informed by the English licensees of the Dubosc patents, Messrs. Selig Sonnenthal & Co., 85 Queen Victoria St., E. C., London, England, that the builders of the tool are preparing a new design, embodying a number of improvements in the mechanism. We hope to be able to describe this new machine at some later time. The machine is ordinarily furnished for cutting involute bevel gears, having a pressure angle of 22½ degrees, this being the usual angle for automobile work. It can be made to order, however, for cutting other angles as desired.

The only other odontographic machine the writer is acquainted with is built by Smith & Coventry, of Manchester, England (see Figs. 161 and 162). It is somewhat easier to

understand than the Dubosc machine, as the curves it employs are simple arcs ot circles. Two tools T_1 and T_2 are used, each set in separate slides S_1 and S_2 pivoted about an axis at the apex X of the pitch cone of the blank being cut. These slides have rearward extensions in the form of arms A_1 A_2, ending in slotted arcs concentric with axis X. Each of these arms is clamped by bolts passing through the slotted arcs to blocks C_1 and C_2 sliding in horizontal guides on parallel bars D_1 and D_2. Bar D_1 is supported on links E and E_1, while bar D_2, pivoted also to double ended link E, is supported by it and short link E_2. As link E is rocked, the two bars swing, one to the left and upward and the other to the right and downward, but with their guiding surfaces always parallel. As they are swung in this way, the two slides A_1 and A_2 are brought together or opened out, as the case may be.

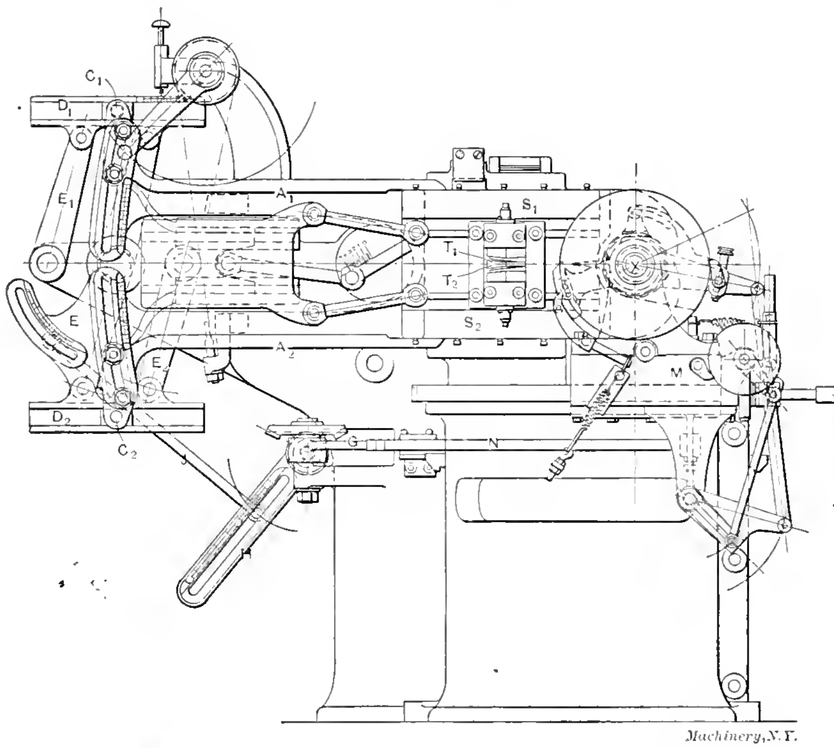

Fig. 162. The Mechanism of the Smith & Coventry Bevel Gear Planer.

The rocking of this parallel linkage system is effected by a connection with the angularly adjustable head M, which carries the work spindle. This is swung inward for the feeding movement to shift the tools down the sides of the tooth until the full depth has been reached. To slide M is clamped a circular bar N, whose rear end has teeth cut in it engaging with those of a sector G, which, by the bevel gearing shown, is connected with slotted arm H. This arm is adjustably connected with link E by a connecting-rod J, which, as shown, may be altered slightly as to length and to the amount of movement given it, depending on the way in which it is clamped to H. From this it will be seen that as the work slide M swings around, moving the teeth of the blank inward toward the tools, its connection with circular bar N through sector G, and the geared connections of the latter with arm H, operate the linkage system E, E_1, E_2, and bars D_1 and D_2, with the tool-slides S_1 and S_2 connected with them. By this means the tools are gradually opened out as the base of the tooth is approached, in such a way as to make their outlines correspond to circular arcs approximate to the desired involutes, the circular form being determined by the swinging of the links E_1 and E_2 about their centers. Tables are furnished for setting J with relation to H, and arms A_1 and A_2 with relation to D_1 and D_2, so as to reproduce on the teeth the proper outlines.

It should have been mentioned that this machine does not work on the principle of completing one tooth, and then indexing to complete the next. The work indexes at every stroke of the double tools. After the first cut has been taken on the first tooth, the work is indexed and the same cut taken on the next tooth. When the work has been once around in this way, the tool starts in with a deeper cut on the first tooth again, this continuous rotation and gradual feeding in of the tool continuing until all have been simultaneously formed to the required depth and proper shape, being similar in this respect to the Bouhey machine in Fig. 152.

A Machine Operating on the Molding-Generating Principle and Employing the Impression Operation.

In Fig. 163 is shown the only example known to the writer of a commercial machine operating on the molding-generating principle. This machine was built by the Brown & Sharpe Mfg. Co., Providence, R. I., for performing the finishing and correcting operations on bevel gears, roughed out in the special full automatic formed-cutter machine, previously described, and shown in Fig. 146. It is not, therefore, a machine which finishes the gear directly from the blank. The impression process is, of course, absolutely impracticable for operations that would require the pressing into shape of as much metal as would be required in that case.

The machine contains two spindles, of which the one carrying the forming gear is driven by suitable belts and pulleys from the counter-shaft, while the other spindle is mounted in a head which, as shown, can be set at any angle with the first, to agree with the angle between the axes of the forming gear and the work being pressed into shape. The forming gear, instead of being a small pinion, as in Fig. 138, is a crown gear; this gear is chosen on account of the facility with which it can be accurately made, the sides of the teeth in the system employed being plane surfaces, as described in connection with Figs. 139 and 140. In the final operation, a forming gear thus correctly made and hardened so as to resist the wear brought to bear on it, is mounted on the belt-driven spindle and brought into proper engagement with the roughly formed gear mounted on the other spindle. The machine is started up and the two are revolved together. The mechanism provided is such that the pair run in one direction for a certain number of revolutions and then reverse and run in the other direction, repeating the process as long as the machine is in operation. Meanwhile a cam mechanism operates to jam

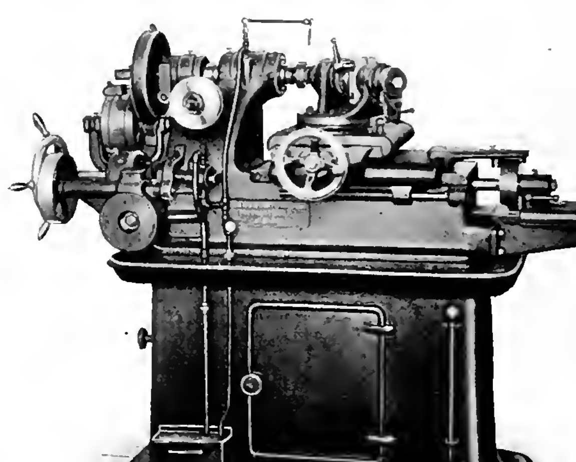

Fig. 163. Brown & Sharpe Machine for Correcting Bevel Gears by the Molding-Generating Principle, employing the Impression Process.

the blank and forming gear together, relieve the pressure for a short space and jam them together again, repeating the process continuously. By this means the hardened surface of the forming crown gear presses out the inaccuracies in the work and smooths the surfaces of its teeth.

The operation we have just described is the final one, however, and does little more than burnish the teeth. The same machine is used for a preliminary operation which does most of the work of smoothing out the inaccuracies of the formed cutter process. This employs the same movements in the machine, but uses a different form of crown gear, shown in action in Fig. 164. As may be seen, the successive teeth are cut off at different heights. The edges thus formed where

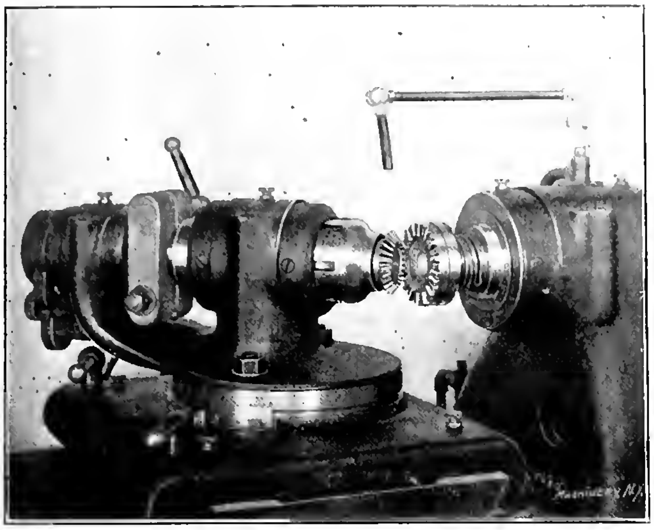

Fig. 164. Near View of the Tool and the Work in the Machine shown in Fig. 163.

the teeth are cut off, dig into the roughed out teeth of the work and remove the metal from the high spots, while they pass freely and without action over the parts of the teeth which are of the correct contour. Being of so many different heights the whole face of each tooth of the work is acted on, though, of course, this is the case only when the number of teeth in the work and in the crown gear do not have a large common factor. In the bicycle trade for which these machines were developed, the gears were so designed that this contingency did not arise.

Machines Operating on the Molding-Generating Principle, and Employing the Planing or Shaping Operation.

The mechanism illustrated in outline in Fig. 139 is one that has been employed in a number of exceedingly interesting and ingenious machines. The first application of this principle was made by Mr. Hugo Bilgram, 1231 Spring Garden Ave., Philadelphia, Pa. His form of machine has been used for a

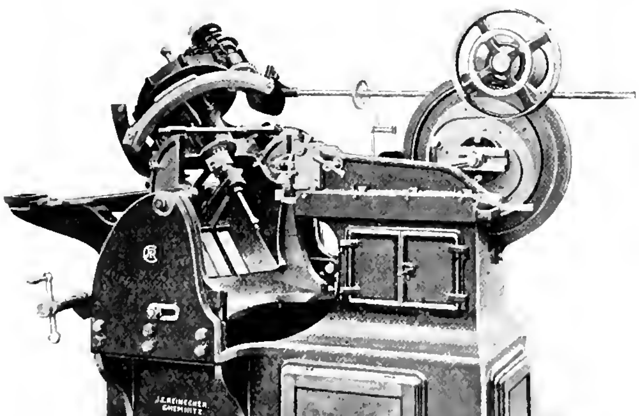

Fig 165. Bilgram Bevel Gear Shaper as built by J. E. Reinecker.

great many years, and produces work whose accuracy has almost become proverbial. An example of this machine, built under Mr. Bilgram's patents by J. E. Reinecker, of Chemnitz-Gablenz, Germany, is shown in Fig. 165. The movements operate on the same principle as that in Fig. 139, but in one of the modified forms explained in the text accompanying that figure. That is to say, instead of rotating the crown gear and master gear together, the imaginary crown gear and, consequently, the tool, remain stationary so far as angular position is concerned, while the frame is rotated about the axis of the crown gear, thus rolling the master gear on the latter and rolling the work in proper relation to the tool. Instead of using crown and master gears, however, a section of the pitch cone of the master gear is used, which rolls on a plane surface, representing the pitch surface of the crown gear. The two surfaces are prevented from slipping on each other by a pair of steel tapes, stretched so as to make the movement positive, in something the same way as shown in Fig. 4. A still further change consists in extending the work arbor down beyond center *O* in Fig. 139, mounting the blank on the other side of the center so that the tool, being also on the other side of the center, is turned the other side up from that shown in the diagram. All these movements can be followed in Fig. 165. As explained, a tool with a straight edge is used, representing the side of a rack tooth, and this tool is reciprocated by a slotted crank, adjustable to vary the length of the stroke, and driven by a Whitworth quick return movement. The feed of the machine is effected by swinging the frame in which the work spindle and its supports are hung, about the vertical axis of the imaginary crown gear.

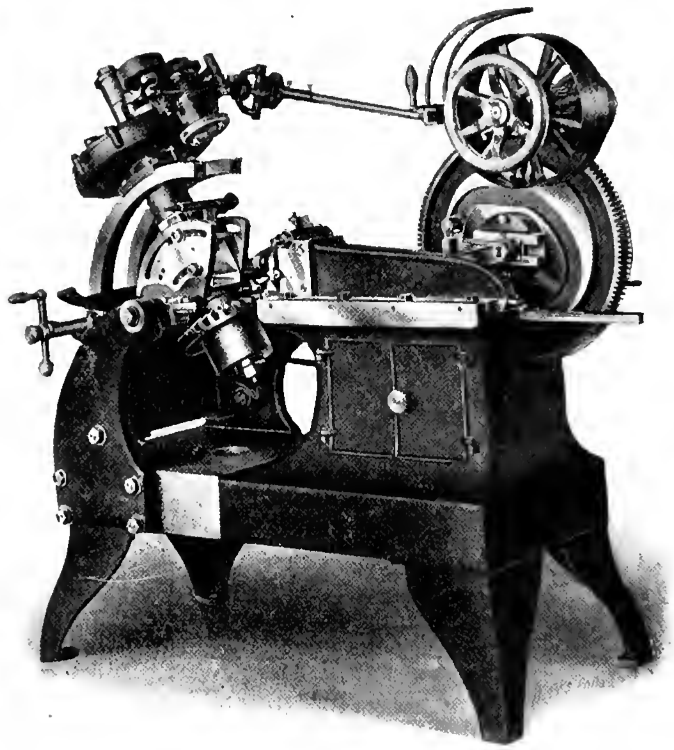

Fig. 166. Full Automatic Bilgram Bevel Gear Shaper, working on the Molding-Generating Principle.

Suitable feed connections, index mechanisms, etc., are provided for convenient operation.

In Fig. 166 is shown a development of this tool, in which the motions are completely automatic. The example illustrated is built and sold by Mr. Bilgram himself. In this case, the operator sets the machine and places a previously-gashed blank on the work spindle and starts the tool in operation. The mechanism provided will, without further attention, complete one side of all the teeth. The machine may be then readjusted and the tool set for cutting the other side, which will be finished in the same automatic fashion. The mechanism does not operate on the principle of completing one side of one tooth before going to the next. It follows the plan adopted by the same builder in his spur and spiral planing machines shown in Figs. 48 and 95, in which the work is indexed for each stroke of the tool, the rolling action being progressive with the indexing so as to finish all the teeth at once. A little thought will show that these three Bilgram machines are identical in principle, with only the modifications required to fit that principle to the making of spur, spiral, and bevel gears, respectively. The bevel gear machine is the only one that has come into extensive use, since the

bevel gear is the only one of the three kinds in which there is any great difficulty in forming the teeth accurately enough for all practical purposes.

Another machine operating on the same principle as the Bilgram is that built by the Ateliers de Constructions

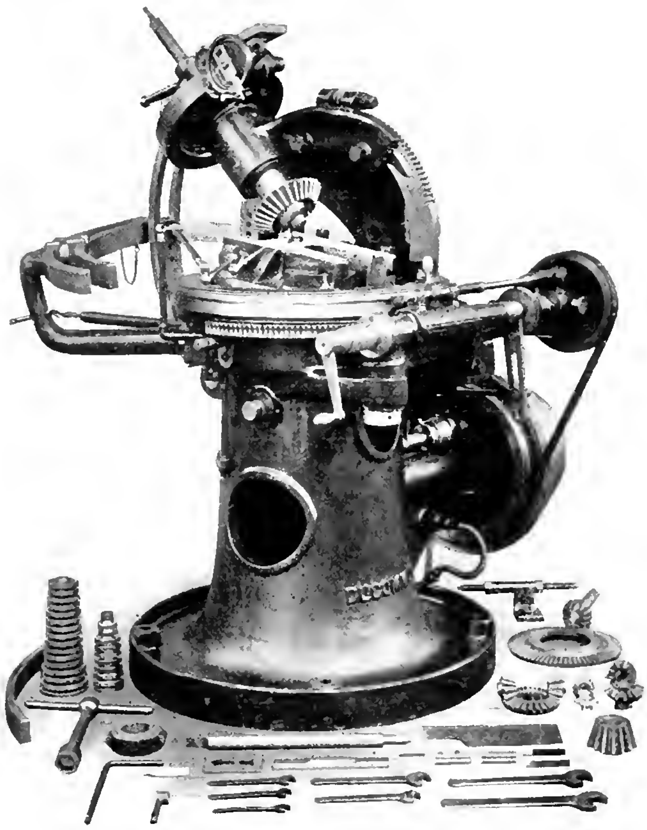

Fig. 167. Ducommun Bevel Gear Generator operating Two Tools.

Mecaniques ci-devant Ducommun, Mulhouse (Alsace). (See Fig. 167.) This machine has been so thoroughly described in MACHINERY* that it will not be necessary to go into minute details here. The principal differences between it and the Bilgram machine (aside from the obvious differences of the shape of the framework and the arrangement of the mechanism) are the link motion used in place of the steel tape for giving rolling movement to the blank, and the provision made for using two tools simultaneously so that both sides of a tooth are finished at once. This machine is not, like the last Bilgram machine described, fully automatic, but is arranged to cut a side of one tooth, after which it is indexed by hand and the side of another tooth cut.

The two tools are each carried in slides of their own, in the center of the circular top of the table. These slides are independently adjusted to bring the movement of the straight cutting edges in line with the plane surfaces of the teeth of the imaginary crown gear of Fig. 139. As in the Bilgram machine, the tool slides are stationary, while the frame carrying the work spindle is revolved about the vertical axis of the crown gear, a tooth of which is represented by the cutting edges of the tool. The swiveling movement of this frame is effected by a sector of a worm-wheel fastened to the circular table on which the frame is mounted. Suitable feeding movements and automatic stops are provided. To roll the blank with the same movement as a master gear rolling with the imaginary crown gear, a circular link, as shown, is clamped at the upper end to the spindle and the dividing mechanism, so that these parts and the work can be rocked by it about their axis. The lower end of this link is controlled by other curved links in such a way that the rolling movement produced on the blank as the circular table is rotated about its vertical axis, is nearly exactly the theoretical movement required. The interesting way in which this is effected has been explained at length in the article previously referred to. The arrangement of the links controlling the rolling movement of the blank shows very plainly the spherical basis of the bevel gear, as illustrated in Fig. 133. This is one of the most interesting of the bevel gear generating machines, and gives evidence of designing ability of a high order.

A French machine of the type we have been considering, built by H. Ernault, 169 Rue d'Alésia, Paris, is shown in Fig. 168. It was designed by Monsieur Monneret, and shown at the Paris exhibition in 1900. The writer is not sure that it is being manufactured for the trade at the present time. It is of such interest, however, as to warrant illustration and description.

This machine is identical in its operation with the typical mechanism shown in Fig. 139, in that the axes of the work and of the imaginary crown gear are fixed in position, and are rotated in the proper ratio with each other to give the desired rolling movement of the tool and the blank on each other. The cutter slide is mounted on what resembles the head-stock of a lathe, at the right-hand side of the machine in Fig. 168. It is driven by a crank seen through the opening at the front of the slide. The tool is carried on the holder at the back upper end of the slide, and is provided with automatic means for positively relieving it on the back stroke.

To understand how this tool slide is rolled about its axis in unison with the rolling of the blank, it is first necessary to state that this machine will cut helical gears only, this being due to the fact that the crank-shaft and the blank are connected positively by change gearing, so that the blank rotates continuously, resembling in this particular the arrangement provided on the Bonhey machine for making, when required, gears of this kind by the templet process. Unlike the Bonhey machine, however, the one we are describing cannot be used for making straight tooth bevel gears; and, since the blank has to have imposed upon it a

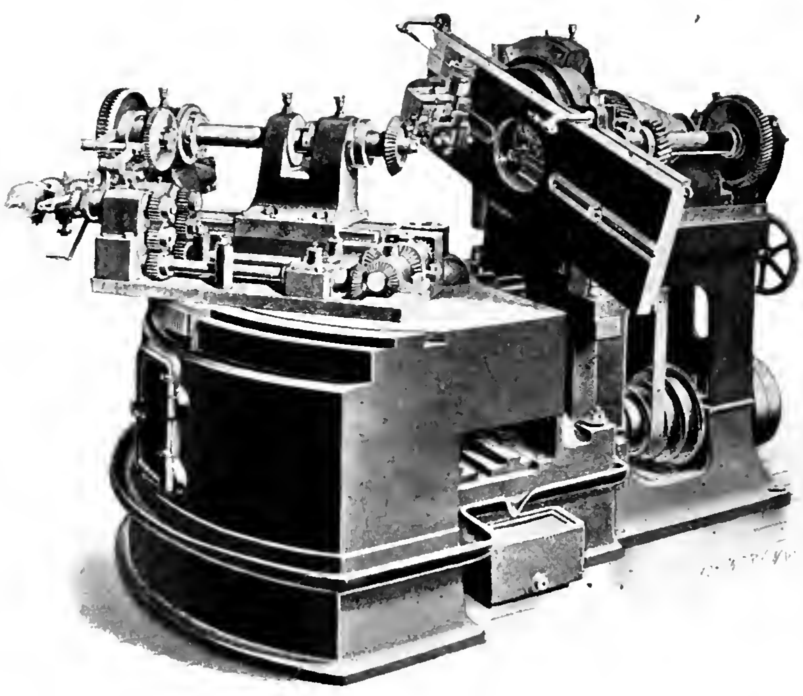

Fig. 168. The Ernault Bevel Gear Generating Machine, which cuts Gears with Helical Teeth.

rotary motion in unison with the rolling of the tool-slide, and in addition to the rotating motion due to its connection through the change gears with the tool-slide crank-shaft, a differential movement has to be introduced for combining the two.

The change gears set for the number of teeth connect the crank-shaft and the indexing worm at the rear of the work

*See article "A European Bevel Gear Generating Machine" in the January, 1907, issue of MACHINERY.

spindle through a train of positive gearing and shafts. The rolling movement of the blank (and of the tool slide about its axis) is driven by a cam and ratchet movement operated by the spur gearing leading from the work spindle at the left of the machine in the engraving. This ratchet-driven motion is connected by bevel gears with a screw which shifts, in the direction of its axis, a cradle or yoke in which is confined the index worm for giving the rotary movement to the blank. This worm is splined upon its shaft, so that it trans-

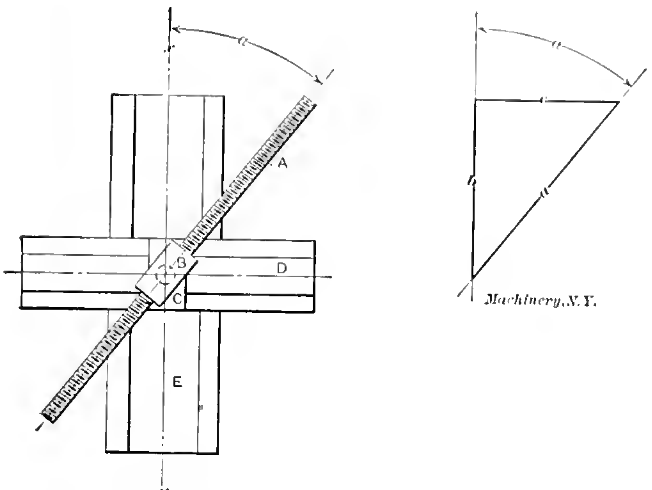

Fig. 169. The Mechanism by which the Proper Ratio of Rolling Movement for the Blank and Tool is obtained for the Machine in Fig. 168.

mits to the work through its longitudinal motion a rolling movement derived from the ratchet feed, and a continuous rotary movement derived from the change gearing and the crank-shaft. These movements are combined without interfering with each other, and either may be started or reversed independently. It will be seen that the mechanism is exactly identical in principle with that described for the Reinecker worm gear hobbing machine in Fig. 128.

The same ratchet mechanism that shifts the indexing worm axially is connected by the train of gearing shown with a vertical shaft passing down through the center of the angular adjustment of the work slide, where it is connected with a screw, shown diagrammatically at *A* in Fig. 169. This screw is supported in bearings connected with the work slide in such a way that, as the latter is adjusted to the angle of the gear being cut, the screw is swiveled with it, being always at right angles to the axis of the work spindle. The nut *B*, which encircles this screw, is pivoted to a sliding block *C*, which is dove-tailed to slide *D*. *D* in turn slides in guiding ways *E* in the direction *xy*. Slide *D* is fastened to a rack meshing with a pinion, connected by shaft and gearing with mechanism for rocking the tool slide, the whole arrangement furnishing the means by which the rolling of the blank effects the corresponding rolling of the imaginary crown gear and the work, in unison.

The ingenious feature of the mechanism in Fig. 169 is the way in which the proper ratio of movement for the rolling of the work and the tool is assured. When the axis of the work and of the imaginary crown gear are set in the same straight line, as would be required when cutting a crown gear, the axis of screw *A* is by that setting shifted until it is parallel with *xy*, and thus the movement of *D* on *xy* is the same as that of the nut *B* along the screw. If, on the other hand, the work spindle is adjusted to angle *a* with the axis of the crown gear, the mechanism will take the position shown in the engraving, and the screw, when moving the nut a distance *a*, will move slide *D* on ways *E* a smaller distance *b*, resolving the motion *a* into two components, *b* and *c*. Of these two, *b* is in exactly the right proportion to *a* to give the rolling movement required for the tool, and it is transmitted to the tool slide by the motion described. This, it will be seen, does away with the necessity for adjusting the rolling movements separately as required for the Bilgram and Ducommon machines.

In Fig. 170 is shown an American machine* of the molding-generating type, employing the planing or shaping operations. It differs from the previous machines of this kind we have described, in employing two tools, one on each side of the tooth, resembling in this respect the Oerlikon templet planer shown in Fig. 155. This tool is identical with the previous one and with the mechanism in Fig. 139, in having the axes of the tool slides and of the blank fixed in relation to each other during the operation, the tool-holders and the blank rocking about their axes to give the rolling movement for cutting. The connections, however, between the blank and the slide are entirely different, and the tools finish each tooth of the work complete before they commence on another. The rocking is effected (in the recent improved form, not shown below) by means of segments of an actual crown gear and master gear. The segment of the crown gear is permanently attached to the face of the rear of the cutter slide frame, while the segment of the master gear (of which there are several furnished with the machine, the one used being chosen to agree with the angle of the gear to be cut) is clamped to the semi-circular arm pivoted at the outer end of the machine at one side, and fastened to the work spindle sleeve on the other. This arm is rocked by a cam mechanism and slotted link at side opposite that shown in illustration.

The cycle of operations is as follows: The machine being adjusted properly in its preliminary position, the tool slide and the head on which it is mounted are swung back about the vertical axis so that the tools clear the work. The blank being set in the proper position, a cam movement swings the cutter slide head inward until the tools reach the proper depth. The cam movement first mentioned now rocks the semi-circular arm extending around the front of the machine upward, rolling the blank and (through the segmental crown

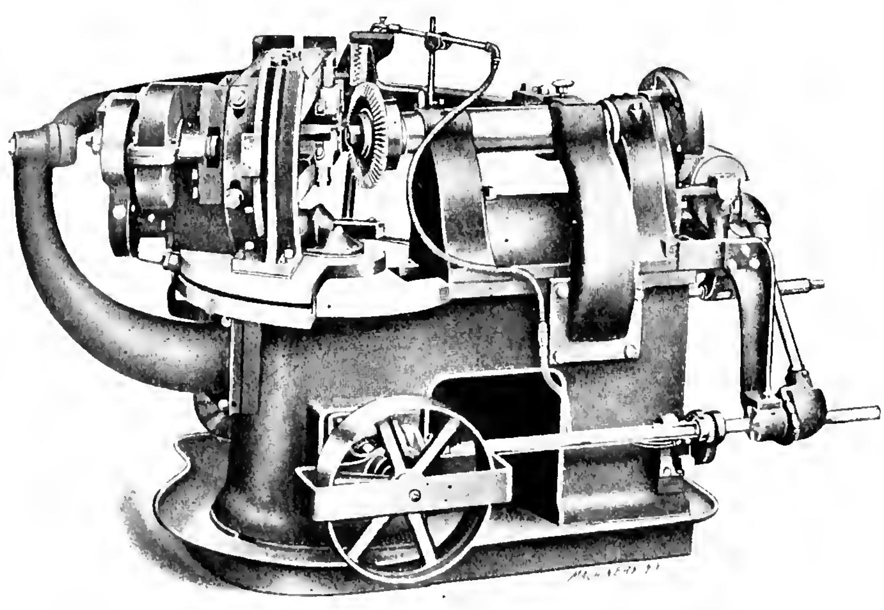

Fig. 170. The Gleason Bevel Gear Generating Machine as first developed.

and master gears) the slide, until the tools have been rolled out of contact in one direction, partially forming the teeth as they do so. The arm is then rolled back to the central position and along downward to the lower position, until the tools are rolled out of contact with the tooth in this direction, completing the forming of the proper shape as they do so. The cam then rocks the arm back to the central position, where the cutter-slide head is swung back to clear the tooth, and the work is indexed, after which this cycle of operations is continued for the next tooth. It will be seen that by starting from the central position, going to each extreme and re-

*See article "The Gleason Generating Bevel Gear Planer" in the July, 1906, issue of MACHINERY.

turning, all parts of each tooth are passed over twice, giving a roughing and a finishing chip.

The machine is entirely automatic. The use of two tools presents a number of advantages. Not only does it increase the rate of working, but it balances the thrust of the cutting action of the two sides of the teeth and reduces chatter and vibration, thus giving greater accuracy. The slides of each of the two tools, of course, have to be relatively adjusted to each other, depending on the size of the tooth being cut.

A GREAT PUBLIC CLOCK.

CHARLES A. BRASSLER.*

The famous clocks of the old world, with their complicated mechanisms, telling of the movements of the planets, their crowing cocks, and processions of figures representing historical celebrities or biblical subjects, interesting as they are

Fig. 1. Great Clock on Factory of Colgate & Co., Jersey City, N. J.

to the antiquarian and curiosity seeker, could find little place in the practical up-to-date United States. On the other hand, a time-piece that will be a mentor to busy thousands in the great mercantile center of the new world, and a land-mark for the voyaging multitude that annually enters and leaves its portals, possesses more than passing interest.

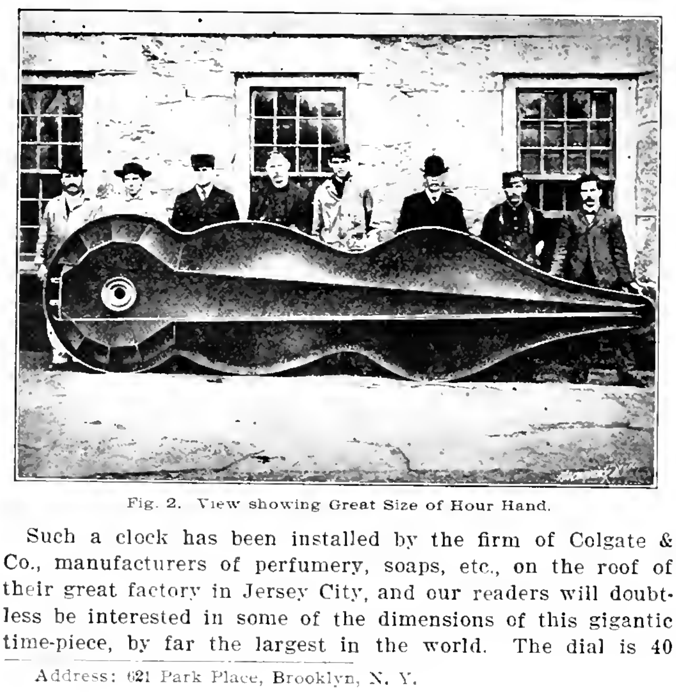

Fig. 2. View showing Great Size of Hour Hand.

Such a clock has been installed by the firm of Colgate & Co., manufacturers of perfumery, soaps, etc., on the roof of their great factory in Jersey City, and our readers will doubtless be interested in some of the dimensions of this gigantic time-piece, by far the largest in the world. The dial is 40 feet 6 inches in diameter, compared with the 37½-foot dial of the church of St. Rombaut at Mechlin (French-Malines), Belgium, hitherto regarded as the largest in the world. The marks used instead of numerals on the Colgate clock are 5 feet long and 30 inches wide.

While this clock is plainly visible and its record easily legible by day from the tall buildings in lower New York and from the decks of the crowded ferry-boats with which the Hudson River is at all times filled, it is after dark that the clock is most conspicuous. Innumerable electric lamps placed in deep grooves to concentrate their light, illuminate the figures on the dial, while the moving hands carry around with them a sufficient number of incandescent lamps to brightly outline them. Forty-two lamps light up the minute hand, which measures 20 feet from hub to tip, and without its counterbalance (which latter weighs 270 pounds) weighs 640 pounds, while twenty-five lamps will outline the hour hand, which is 15 feet from the edge of the hub to the tip, and weighs complete 500 pounds. The circumference of the dial is approximately 120 feet, and the point of the minute hand travels 3 2/3 miles in seven days. For every minute the clock goes, the point of the minute hand covers 23 inches. The distance from center to center of the hour graduations is 10 feet, and the minute spaces or marks are 2 feet apart.

The clock, which was built by the Seth Thomas Clock Co., of Thomaston, Conn., is what is known as the Seth Thomas remontoir tower clock, and will require about 1,500 pounds of weights to propel the hands. It is claimed to be the most

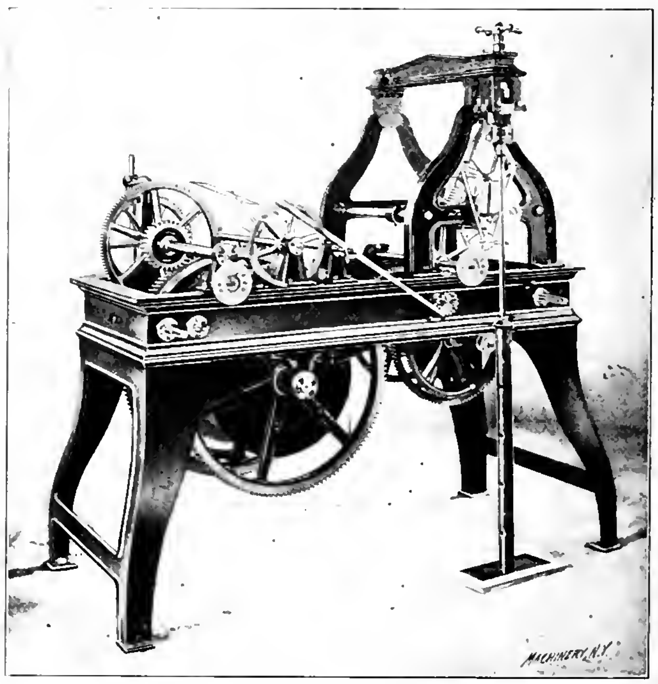

Fig. 3. The Seth Thomas Movement.

powerful as well as the most mechanically correct tower clock ever constructed. The pendulum rod, 8 feet in length, carries a cylindrical bob 330 pounds in weight. A refinement worth noting is that the bob is made with a rounding top to prevent dust from settling on it and affecting the accuracy of the time-keeper.

* Address: 621 Park Place, Brooklyn, N. Y.

* * *

Count Zeppelin made a very successful trial of his airship in Switzerland, July 1, when the ship remained in the air for twelve hours, with Count Zepplin and a crew of fourteen men. He sailed over Lake Constance, making complicated evolutions, and over a large part of Northern Switzerland, visiting Zurich, Winterthur and Lucerne. It was claimed that no automobile was under more perfect control of the driver than the airship. It sailed with and against the wind, and throughout the voyage maintained an average speed of 34 miles per hour. The greatest altitude reached in the long voyage was 2,500 feet and the total distance covered was about 220 miles. This is the fourth large airship built by Zeppelin with a structural frame to hold the cigar-shaped body rigid. It is 435 feet long and 43 feet diameter.

LOCAL HARDENING AND TEMPERING.*

MANIPULATION OF TOOL STEEL BY THE FLEXIBLE COVER OR SHIELD METHOD.

WILLIAM A. PAINTER,†

William A. Painter.‡

In describing the shield process or method of local hardening and tempering of tool steel, I record some of the results of over four years of experimenting and practical application. The process is a radical departure from any practice in use at the present time so far as I know, and acts on a principle that appears not to have been recognized heretofore. We have demonstrated the wearing qualities of dies and tools so treated, by every-day use, and the efficiency of these as compared with tools treated by the conventional processes is decidedly superior. Breakage is reduced to a minimum, both in hardening and tempering and in use.

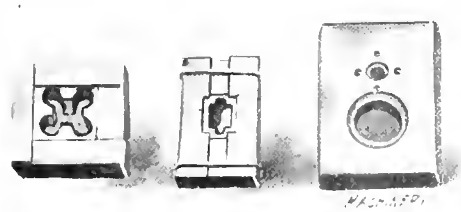
In using the shield method, the same judgment and common sense must be employed as in hardening by the regular method. If the hardener is hardening a piece that should be dipped in clear water, following the usual practice, it should be dipped in clear water when provided with the shield, and allowed to cool with the shield on. Or, if the piece is complicated and of delicate structure that requires cooling in oil, the same practice should be followed with the cover piece, dipping it in oil in the same manner. Again, if a special bath is required for certain work, use the bath in the same way for the shielded work. The results are exactly the same, except that with the shield method only the parts exposed harden, while the parts covered remain soft and in their natural condition.

A B C

Fig. 1. Blanking and Threading Dies in Protective Shield.

Heating.

For heating tool steel to be hardened by the shield method, the operator has the choice of any fire he prefers. An open forge answers the purpose for small work, but the furnace is better on account of the more even heat. A lead bath cannot be used because of the lead getting between the covers and the steel to be hardened, which will cause an explosion when dipped into water. This is not a serious drawback, as I do not consider that a lead bath has any marked advantages over a good coke or gas furnace. Moreover, the lead bath has a disadvantage in that it leaves a thin film or coating on the steel, which tends to keep the cooling bath from penetrating to the steel and cooling the piece as rapidly as it would cool if heated in a furnace.



A B C

Fig. 2. Square Threading Die, and Press Dies with Covers ready for Hardening

General Application of the Shield or Cover Method.

The shield method can be applied to almost all tool steel. Any brand or grade that is desirable to use can be handled in exactly the same way as without the shield. The advantage of the shield is that the essential wearing surfaces are hardened, and if these parts only require hardening, why harden the piece all over? A piece hardened all over is weakened by setting up internal strains and stresses which are likely to develop cracks and fractures and perhaps cause the ruination of an expensive part after it has been made all ready for use.

Gages of all kinds for external and internal use can be treated to advantage, and many gages now being made of machine steel and case-hardened can be made advantageously of tool steel in this manner, only the wearing parts being actually hardened, while the remainder is left soft. Multiple-throw crank-shafts for automobiles and high-duty automobile parts are readily treated by the shield method so that the actual wearing parts are hardened while the remainder of the piece is unchanged. Tool steel bearings for machinery may be hardened on the inside only, whether the bearing is in one piece or is split in two parts. Large rolls for rolling mills can be made with the journals soft or partly soft, thus avoiding the breakage of same at the shoulders. Hammer faces for pneumatic hammers can be treated at the shank so that the shank is soft while the die part is hard, thus avoiding the breakages now generally experienced. All kinds of drill jig bushings can be hardened, either externally or internally, as desired. Shear blades and other large pieces of similar use can be hardened on the cutting edges while the bulk of the metal is left soft.

A B

Fig. 3. Drop-hammer Die, and Punch with Shields.

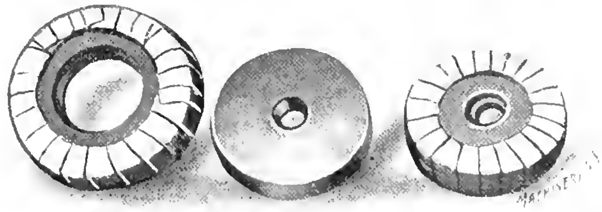


Fig 4. Two Drawing Dies prepared for Local Hardening and One after Hardening.

Materials used for Shields.

In practice the thinnest possible cover to accomplish the desired results should be used. I have not had to use material thicker than 0.020 inch for ordinary work, and not thinner than 0.010 inch for small work. The thickness that serves best for average work is about 0.014 inch. The object of the shield is to cool the steel as quickly as possible under the cover without hardening same and without leaving a line of tension between the hardened and unhardened areas. The cover or shield can be made of any sheet iron or sheet steel, and scrap pieces, even if rusty, answer the purpose satisfactorily. Galvanized iron or tin plate should not be used, as the coating of zinc or tin when heated enters the steel and deteriorates it.

The shields or covers are made in different ways to suit the conditions. Some are made with top and bottom pieces with another strip or piece for the edge to act as a binder to hold the top and bottom in place and to protect the edges of the

* For previous articles on local hardening see "Tempering Hollow Mills and Other Tools," by J. F. Sallows, February, 1907, and "Pack-Hardening Gages," by E. R. Markham, June, 1908. The process here described was patented March 17, 1908, No. 882,162.

† Address: Pittsburg Lamp, Brass & Glass Co., Allegheny, Pa.

‡ William A. Painter was born in Waterbury, Conn. He was educated in the grammar schools of New York City and the College of the City of New York. He served an apprenticeship with the Matthews & Willard Mfg. Co., Waterbury, Conn., and has worked for the Miller Mfg. Co., Torrington, Conn.; Trenton Lamp Co., Trenton, N. J.; and is now master mechanic of the Pittsburg Lamp, Brass & Glass Co., Pittsburg, Pa. His specialty is manufacturing sheet metal goods and castings of all kinds.

piece. Some shields are made in one piece where the shape is not irregular. This applies in the case of round drawing dies and similar parts. In such cases, of course, the shield is formed to shape by cutting and bending. Where an irregular shape is to be cut out, the piece to be hardened is laid on the sheet metal and the outline scratched on same. The shape is cut out with a chisel, leaving a margin of the required width around the edges that are to be hardened. The width of this margin depends on the size of the part and the nature of the work. A pair of hand shears or snips, a small chisel, a scriber, hammer, punch and pliers are the principal tools necessary. A supply of sheet metal, rivets, and iron binding wire completes the outfit.

How the Shield Method Differs from Other Protective Methods.

Mechanical journals and books on shop practice have not treated of this method, although other methods very similar have been described. There are several methods moderately successful for local hardening and tempering, one being by dipping the piece part way into a bath, a practice that is commonly followed in hardening chipping chisels. Another method is holding a heated piece over and above the bath and directing a stream of water onto the part to be hardened. Large, round drawing dies having to be hardened on the inside are examples of this practice, a cone-shape spout being used at the bottom of the pipe to deflect the stream onto the interior of the die. A third method is that of making a box or form of heavy steel, cutting or drilling out the shape of the piece to be hardened. A lid is fitted to the box and the piece is heated in the fire, and after being heated is placed in the box and quenched. This method is objectionable in that the box, being made of thick material, causes uneven cooling, most of the heat having to be drawn off through the exposed parts of the piece. A fourth method is the use of fire-clay or asbestos wrapped around the parts to be left soft, the holes being plugged with fire-clay, asbestos or even putty. Iron wire is used to wrap around a non-conducting material to hold it in place. It then has to be baked in an oven or furnace until the moisture is dried out. Then the part is heated in the furnace to the hardening heat, and dipped. Inasmuch as these materials are poor conductors of heat and as the heat must be drawn quickly in order for the steel to contract evenly with the hardened or exposed parts, this method has not been very successful.

A B
Fig. 5. Reverse Drawing Die.

Fig. 6. Embossing Die.

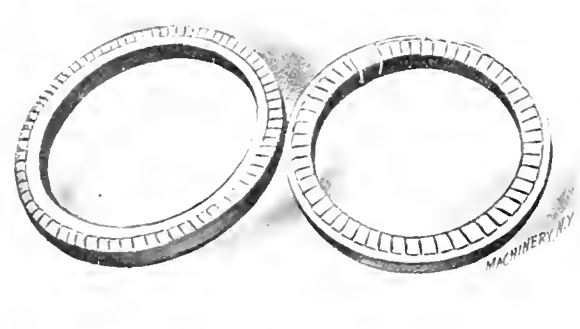

Fig. 7. Blanking Dies.

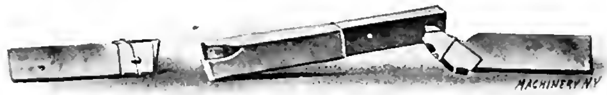
A piece of steel heated to a proper hardening heat and quenched in a box or shield of very thin steel or iron material, will remain soft because the water cannot cool it directly. Steam or vapor forms between the cover and the steel, driving the water away until the piece has cooled down. If holes are cut through the cover to let the steam out more rapidly, that part of the steel exposed will harden. To show that the steam imprisoned between the steel and the shield is a non-conductor of sufficient efficiency to make the difference between hardening and annealing, take a round piece of tool steel and fit a cover tightly around it, leaving half its length exposed. Heat this piece all over and cool all over. It will be found that the steel has hardened its full length under the cover, as well as on the exposed parts. The reason is that when the cover is tightly fitted no water can penetrate between the shield and the steel, and hence no steam is formed. The cover being thin, the steel cools rapidly and hardening takes place. This proves that the cover itself is a good conductor of heat, but the thin stratum of steam which will always exist between the cover and the piece as ordinarily fitted, is sufficient to check the hardening process.



A B C
Fig. 8. Samples of Lathe Tools with Shields.

Description of Work Locally Hardened.

The part shown in Fig. 1 at *A* is an ordinary blanking or cutting die and is an example showing how any shape to be hardened can be outlined in the cover. The cover is made in two pieces, the top and sides being one piece and the bottom the other piece. The material of this shield is No. 26 sheet steel and is about 0.018 inch thick.

The second piece shown in Fig. 1 at *B* is a round threading die, and the shield is applied so that the threads only are hardened, the exterior remaining soft. It illustrates a very practical use of the shield method. The die is split at one point, being of the adjustable type. Inasmuch as only the teeth are hardened, there is no danger of cracking the die in adjustment, and there is less distortion and change of pitch. The cover is made in one piece and can be used several times before being destroyed by the heat.

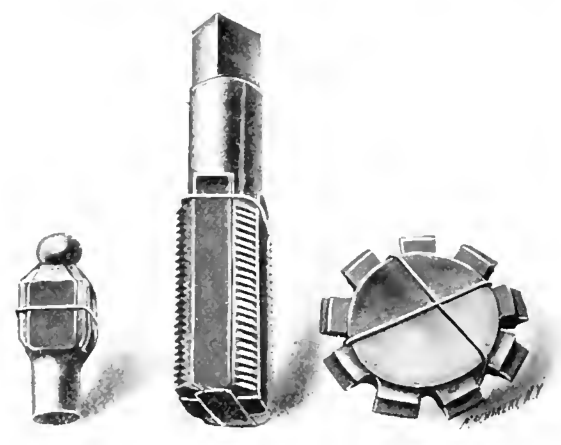


Fig. 9. Miscellaneous Examples.

The third piece shown in Fig. 1 at *C* is a plain blanking die, but instead of being hardened around the edge of the cutting part as in *A*, it is hardened half the thickness of the steel, leaving the whole lower half soft, this being protected by the cover, while the upper half is hardened. This gives the die all the advantages of a die made of composite steel, a material that is made of half tool steel and half soft steel or iron welded together. This material is extensively used on small die work, but the shield method makes its use unnecessary as all its advantages are obtained very simply, and it never splits at the weld as is sometimes the case with composite steel.

A square threading die is shown in the shield at *A* in Fig. 2, and the same remarks apply in regard to distortion and change of pitch as in the case of the round threading die. At *B* is shown a press die in its cover ready to be hardened. The exposed portion is not large in proportion to the size of

the die, but it will harden just as well as if there were a half inch margin exposed all around the edge. The cover is held on by iron wire. Brass wire or rivets should not be used, as the heat destroys them. At C is shown a progressive or following die. There is nothing of special interest in the design, but the method of hardening a narrow ring around each hole is unique. The cover is cut out so as to leave a narrow margin of exposed steel around each hole. The die is hardened exactly as the cover shows, the remainder of the body being soft, as before dipping.

In Fig. 3 at *A*, is a forming die for drop-hammer. It is 8½ inches long, ¾ inch thick and 4 inches high, and has been

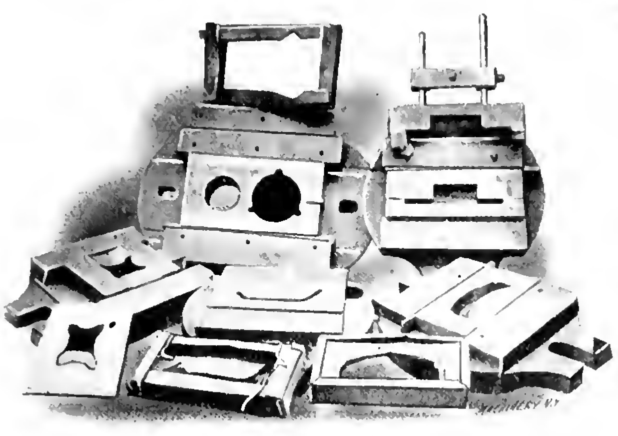

Fig 10. Group of Large Dies and Covers.

hardened all around the outline of the top or face for a width of ½ inch. The scale is still on the steel and no finishing has been done. The cover had two large holes cut out to balance the cooling as the narrow center would warp the bottom. This piece was hardened without warping. At *B* is shown a large blanking punch with the face up. In hardening large punches it is only necessary to harden an area around the cutting edge. The steel plate or cover on the face of the punch is 0.020 inch thick and was held to the face of the punch by three 3/16 inch screws, holes being drilled in the face of the punch to correspond. This is a good example of cover hardening and demonstrates its value, as the punch retains its shape perfectly after being dipped.

Two drawing dies are shown in Fig. 4 with the covers on ready to harden, and a third die is shown without a shield. These shields are made in one piece and can be used over

Fig. 11. Another Group of Large Dies.

again. A drawing die needs to be made as hard as possible, and yet when a die is hardened all over it is necessary to draw the temper in order to relieve the internal strains. By the shield method the working part is made as hard as it can be made while the soft part gives it a suitable backing and strength. The shrinkage can be regulated by the thickness of the shield or by putting vent holes around the edge of same. The vent holes let out the steam and cause the shielded part to cool more rapidly. Dies hardened by the shield process can be shrunk repeatedly to take up the wear.

A reverse drawing die 6 inches outside diameter, 5 inches inside diameter, with hardened ring riveted to the top or wearing edge, is shown in Fig. 5 at *A*. At *B* is illustrated the method of hardening the ring, leaving the shoulder or bottom edge soft by covering it with a shield of thin steel. The ring can be fitted after hardening, driven on a shoe and holes drilled through from outside of the machine steel shoe, and riveted. The hardened portion is then ground to size. If the top ring were welded to the shoe it would have to be discarded when worn down.

In Fig. 6 is shown an embossing die made of tool steel. It is 8½ inches diameter and 3 inches thick. This die was covered on the bottom and sides with No. 25 sheet steel 0.020 inch thick and placed in a basket or hanger so that it could be immersed by a tackle. The embossed part was filled with bone dust for protecting it in the fire, but charcoal or any suitable filling will do as well. When covering shallow dies, the top edge should be left standing about a half inch above the face of the die instead of being folded over, as shown in the illustration. This face is filled in as described above as the filling will protect the face of the die. It should be left in, when dipped, and the die should be suspended face up and about 3 inches below the water level, while a stream of water of large volume but low pressure is directed against the center of the die while the die is moved around in the tank. This can be done with one hand holding the tackle while the other hand directs the stream. The filling or packing will float away, leaving the surface of the die clean. A ¾-inch hose without nozzle is about right for ordinary work.

In this connection it may be mentioned that a skeleton platform with hanger is an advantage for handling large work, as any piece too large for tongs can be placed on the platform and lowered into the tank. It may be cooled from the

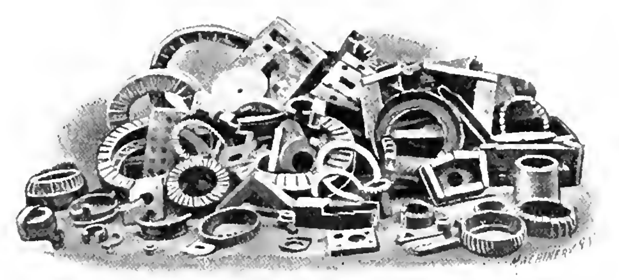

Fig. 12. Miscellaneous Collection of Shields or Covers showing Range of Application.

bottom, if necessary, as well as from the top. Some shapes give better results if covered only on the sides, leaving the top and bottom exposed. The hanger gives the bottom a chance to cool off, but not as rapidly as the top where the stream of water is directed. This method is an improvement over the present way of hardening drop forging dies, this class of hardening being regarded as very difficult where the shapes are irregular and the thickness of the walls uneven. It will apply to all deep or hollow dies.

To the left in Fig. 7 is shown a blanking die 11⅛ inches inside diameter, 1¼ inch thick and 1¼ inch width of walls. This die is covered and hardened in the regular way. The temper is drawn, after which it can be placed in the lathe and trued up. The outside is as soft as it was before dipping. Obviously, this die is much stronger than one hardened all over. At the right is shown a blanking punch 11⅛ inches outside diameter, 1⅛ inch thick, with walls 1⅛ inch wide. It is hardened on the outside only and the temper is drawn. The inside is as soft as before hardening, and is made a driving fit on a cast iron holder. The fit can be made a very tight drive without danger of cracking the ring.

Fig. 8 shows the application of the shield method to hardening lathe tools. At *A* is shown a right-hand side tool of carbon steel hardened on the cutting face only, the back being left soft. The cutting edge can be left much harder than usual without danger of weakening the tool. At *B* is shown a self-hardening tool that has been heated up to the proper temperature without cover and the cover applied to the tool before dipping in oil. This method works equally as well on air-hardened tools, the cover being put on before holding the tool in the air-blast. The breakage of self-hardening steel tools is an expensive item and usually amounts to

more than the actual wear of the tools, but if they are made with a soft back or partly soft back and with only the working parts hard, as will be the case with the shield process, the tool is much stronger, and is much less liable to fracture in service. At C is a half diamond point lathe tool which is hardened only on the working face. The sheet covers can be applied to any shape of lathe or planer tool by any one of ordinary mechanical skill.

In Fig. 9 a ball peen hammer is shown placed ready for hardening and the eye for the handle is not filled, but is covered with a shield of steel wrapped around the part to be kept soft. The eye will not harden, as the heat of the steel inside of the cover, when dipped, creates steam which drives the water back until the heat is reduced. The milling cutter in this illustration is shielded with two circular plates 0.020 inch thick and the hole in the center is not filled. The disks of sheet metal are held together by iron wire, and any desired area on the sides of the cover can be left soft by making the size of the disks to suit. This is far better than the heavy plates that are generally used, as the heat is drawn off more rapidly, leaving less internal stresses in the steel. The tap shown has been hardened on the teeth only, the body and shank being shielded so that they are left soft. Taps hardened in this manner are truer in the pitch and the size is less likely to be changed than if hardened all over. The preparation of the cover took less than 5 minutes' time, only two strips of sheet steel being required and a short section of iron binding wire. Flat drills are hardened on the point and sides only, the center being left soft. Such drills will not snap off short when caught in the work, but will bend before breaking. The shield consists simply of two thin plates held on by iron wire.

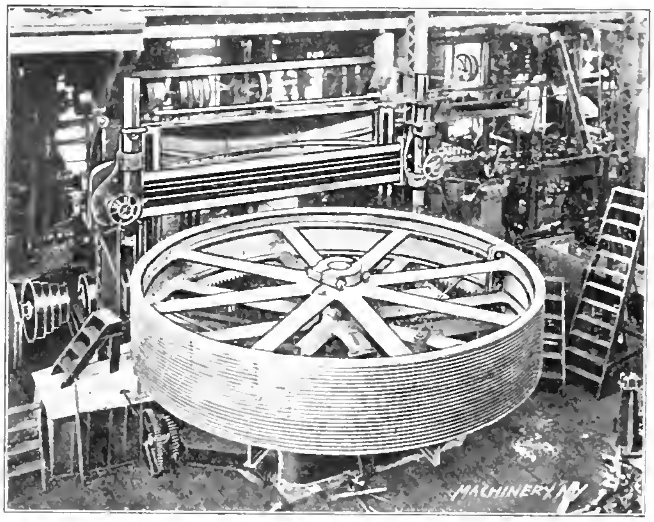

Fig. 1 Rope Sheave 20 Feet in Diameter for Driving Refrigerating Plant.

Fig. 10 illustrates a group of large dies and their covers. In Fig. 11 is illustrated another group of large dies, and in Fig. 12 is shown a miscellaneous collection of covers that have been used to shield work from $\frac{1}{4}$ inch diameter to 12 inches diameter. The shields are made mostly from stock 0.010 to 0.020 inch thick. Some of the circular shields have been in the fire several times.

My conclusion is that the shield method of local hardening is applicable to a vast range of work, and that the cutting tools, dies, taps, gages, etc., locally hardened and tempered, are less likely to warp and change in shape in hardening and are more durable in service than when hardened in the common way. The application of the shields is cheap, and any one of ordinary skill is able to cut them out and apply them to the work. The saving in breakage alone will more than pay the expense of applying the shields, while the greater durability of tools so hardened makes the process profitable to follow.

* * *

One of the most remarkable flying machine performances, undertaken under the auspices of official supervision, is that of Delegrange, a French aeronaut, who, on June 22, with an aeroplane covered a little more than 11 miles in $16\frac{1}{2}$ minutes, making nine rounds of a measured course.

LARGE ROPE SHEAVE—CUT GEARS OF UNUSUAL DIMENSIONS.

A rope sheave 20 feet in diameter, with 20 grooves for 2-inch rope, weighing 48,000 pounds finished, was recently made by H. W. Caldwell & Son Co., Chicago, Ill. The sheave is shown in Fig. 1 on the boring mill. It has a double set of arms, and was cast in one piece and then split apart for convenience in handling and erecting. It was cast in the foundry of the company, and was finished on a 20-foot boring mill. The sheave will be used in connection with the main drive of a refrigerating plant in Mexico to reduce the speed of an electric motor, the motor being direct connected to a small sheave. The transmission is by means of what is generally known as the American or single rope system.

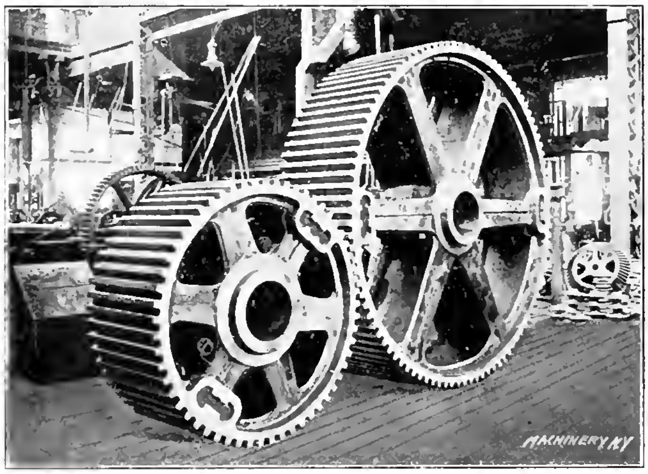

Fig. 2. Heavy Cut Gears of Unusual Dimensions.

Figs. 2 and 3 show a pair of heavy cut gears of unusual dimensions, recently produced in the same works. The gears are of semi-steel mixture, and were cast in halves and the joints planed. The weight of the large gear is 13,800 pounds and of the small gear 8,000 pounds. The diameter of the large gear is 95.51 inches, 100 teeth, and of the small gear 55.41 inches, 58 teeth. The width of the face is 27 inches and the pitch is 3 inches. The teeth were machined in a Gleason gear planer, it being preferable to plane the teeth rather than mill them on account of the extraordinary dimensions of the gears. It may be said as a general proposition that it is preferable to plane spur gears in all sizes above 2 or $2\frac{1}{2}$ circular pitch. The gears illustrated are to be used in connection with the drive of a mining hoist in the Lake Superior copper mines.

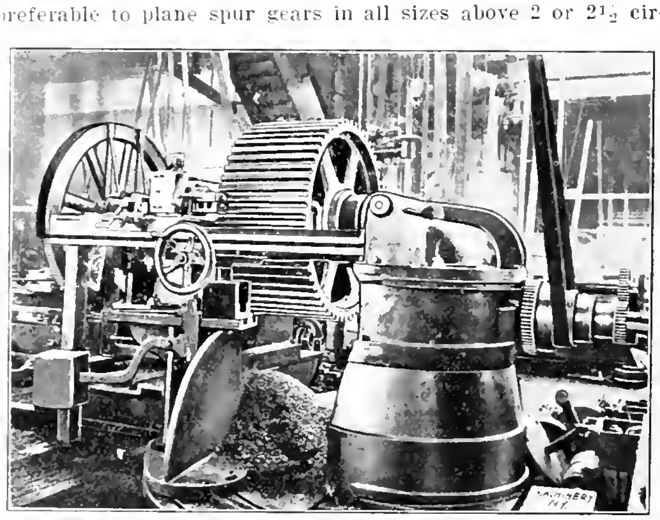

Fig 3 Gears being planed on a Gleason Gear Planer.

* * *

The Pennsylvania Railroad has had a long line of engineers for presidents, and for many years it did not list its stock on the New York Stock Exchange. The pre-eminence of this corporation over all other railway organizations as a legitimate enterprise is undoubtedly due to these facts and to the sense of duty and practical ability of its presidents.—*W. D. Marks, in Engineering News.*

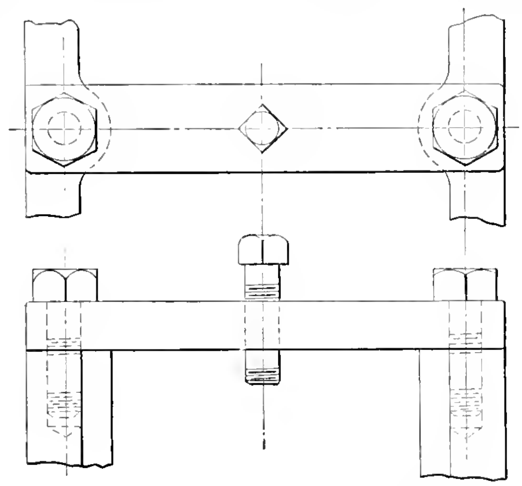
JIGS AND FIXTURES—5.

EINAR MORIN *

CLAMPING DEVICES (Continued.)

It was mentioned in the previous installment, appearing in MACHINERY last month, that the loose leaf construction, as a rule, is only used when a guide bushing can be put into the leaf, because its construction is rather expensive to use for the single purpose of clamping. When the leaf is simply intended to hold one or more set-screws by which the work is held down, it may be made and fastened as shown in Fig. 51. In this case, the name "leaf" is rather out of place, and this fastening device becomes merely a strap. Some improvements of this kind of clamping device are shown in Fig. 52, where the ends of the strap are slotted in various ways so as to permit getting the strap out of the way rapidly when the work is to be removed.

The ordinary jack-screw is used to some extent as a clamping device in drill jigs, but the objection to its use is that, not being an integral part of the jig, it is very apt to get lost. In Fig. 53 are shown two simple devices working on the same principle as the jack-screw, but having the advantage of being connected to the jig by the pin shown at *B*. At *A*, in Fig. 53, a set-screw screws directly into the end of the eye-bolt, and at *C* a long square nut is threaded on the eye-bolt. These nuts must be made of special length, and be made up especially for this purpose. The eye-bolts are fastened, as



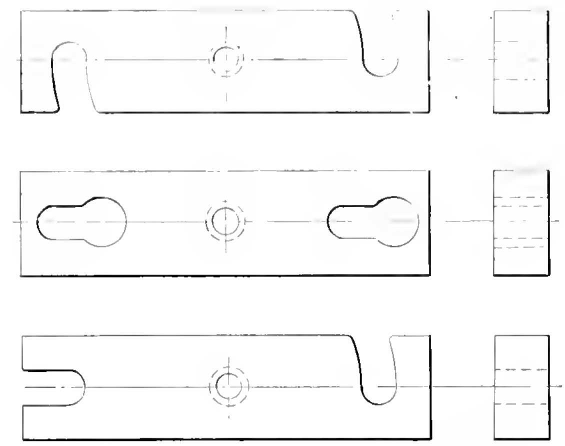
Machinery,N.Y.

Fig. 51. Common Clamping Strap.

shown, directly to the wall of the jig, and the set-screw or nut is tightened up against the work. The eye-bolt can be set at different angles to suit the work, thereby providing a clamping device which may be said to possess double adjustment. This device makes a very convenient clamping arrangement. It works satisfactorily, and has the advantage of being easily swung out of the way.

The principles of clamping work in the jig by means of a wedge or tapered gib is illustrated in Fig. 54. The work is located between the wedge *A* and the wall *B* of the jig and pressed up against the wall by the wedge which can be driven in by a hammer, or screwed in place when the jig is constructed as shown. It is preferable to have the wedge screwed in place, as it is then less apt to loosen by the constant vibrations to which it is subjected, and at the same time the wedge is less apt to get lost, being an integral part of the jig. The ear for the screw may be placed in any direction in regard to the gib, as indicated by the dotted lines in the end view of Fig. 54. This tightening device is, in particular, adapted to work of dove-tail shape, as shown in Fig. 55. In this case the wedge is made similar to the common taper gib used for taking up the wear in dove-tail slides. It is sometimes of advantage to relieve the bearing surface opposite the wedge, as shown in dotted lines in Fig. 54, in order to provide two distinct bearing points, which prevents the work from rocking.

If it is required to get a bearing on two points of a surface that is likely to vary in its dimensions, a yoke can be used, designed on the principle of that shown in Fig. 56. In the engraving, *A* is the work to be clamped, and *B* is the yoke which fits into a slot in the center of the strap or clamp *C*. The yoke is held by a pin *D*, around which it can swivel to adjust itself to the work. It is evident that the amount of pressure at the two points *E* and *F* will be equal, or at least near enough for all practical purposes, even though the screws at the ends of the strap may not be equally tightened. In

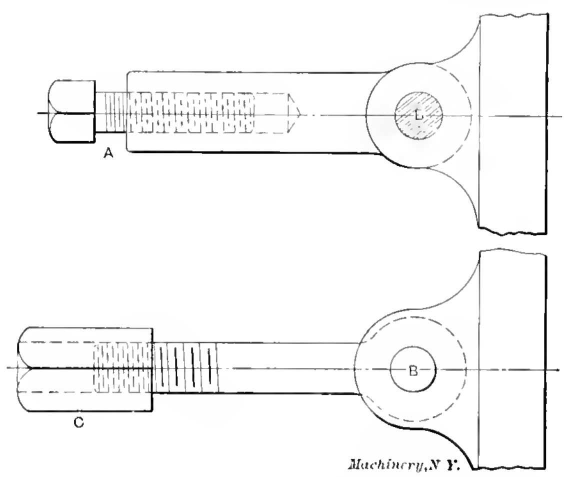


Machinery,N.Y.

Fig. 52. Improved Designs of Clamping Straps.

this device the pin *D* takes the full clamping strain, and should therefore be designed strong enough, and the strap which is weakened by the slot and the hole in the center, should be reinforced, as indicated, at this place. It is preferable to have spiral springs at each end of the strap to prevent the strap from slipping down when the work is taken out. The strap may be made either of cast iron or machine steel, the yoke being made out of machine steel.

Eccentric clamps and shafts for binding purposes are often used. In Figs. 57 and 58 are shown two applications of the principle of the eccentric shaft. In Fig. 57 the eccentric shaft *A* has a bearing at both ends, and the eye-bolt *B* is connected to it at the center and is forced down when the eccentric shaft is turned. This causes the two end points of the clamp *C* to bear on the work. This clamping arrangement has a very rapid action and gives good satisfaction. The throw of the eccentric shaft may vary from 1/16 inch to about 1/4 inch, depending upon the diameter of the shaft and the accuracy of the work. In cases where it is required that the clamp should bear in the center, an arrangement like the one shown in Fig. 58 may be used. Here the eccentric shaft *A*



Machinery,N.Y.

Fig. 53. Clamping Devices working on the Jack-screw Principle.

has a bearing in the center and eye-bolts *B* are connected to it at the ends. As the eccentricity is the same at both ends, the eye-bolts or connecting-rods will be pulled down evenly when the lever *C* is turned, and the strap *D* will get an even bearing on the work in the center. If the force of the clamping stress is required to be distributed equally at different points on the work, a yoke like that shown in Fig. 56 may be used in combination with the eccentric clamping device in Fig. 58.

*Address: 833 W. Sixth St., Plainfield, N. J.

When it is essential that the strap *D* should also be used for locating purposes, necessary guides will be provided for the strap, so as to hold it in the required position. These guiding arrangements may consist of rigid rods, ground and fitted into drilled and reamed holes in the strap, or square bars held firmly in the jig, and fitted into square slots at the ends of the strap. The bars can also be round, and the slots at the ends of the strap half round, the principle in all cases remaining the same, excepting, of course, that the more rigid the guiding arrangement is, the more may the accuracy of the locating be depended upon.

The ordinary eccentric lever works on the same principle as the eccentric rods just described. There is a great variety of eccentric clamping devices, but they are not as commonly used in present-day jig design as they used to be a few years ago. The eccentric clamping levers, however, provide good and rapid clamping action. In Fig. 59 is shown one especially intended for clamping finished work. It is not advisable to use this kind of lever on rough castings for the reason that these latter may vary so much that the cam or eccentric will have to have too great a throw for rigid clamping to suit the rough castings. The extreme throw of the eccentric lever

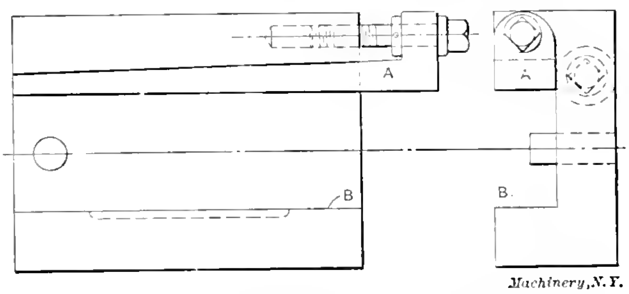


Fig. 54. Wedge or Taper Gib used for Clamping.

should in general not exceed 1/6 of the length of the radius of the eccentric arc if the rise takes place during one-quarter of a complete turn of the lever. This would give an extreme throw of say 1/4 inch for a lever having 1½ inch radius of the cam or eccentric. Even to one unfamiliar with this kind of work it is plain that as the eccentric cam swivels about the center *A*, the lever being connected to the jig with a stud or pin, the face *B* of the cam, which is struck with the radius *R* from the center *C*, recedes or approaches the side of the work, thereby releasing it from, or clamping it against, the bottom or wall of the jig. The lever for the eccentric may be placed in any direction, as indicated by the full and dotted lines in Fig. 59. In Fig. 60 is shown another eccentric lever, which is used frequently on small work for holding down straps or leaves, or for pulling together two sliding pieces, or one sliding and one stationary part, which in their turn hold the work. These sliding pieces may be V-blocks or some kind

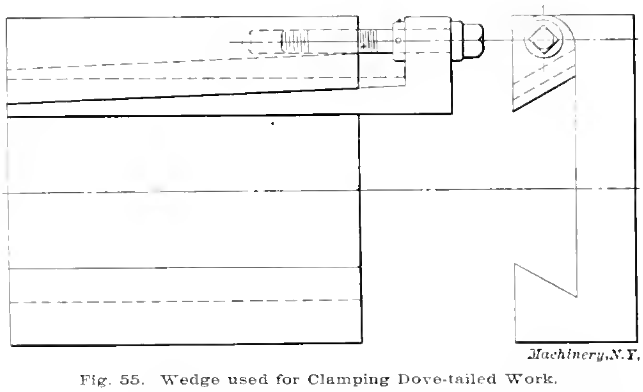

Fig. 55. Wedge used for Clamping Dove-tailed Work.

of jaws. The cam lever is attached to the jig body, the leaf, or the jaw, by a pin through hole *A*. The hook *B* engages the stud or pin *C* which is fastened in the opposite jaw or part, which is to be clamped to the part into which the pin through hole *A* is fastened.

The variety of design of eccentric cam levers is so great that it is impossible to show more than the principles, but the examples shown embody the underlying action of all the different designs.

The Design of Jigs.

To give any rational rules or methods for the design of drill jigs would be almost impossible, as almost every jig has to be designed in a somewhat different way from every other jig, to suit and conform with the requirements of the work. All that can be done is to lay down the principles. The main principles for jigs as well as fixtures were treated at length

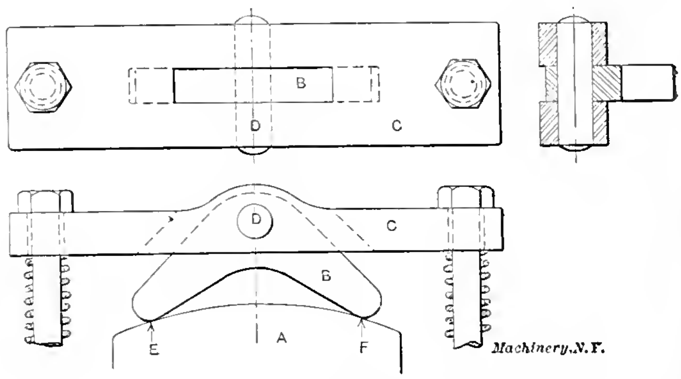

Fig. 56. Equalizing Clamp.

in the first installment (April issue) of these articles. It is proposed in the following to dwell more in detail on the carrying out of the actual work of designing jigs.

Before making any attempt to put the lay-out of the jig on paper, the designer should carefully consider what the jig will be required to do, the limits of accuracy, etc., and to form, in his imagination, a certain idea of the kind of a jig that would be suitable for the purpose. In doing so, if a model or sample of the work to be made is at hand, it will be found to be a great help to study the actual model. If the drawing, as is most often the case, is the only thing that is at hand, then the outline of the work should be drawn in red

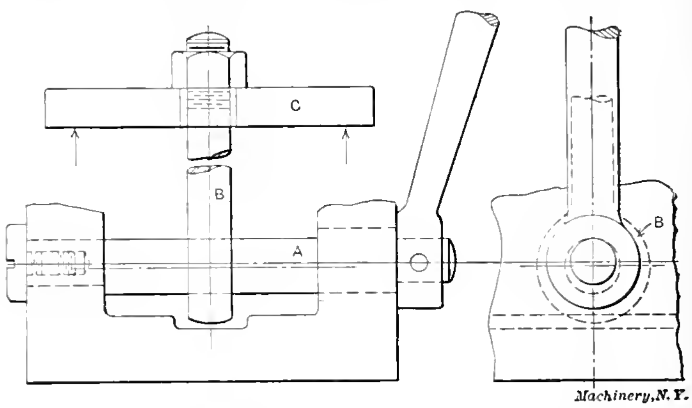

Fig. 57. Eccentric Clamping Bolt.

ink on the drawing paper, on which the jig is subsequently to be laid out, and the jig built up, so to speak, around this outline. The design of the jig will be greatly simplified by doing this, as the relation between the work and the jig will always be plainly before the eyes of the designer, and it will be more easily decided where the locating points and clamping arrangements may be properly placed. When drawing and projecting the different views of the jig on the paper, the red outline of the work will not in any way interfere, and when the jig is made from the drawing, the red lines are simply ignored, excepting to the extent in which the outline of the pieces may help the toolmaker to understand the drawing and the purpose of certain locating points and clamping devices.

If it is possible, the jig should be drawn full size, as it is a great deal easier to get the correct proportions, when so doing. Of course, in many cases, it will be impossible to make the jigs full size. In such cases the only thing to do is to make them to the largest possible regular scale. Every jig draftsman should be supplied with a set of blue-prints containing dimensions of standard screws, bolts, nuts, thumb-screws, washers, wing nuts, sliding points, drills, counterbores, reamers, bushings, etc.; in short, with blue-prints giving dimensions of all parts that are used in the construction of jigs, and which are, or can be, standardized. It should be

required of every designer and draftsman that he use these standards to the largest possible extent, so as to bring down the cost of jigs to as low a figure as possible.

If it does not meet with objections from higher authorities, which it ought not to, it is highly advantageous for the obtaining of best results, that, before starting on the drawing, the draftsman who is to lay out the jig should converse with the foreman who is actually going to use the jig. Oftentimes this man will be able to supply the best idea for the making of the jig or tool. Not only is advantage taken of the combined experience of the draftsman and the foreman, but it is also a precaution of great importance for making all parties feel satisfied.

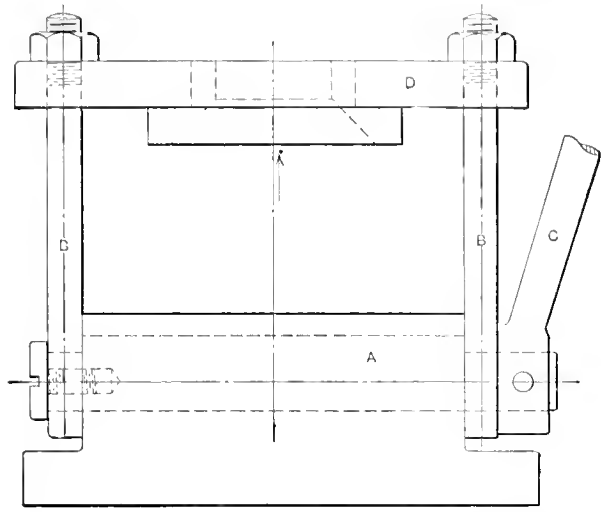

Fig. 58. Another Example of Eccentric Clamping Bolt.

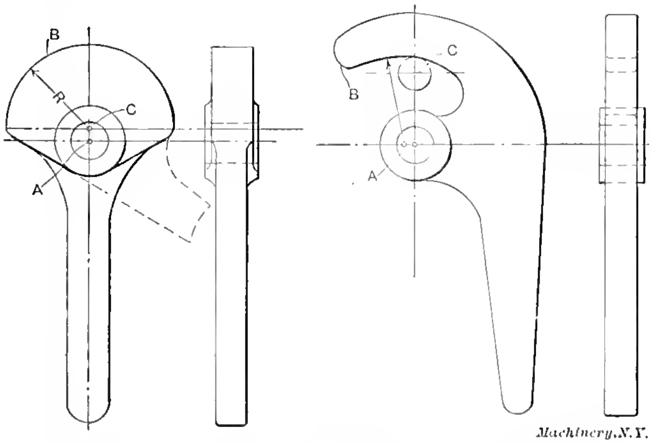
As a jig drawing, in most cases, is only used once, or at most only a very few times, it is not considered worth while to make a tracing or blue-print from the drawing, but, as a rule, the pencil drawing itself may be used to advantage. If, however, it is given out in the shop directly as it comes from the drawing-board, it is likely to get soiled, and to be used in such a manner that, after a while, it would be impossible to make out the meaning of the views shown on it. For this reason, in the first place, jig drawings should be made on some heavy paper, preferably of brown color, which is not as quickly soiled as white paper. In order to prevent the drawing being torn, it should be mounted on strawboard, and held down along the edges by thin wooden strips, nailed to the board. It is also desirable to cover the drawings with a thin coat of shellac before they are sent out in the shop. When this is done, the dirt and black spots which will always be found on the drawing when it stays in the shop, even if but for a few hours, may be washed off directly; and the shellac itself may be washed off by wood alcohol, when the drawing is returned to the drafting-room. The drawing, after having been cleaned, is then detached from the strawboard, which latter may be used over and over again. The drawing is, of course, filed away, according to the drafting-room system.



Figs. 59 and 60. Cams or Eccentrics used for Clamping.

The most advantageous sizes for jig drawings for medium to heavy work are as follows:

Full size sheet, 40 × 27½ inches.
Half size sheet, 27½ × 20 inches.
Quarter size sheet, 20 × 13¾ inches.
Eighth size sheet, 13¾ × 10 inches.

Of course, these sizes will vary in various shops, and in many cases, particularly when the tool designing department and the regular drafting-room are combined as one drafting department, the jig drawings should be of the same regular sizes as the ordinary machine drawings.

It is common in a great many shops to make no detailed drawings of jigs, but simply to draw a sufficient number of different views and sections, and to dimension the different parts directly on the assembly drawing. In cases where the jig drawings are extremely complicated, and where they are covered with a large number of dimensions which make it hard to read the drawing and to see the outlines of the jig body itself, it has proved a great help to trace the outlines of the jig body, and of such portions as are made of cast iron, on tracing paper, omitting all loose parts, and simply putting on the necessary dimensions for making the patterns. A blue-print is then made from this paper tracing, and this is sent to the pattern-maker, who will find the drawing less of a puzzle, and who will need to spend far less time on making out how the pattern actually looks. A less skilled, and consequently a cheaper, man may also be used for making the pattern. It is, however, greatly to be doubted whether it is good policy not to detail jig drawings completely, the same as other machine details.

When jigs are made up for pieces of work which require a great many operations to be carried out with the same jig, and where a great number of different bushings, different sizes of drills, reamers, counterbores, etc., are used, a special operation sheet should be provided which should be delivered to the man using the jig, together with the jig itself. This enables him to use the jig to best advantage. On this sheet should be marked the order in which the various operations are to be performed, and the tools and bushings which are to be used. Of course, the bushings in such a case should be numbered or marked in some way so as to facilitate the selection of the correct bushing for the particular tool with which it is used. If this system is put in force and used for simpler classes of jigs also, the operator will need few or no instructions from his foreman, outside of this operation sheet.

* * *

A summary of the available water powers of the world has been published by the *Revue Electrique*. It is stated that in the United States there is 1,500,000 horse-power possible of utilization. Among the European countries, France has an estimated available water power of 4,500,000 H. P., of which 800,000 H. P. is utilized. The region of the Alps extending into France brings the figure as high as mentioned. Italy, it is stated, has an equal amount of water power available, but only 300,000 H. P. is utilized as yet. In that country, falls of 10,000 H. P. are abundant. The estimate for the available water power in Switzerland is incomplete, but 300,000 H. P. is in use. The available power in Germany is 700,000 H. P., 100,000 H. P. being utilized. In Norway the estimated power is 900,000 H. P., and in Sweden 760,000, a large part of which is already developed in both countries. As regards available water power, Russia heads the list, it being estimated that 11,000,000 H. P. could be taken out of the Russian rivers, of which only 85,000 H. P. has been developed. Great Britain and Spain come last in the estimate, only 70,000 H. P. being utilized in either country. It is stated that Japan has available water power of 1,000,000 H. P., of which only 7 per cent has as yet been utilized. The estimate for the water power in the United States is without question considerably below the actual figures. It has been stated, on good authority, that there is already developed, or under development, in the United States, 4,500,000 H. P. from water sources, and the government's statistical figures indicate that the available water power in the country is nearly 10,000,000 H. P. In New England alone there is 1,000,000 H. P. developed, with probably another half million available.

CUTTING LONG LEAD-SCREWS ON THE THREAD MILLING MACHINE.

There is, perhaps, no work on which the convenience and economy of using the thread milling machine has been better exhibited than when cutting long lead-screws, which, if the thread should have been produced in an ordinary lathe, of about the same capacity as the thread milling machine, would have caused a great deal of trouble in order to obtain proper supports while cutting the thread. The accompanying half-tones, Figs. 1 and 2, show two long lead-screws being cut in thread milling machines. These lead-screws are used on the gun-barrel drilling machines built by the Pratt & Whitney Co., Hartford, Conn., and the photographs were taken when the lead-screws were being cut in thread milling machines in the company's shop.

The lead-screw shown being cut in Fig. 1 is shown in detail in the engraving, Fig. 3. It was not possible to include in the photograph the full length of the screw, as it extended a considerable distance from the left side of the machine. The length of the threaded portion of this lead-screw is 34 feet 8 inches, and the diameter of the thread is $2\frac{1}{2}$ inches, there being 3 Acme threads per inch. The thread

The lead-screw shown being cut in Fig. 1 is shown in detail company's 6 x 80-inch thread milling machines, and, on account of the length of the screw, it was required to move or shift the carriage back five times to complete the screw, so that the carriage traversed the full length of the machine six times in all before having completed the screw. The cutter, of course, milled the thread to its full depth and shape in one cut, no finishing cut or second operation whatever being required. The surface speed of the cutter, while cutting, was about 96 feet per minute, and the surface feed of the work 3.9 inches per minute, 42 hours being required to complete the cutting of the whole lead-screw.

The lead-screw shown in detail in Fig. 4 was cut on one of the company's thread milling machines, as shown in Fig. 2. This machine is of a far heavier construction than the one shown in Fig. 1, and is known as a 12 × 48-inch thread milling machine. As this machine does not permit as long travel of the carriage, on account of the bed being so much shorter, it was necessary to shift the carriage eight times, or to traverse the length of the bed nine times in all, in order to cut the full length of the thread, which, in this case, was 34 feet, $8\frac{7}{8}$ inches. This screw had but one Acme thread per inch, right-hand, single, the diameter of the lead-screw being $3\frac{1}{2}$ inches. The surface feed was $2\frac{1}{2}$ inches per minute, and the surface speed of the cutter was about 66 feet per minute.

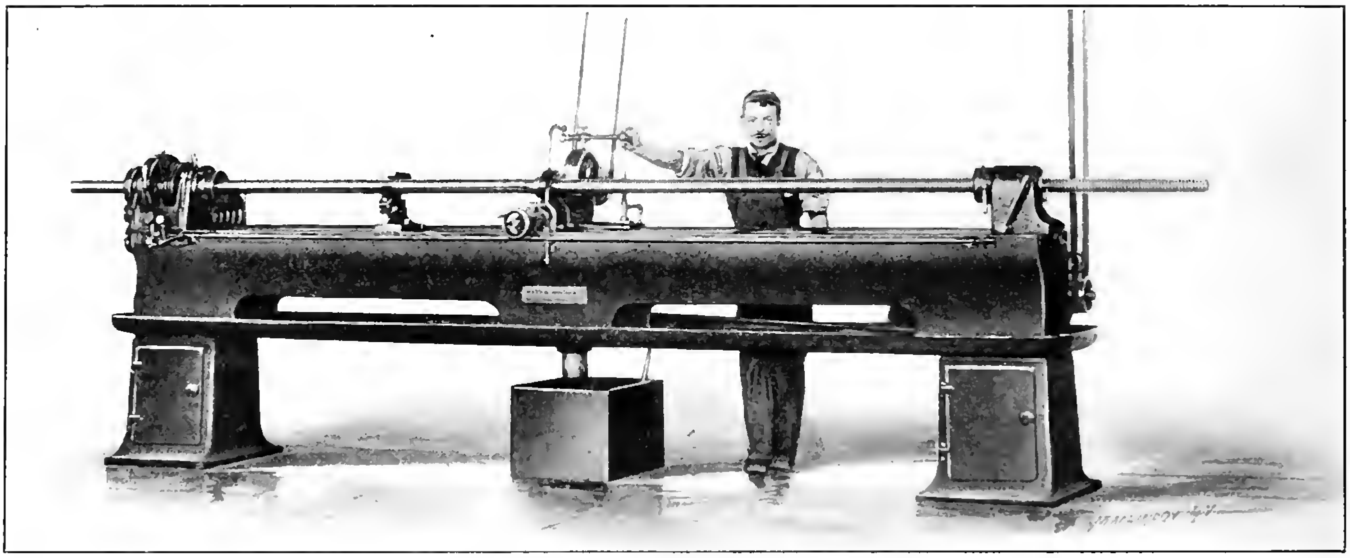


Fig. 1. Milling Lead-screw shown in Detail in Fig. 3.

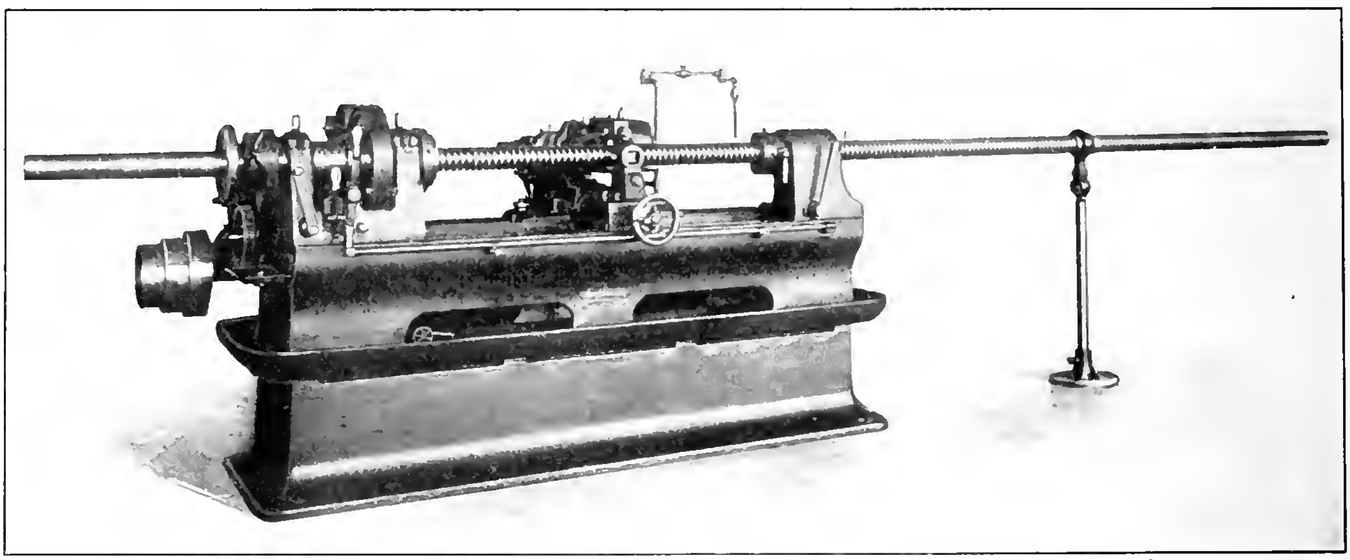

Fig. 2. Lead-screw shown in Detail in Fig. 4, cut in a Pratt & Whitney Thread Milling Machine.

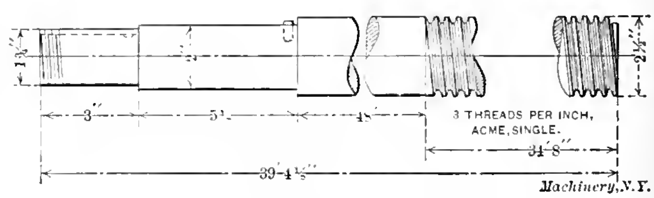

Fig. 3. Detail of Lead-screw for Pratt & Whitney No. 3 Gun-barrel Drilling Machine.

With the feed stated the actual cutting time was about $30\frac{1}{2}$ hours, but it would have been possible to cut with a heavier feed, at least 3 inches, in which case the time required would only have been $25\frac{1}{2}$ hours. The thread of this lead-screw, the same as the thread of the lead-screw previously referred to, was finished with a single cut, and it was considered that

the thread was fully as smooth and more perfect to shape than would have been the case if the thread had been cut with the greatest of care in an ordinary lathe.

We have no records on hand which intimate how long it would take to finish a screw on an ordinary lathe, with an equal degree of accuracy, but such comparative figures would be highly interesting. The thread miller requires less attendance, and outside of the operator's time gained, the convenience in doing the work, passing the bar right through

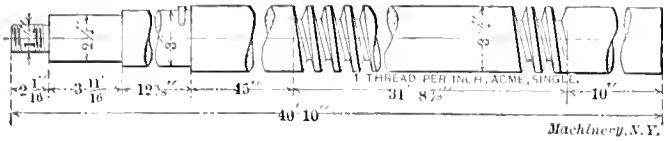

Fig. 4. Detail of Lead-screw for Pratt & Whitney No. 4 Gun-barrel Drilling Machine.

the spindle and foot-stock, and simply supplying standards for the support of the overhanging ends of the screw, is apparent to anybody who has seen or had experience with the difficulties attending the cutting of long lead-screws in ordinary lathes, where, for instance, sometimes portion after portion of the length of the screw has to be welded onto the previously completed part, in order to enable the length of the lathe bed to accommodate the excessive length of the lead-screw being cut.

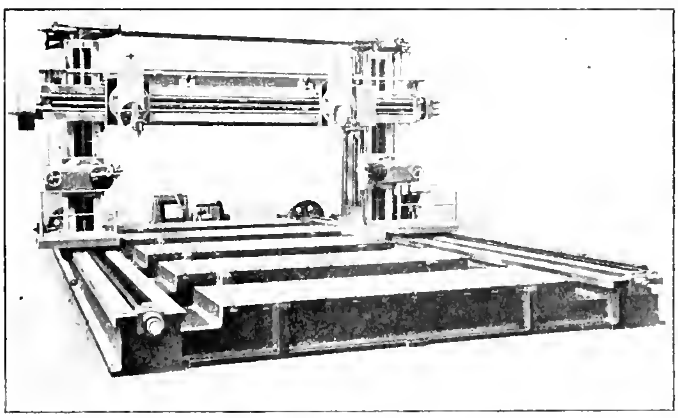
A LARGE PLANER OF ENGLISH DESIGN.

The accompanying half-tone engraving illustrates an exceptionally large planer of a type built by Messrs. Joshua Buckton & Co., Ltd., of Leeds, England, which was described and illustrated in a recent issue of *Engineering*. This planer is intended, in particular, for planing the casings for large steam turbines, and for other work of a very heavy nature



A Large English Planer which takes Work 20 Feet Wide, 10 Feet High, and 30 Feet Long.

occurring in steam engine design. The particular feature of the machine, it will be noticed from the illustration, is that the standards or housings travel, while the bed proper is stationary. The machine is of exceptionally large dimensions, it having a capacity for planing work 20 feet wide, 10 feet high, and 30 feet long. The table of the machine is built in sections, separated by large gaps. On each side of the table are longitudinal flat ways on which the standards travel. These latter are driven by two screws of steep pitch, one for each housing. The screw in turn receives motion through a bevel gear connection with a cross-shaft at the back end of the bed. The sliding ways are furnished with roller lubricators, and the thrust of the screws is taken by ball bearings. In the machine illustrated the cross-slide is adjustable vertically, the same as in an ordinary type of planer, but another type is made by the same firm with fixed cross-slide, the work being placed in a pit in the center of the machine. The tool heads are fitted with double-cutting tool-holders, carrying two self-relieving tools for cutting on both the forward and the backward strokes of the machine. One of the heads on the cross-slide can be arranged for traverse planing, the tool traversing to and fro on the slide for this purpose, and cutting in both directions. The drive for this motion is obtained from a separate electric motor, mounted on the back of the cross-slide. When work is being planed in this manner, the feed is given to the cutting tools by a slow automatic travel of the standards on the ways along the bed. A headstock for drilling and milling is also provided which fits on the cross-slide. It is of interest to compare this planer with the one illustrated in the January, 1908, issue of MACHINERY, built by the Bement-Miles Works at Philadelphia. In this planer the distance between the uprights was 11 feet 1 inches, the maximum distance from the table to the bottom of the cross rail, 12 feet 2 inches, and the maximum stroke of the table 30 feet. In this planer the table moved while the housings were stationary, the same as in ordinary planers.

* * *

LARGE HORIZONTAL BORING AND TURNING MILL.

The accompanying two half-tone engravings illustrate what is undoubtedly the largest boring mill ever built. This machine was completed some time ago in the works of the firm

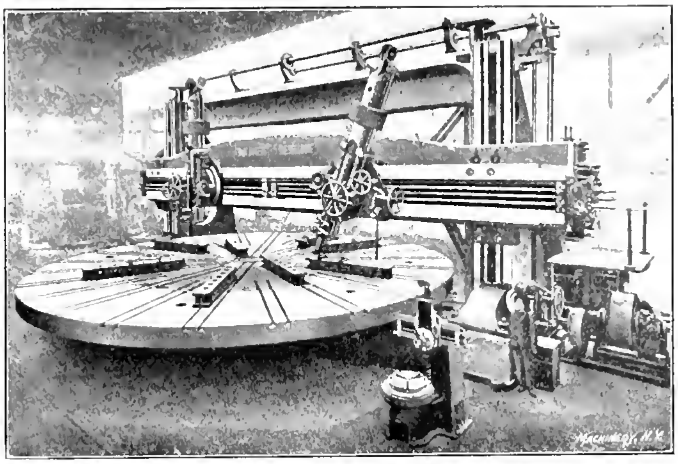


Fig. 1. A Mammoth Boring and Turning Mill with Table 36 Feet in Diameter.

of Ernst Schiess, A. G., Düsseldorf, Germany, and the illustrations are reproduced from the June 20 issue of the *Zeitschrift des Vereines deutscher Ingenieure*. The machine will take in work 39 feet 4 inches in diameter, and 11 feet 2 inches high, the table of the machine itself being 36 feet in diameter. The machine is motor-driven, and the speed of the table varies between the limits of 0.085 to 4 R. P. M. The control of the electrical motor, as well as the feed and speed changes, are all effected from devices placed on the traveling tool heads, in order to eliminate the necessity of the operator descending from the table whenever changes in this respect are to be made, or the machine started or stopped. The firm mentioned has built, in all, nine of these machines. The propor-

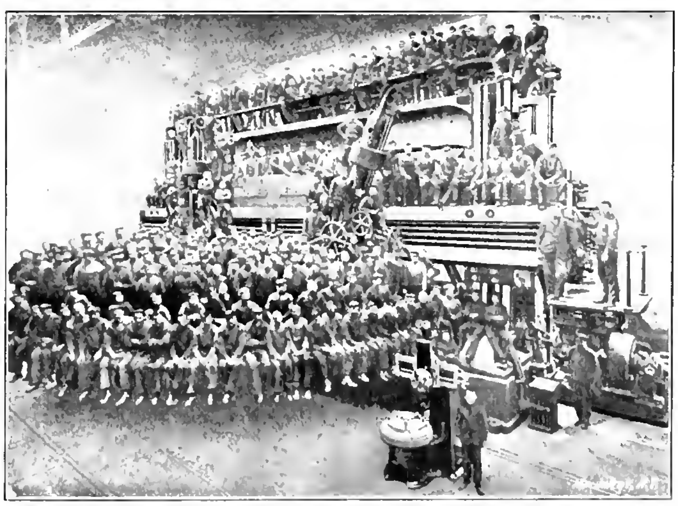

Fig. 2. A Group of 227 Men on the Machine.

tions of these machines are perhaps best exhibited in the half-tone, Fig. 2, this photograph being taken with 227 men sitting or standing on the machine. The total weight of the machine is 330 tons. In the foreground the smallest size of boring and turning mill built by the firm is shown for comparison.

HELPS AND DON'TS FOR GRINDING.*

Selection of Wheel.

Don't believe that all materials can be ground equally well with one and the same wheel.

Get the proper wheel for the work.

You would not expect to turn all kinds of lathe work with one tool having only one form of cutting edge. The grinding wheel is a tool for cutting.

Different shapes of work, different kinds of metal, require different cutting edges as well when grinding, as when turning. Different grades and grains of wheels are required for different kinds of work.

Grinding wheels are numbered from coarse to fine, and graded from soft to hard. The grade is denoted by the letters of the alphabet from E to Z.

Don't decide on the wheel without knowing the work.

Spindle speed and character of the material, shape of work to be ground, and surface of wheel in contact are prime factors.

In cylindrical grinding, speed of work, diameter of work and depth of cut must all be reckoned with in the selection of the right combination of grain and grade.

The condition of the machine affects the efficiency of the wheel. Heavy machines with large wheel spindles and massive wheel support call for a wheel different than lighter machines with smaller spindles.

Don't order a certain grade wheel merely because that grade is used on similar work in another plant.

Don't use a hard wheel to economize—it is production you are after.

A hard wheel is more likely to change the temperature of the work or to become glazed than a soft one; furthermore, it requires more power to do the same amount of work.

It is a common error to assume that a wheel for grinding steel and cast iron, chilled iron and hardened steel, must be as fine as the surface desired. A coarse wheel will produce a fine finish if the proper relations between grade, depth of cut, speed of work, speed of wheel, etc., are observed.

When grinding brass and the softer bronzes, the wheel must be as fine as the finish required. Bronzes with "manganese" or "phosphor" permit the use of coarser wheels.

Don't get a wheel made for soft steel for use on hard steel.

For a fine finish on hard stock, a coarse wheel may be necessary, and the harder the stock the coarser the wheel.

When ordering wheels, don't forget the diameter, width, style of face, arbor hole, description of work, speed of spindle, and the number and letter denoting the combination of grain and grade, if known.

The width of the wheel should be in proportion to the amount of the material to be removed with each revolution of the work.

If you reduce the width of the wheel, you must use a finer feed, and consequently do less work.

Mounting.

Never mount wheels without flanges.

Flanges should be, at least, one-third the diameter of the wheel; one-half is recommended. Flanges should be concave—never straight or convex.

Use fiber or rubber washers a trifle larger than the diameter of the flanges, or flanges with soft metal facings.

Hooded machines are desirable when practicable.

Truing.

Don't start work on a new wheel until you are sure it runs true.

Always have a wheel dresser handy for truing wheels for off-hand grinding.

Never use a dresser on wheels that grind circular work on centers.

For truing wheels used on plain cylindrical and universal grinding machines, cutter and reamer grinders, etc., the diamond is recommended. To obtain the best results it is absolutely necessary.

Never attempt to true a wheel for circular grinding unless the diamond is held in a rigid tool-post on the table of the machine. You cannot do good work with such a wheel when it is trued "by hand."

To get a truly ground surface, you must keep the face of the wheel true.

The quality of surface finish is dependent on the conditions of the wheel face and depth of cut.

Speed.

Don't start grinding until you know the speed is right—not "near enough," but right.

Even a slight variation in speed may be the cause of success or failure of any wheel.

Failure is sometimes turned into success by merely changing the speed of either the wheel or work.

Speed up the spindle as the diameter of the wheel is decreased. Approximately the same peripheral rate should be maintained as the wheel wears down.

Complaint is sometimes made that wheels appear to be softer toward the center. Usually this is because the same surface rate of speed is not maintained as the wheel is reduced in diameter. This causes the wheel to wear away faster and appear softer. It is also true that while the grade of the wheel may be uniform throughout, yet the smaller line of contact due to the smaller diameter will cause the wheel to appear softer.

Increasing the speed of a grinding wheel gives the effect of a harder wheel; decreasing the speed gives the effect of a softer wheel.

For surface grinding, it is customary to run wheels at a somewhat slower rate of speed than for general grinding. A speed of 4,000 to 5,000 surface feet is usually employed.

Wheels are run in actual practice from 4,000 to 6,000 feet per minute.

General Suggestions.

Transferring a wheel worn down to a small diameter, from a large machine to a small one, is good practice.

Keep the tickets or tags which are sent on the wheels in a record book, so that if a wheel is not satisfactory, reference can be made to order number when making complaint. It is equally valuable as a reference when ordering duplicate wheels.

Don't use the wrong wheel on a job because it will require a few minutes time to change wheels. A stop watch will prove to you that changing wheels is cheaper.

There is seldom a case where one and the same wheel can be used on all work without a greater loss of time than the change of wheel would involve. Many times, the time saved in grinding a single piece more than pays for changing the wheel.

Considerable difference in diameters of work will affect the cutting quality of a wheel on any given material.

A successful wheel on the small diameters may work much slower on the larger diameters.

The wheel most suitable for work of very large diameter may wear away too fast on work of smaller diameter.

A suitable wheel for small diameters may cause chatter on pieces of large diameters.

Don't grind circular work dry.

A good wheel will grind in water, soda water or oil.

Water keeps the wheel working cool, and increases grinding production.

Soda water keeps the work and the machine from rusting.

Oil in soda water increases the wheel's effectiveness.

The particles from a grinding wheel do not adhere to steel. Don't let any one convince you to the contrary.

Grinding is profitable for removing stock as well as for finishing.

Keep the face of the wheel true and parallel with axis of spindle.

Vibration makes grinding wheels wear.

Keep all rests adjusted close to the wheel, otherwise work is liable to be caught and injury result.

Keep boxes well oiled and adjusted.

When practicable, indicate on each machine the revolution of spindle and size of wheel to be run upon it.

Don't disregard the setting up instructions that go with the grinding machine.

* Extracts from booklet issued by the Norton Co., Worcester, Mass.

HOW TO HANDLE A FILE.*

W. A. KNIGHT.†

Probably no branch of the machinists' trade requires more skill than the proper handling of a file. To make a file cut smooth when desired, and to make it cut where you want it to, and at no other place, is an art worth cultivating by all the younger men of the trade. It is possible to train an apprentice to operate a lathe, planer, or milling machine, and do good work on it, in much less time than it takes to teach him to do good filing. Probably this is the reason that most of the filing and fitting is done in the shops by the older class of mechanics. This article is not directed to them, for doubtless there are many such who can handle a file much better than the writer, but it is assumed that the points herein mentioned may prove of value to some of the younger men of the trade.

Filing a Flat Surface.

In filing a flat surface the choice of file depends on the degree of flatness and finish required. For a really flat surface, the writer would use a square file with which to do the first

Fig. 1. Cross-filed Flat Surface.

filing, and a pillar for the finishing. If one has to get along with one kind of a file for all kinds of filing, the writer would prefer the square safe edge file to all others. The reason for this is that the square file has more "belly" to it, and possesses greater stiffness in the direction of applied pressure in proportion to its bearing surface on the work than any other, and, being narrow, requires less pressure to make it "bite" into the work.

In order to file straight it is necessary that the file "hold its cut," any slipping or sliding over the surface being fatal to straight filing. Whatever kind of a file is used, the downward pressure should be sufficient to cause the file to bite and hold its cut, and with a wide flat file such as a hand file, or one that has become dulled by use, this pressure becomes so great as to make straight filing extremely difficult. The square file requires less pressure, is under better control, and responds to the "touch" and "feel" of the operator better than any other. The pillar file is next to the square as regards the foregoing points, and for some cases might be preferred. The writer would here offer the suggestion to file makers that for flat surface filing, the hand and pillar files should have more "belly," being thicker in the center than as at present made, and that the curvature be made uniform from point to heel. With such a file we could do more and better work, and do it easier than with the present styles. Another point, but on which there may be some doubt, is that in a double-cut file the cuts across both ways should be of equal depth, so that the diamond shaped squares left by the chisel marks stand out sharp and distinct. The writer can give no definite reason for this, except that he instinctively prefers a file like that to one with teeth having somewhat the appearance of a single-cut file.

To file a surface flat it is necessary to "cross file" it, that is, file it in different directions until the tool marks are eliminated and the desired degree of flatness obtained. This cross filing is most important, and is a prime factor in the production of flat surfaces. By frequently changing the direction of file marks, the operator can see at all times just where the file is cutting. If it is desired to lower any part of the surface after testing with the square, straight-edge, or mating piece, the file should be made to cut across the marks left by the previous filing. The cross marks then serve as an indication of the amount being taken off. After cross filing, the surface will have the appearance shown in Fig. 1.

When using a square or pillar file for the cross filing, it should be given a slight side motion while making the cutting stroke. It should be lifted *clear* of the surface on the back stroke, care being taken not to have it come up with a sweep and down with a sweep, but the path should be like that indicated by Fig. 3. If the surface is to be finished, then go over it lightly in one direction just taking out the cross marks. For this purpose a new file is best, second cut, smooth or dead smooth, according to the finish desired, but previous to using the file, it should be rubbed down lightly with a flat Arkansas oil stone. A new file often has a few teeth projecting above the general surface, especially at the corners, and this light stoning takes them off so that the file is more likely to cut without scratching. It might be mentioned that the last cross filing should be done with as fine a toothed file as that used for finishing, so as not to have deep scratches to take out in the final filing. For this finishing, "straightaway" filing is to be preferred to draw filing, because of being quicker and leaving the corners in better shape than the draw filing; but, of course, there are many surfaces for which draw filing must be resorted to. If the surface has been properly filed, a very few strokes with emery cloth will "lay the grain," giving it a uniform appearance, and with corners sharp like knife edges.

Fig. 2. Example of Cohesion between Two Surfaces, One of which is scraped Flat and the other filed to fit it.

To prevent pinning when filing soft steel, some mechanics use chalk on the file, others use oil. In the writer's opinion, chalk is a poor substitute for oil; the only case where it would possibly have any advantage would be with a dull file. However, one might about as well think of shaving with a case knife as trying to file straight with a dull file. The file is like all other wood or metal cutting tools; if it is to cut where you want it, it must be sharp. Care should be taken, however, not to use too much oil; a good plan when using a fine file is to oil it and then draw it through a piece of waste. This at once cleans the teeth, and leaves sufficient oil on the file. After it has been used a little while, it should be again drawn through the waste to clean out the chips. No file card is necessary.

The half-tone Fig. 2 shows two pieces held together by atmospheric pressure. One piece is a small cast iron surface plate 3 x 2 inches, ribbed as shown, the other is a steel block of the same size, but 5/8 inch thick. The surface plate was scraped to a master plate and the steel block filed to fit it. These surfaces are *dry*, not wiped off with greasy waste, but washed with gasoline and dried with a clean cloth.

Nearly all of the foregoing can be summed up in a single sentence: *For flat surface filing use a sharp file and localize its cutting action.*

---

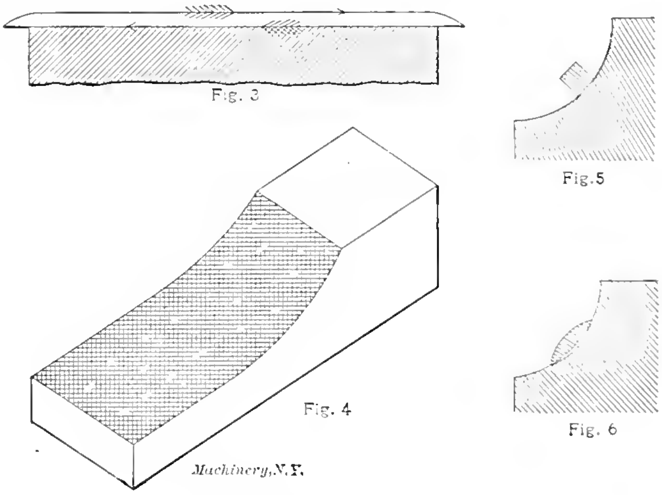
Filing a Concave Surface.

For filing a concave surface such as shown in Fig. 4, an ordinary half round file will do for roughing; outside of that it is a poor tool. A square file, as shown in Fig. 5, is much to be preferred, as it will "lay to the surface," and make it possible to get the surface straight cross-wise with much less effort than with the half round file. The file should be held straight across, and swept round the curve while it is being advanced, sweeping it both ways to insure a smooth curve. To be sure, the file is cutting only on its corners while being used this way, but it is surprising how much work these corners will do, how little pressure is required to make the file cut, and how easy it is to keep it from rocking.



Figs. 3 to 6. Methods and Tools for Filing Flat and Concave Surfaces

The crossing file is, however, a more scientific tool for this kind of work than the square. It should be used with the flattest side next to the surface, or, in other words, the radius of curvature of the file should be *greater* than that of the surface being swept out, as indicated in Fig. 6. The only difference between this file and the square file is that the former has more bearing surface on the work. The essential point is that the file has a bearing along its two edges, and *not in the center*. After the piece has been brought to shape and dimensions by cross filing, it can be finished by draw filing, using a half-round or crossing file with radius of curvature *less* than that of the surface. It will often be found a help, if there is any tendency to get the surface high in the center, to use a scraper made of a three-cornered file to ease

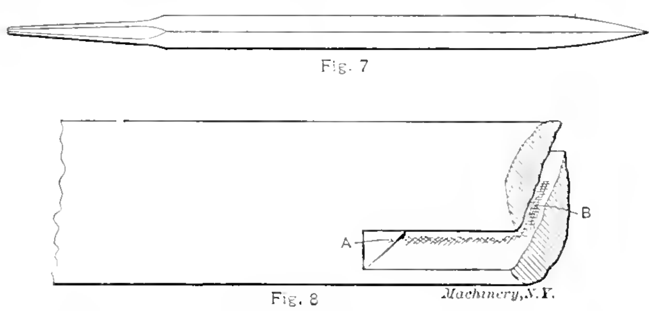


Fig. 7 Three-cornered Scraper made from Old File. Fig. 8. Filing a Rectangular Slot.

off the center a little. The scraper is ground as shown in Fig. 7, and used the same as when scraping out a babbited box. A little oil should be used when scraping steel.

Filing a Convex Surface.

The same general principles as just explained are adhered to in filing a convex surface. If the piece is of such shape that the file can be held at an angle with the axis of the curved surface, that is, not straight across, then the cross filing can be done by making the stroke of the file go partly round the curve as well as across, practically no side motion being given the file. If, however, the nature of the case prevents this kind of a stroke, the file should be held straight across, and then given a little side motion to carry it around the curve, while its motion in the direction of its length is straight across. When the surface is thus properly cross filed, it can be finished by draw filing, if the grain is to run with the curve, or by straightaway filing, if the grain is to be across.

Filing Out a Slot for Boring-bar.

Ordinarily it is a difficult job to file out a square hole or slot through a bar, principally for the reason that one cannot see the place of application of the file. It is a great help after the hole has been roughed out, to take a flat scraper with a good square end, and scrape out the corners and the central portion of the flat surfaces as at *A* and *B*, Fig. 8. The metal can be removed just about as fast with a scraper as with a file (sometimes faster), and by hollowing out the center and corners a little, the file will have a bearing on the outer edges, which renders it easy to prevent rocking. For this work the writer again prefers the square file, and always gives it a side motion whenever possible, cross filing the surface to keep it true. When filing through a hole, use the file without a handle, firstly, because of the danger to the eye should the file handle slip off, and secondly, because it is largely a matter of "touch" to ascertain what the file is doing, and the "touch" is much more sensitive without the handle.

A few good scrapers, say a half-round, triangular, square, flat, and round, of different sizes, with square ends, are very handy tools to have around when doing vise work. They can be used to help the filing along by squaring out corners, easing a place off a little here and there, and will prove time savers in many ways.

* * *

SOLDERING ALUMINUM.

The statement is frequently made that aluminum cannot be soldered, but this is a mistake, and the *Brass World* gives the following information in regard to this question, from an experience extending over the time that has elapsed since aluminum became extensively used. This experience has demonstrated in the first place that pieces of aluminum can be soldered together; but that aluminum cannot be readily and successfully soldered to other metals. The problem of soldering is not alone that of the solder, but account must be taken of the fact that the surface of aluminum is always covered with a film of aluminum oxide. Even when freshly cleaned, this oxide forms immediately, and being of nearly the same color as the metal itself, it is not visible to the eye.

There is no solder which allows aluminum to be soldered with the facility and success that attends the soldering of other metals. The best solder, however, consists of the following ingredients:

Tin	29 ounces
Zinc	11 ounces
Aluminum	1 ounce
5 per cent phosphor-tin	1 ounce

This solder, the Richard solder, was first made in 1892, and has withstood the test of time better than any others. Many of the so-called aluminum solders have disintegrated within a few years after the joint had been made. The solder may be applied to the parts to be soldered with a soldering iron or blowpipe. It is admitted that the operation of soldering aluminum leaves much to be desired, but the results obtained by the solder mentioned are as satisfactory as any that have hitherto been demonstrated.

* * *

The draftsman who can make satisfactory sketches and drawings without erasures is not yet born, but it is quite possible for all to learn to make sketches and use the rubber so little that erasers are not noticeable. In the first place, avoid the use of hard pencils and hard lines in the preliminary work. In the second place, use special sponge rubber, adapted to the cleaning of the surface of the paper, rather than its removal by friction. A coarse gritty rubber tears away the paper and destroys the surface. Fresh bread is good for cleaning off lines and grime from drawings, but ordinarily it is not convenient to use because of being hard to keep in the right condition, that is, neither too fresh nor too stale. For light erasing on water color work, small pieces of white kid leather from old gloves is recommended. These should be used once only and then thrown away.

SYSTEM FOR THE BLACKSMITH SHOP.

JAMES CRAN *

James Cran.†

It is not necessary that a system for the blacksmith shop be of the kind usually known as red tape, which often takes more time to handle than the time it saves; but a simple method of keeping track of work, tools, and material will save time and expense.

To begin with, the blacksmith shop ought to be large enough to provide a place for everything in the shape of tools and equipment, and permit everything to be in its place. Forges should be numbered with figures of size and color which can be easily seen from any part of the shop. The forges should be referred to by their numbers, instead of "so-and-so's" forge. This would insure work being taken to the place it was meant for. With each forge there ought to be a tool bench of size and design which would accommodate one full set of blacksmith's tools such as are used at the anvil. Each tool should be marked with its size and the number of the forge to which it belongs, so that each blacksmith will know the tools which form part of the set he is supposed to use, even if they should in any way get mixed up with others. To insure keeping a full set at each forge, it would be well to give each man a list of the tools belonging to the forge at which he is expected to work, with the understanding that he will be held responsible for all tools not worn out or accidentally broken. Any tool worn out or broken should be reported to the man in charge, so that they could be replaced as soon as possible. Having a full equipment at each forge would be a decided advantage to new men starting in to work, because, as anyone who has ever been employed in a blacksmith shop knows, as soon as a blacksmith leaves the shop in which he has been working, he is no sooner gone than there is a raid upon the tools he used, and it usually takes but a short time to have them exchanged for the poorest tools in the shop, or, perhaps, just removed without any attempt at replacing. When a new man comes along, he is heavily handicapped, having the worst tools in the place to work with, and it sometimes takes weeks before he has a chance of showing what he can do.

It would be well, in arranging forges, to have them so that light work could be done at one end of the shop, medium work in the center, and heavy work at the other end, so that trip- or steam-hammers could be installed in the most convenient places according to their capacities. Every shop ought to have one or more sets of hammer tools, such as spring swages, spring fullers, bolsters, V-blocks, drifts, hacks, and breaking-down tools, which could be classed as general tools and used at any hammer, and kept on a rack where they would be most convenient. Special and larger tools than those forming sets for forges could be given out on the check system, which is common in most manufacturing plants where tools are given out from the tool-room.

To keep track of stock, it would be well to have each kind or grade marked on the end of the bars with different colors. Thus wrought iron may be marked red; Norway iron, blue; machinery steel, white; and so on until all the different grades are marked, care being taken to cut from the end not painted. When a blacksmith starts on a new piece of work he should be furnished with a card for stock to be used, along with his time card. Stock cards could be printed forms to be filled in and signed by the various hands they would pass through. The following outline would cover the most essential points: Date of issue, order number, workman's number, name of pieces to be made, number of pieces to be made, grade of stock to be used, size of stock to be used, amount of stock issued, amount of stock returned, amount of stock used, and date when work is completed. The card should be signed by the man in charge of the stock and the foreman of the shop, before being sent to the stock clerk.

Piece work is preferable to day work when the number of pieces to be made is such that it can be done to advantage, as it insures the best men getting the most compensation, especially if there is no limit set on the amount they may earn. This is a very important point. It is by no means an uncommon occurrence for a piece of work to be done the same way, and remain at the same price for years until some one comes along who uses a little more common sense than the average man. He sees a way of doing it to save time, and will perhaps turn out double the amount of work as compared with what has been done in the same time before. The result is that he earns on piece work 100 per cent more than the other men have earned. He may be paid for the first lot without any comment being made, but by the time the next lot is to be made, more than likely the price is cut in two, and another man gets the job which is nothing but taking an unfair advantage of a good workman, and does not encourage him to bring out his best ideas. If a man can make two pieces in the time it used to take to make one piece, it means a saving of 100 per cent in fuel. If the manufacturer has a profit on one piece, it is doubled if two pieces are made at the cost of one piece, which, if looked at in the proper way, would be an advantage to both employer and employe.

When day work is the rule, it is quite common to have a scale of wages, and all men at the same class of work are paid at the same rate. One man might be capable of doing considerably more work than another, but at the end of the week they both receive the same amount of compensation, which is anything but encouraging for good workmen. To a great extent this is responsible for the blacksmith's present lack of pride in his work, a pride which used to be common amongst the old-time mechanics. On the other hand, some men seem to worry if they think they have done a little more than their pay calls for; but this class seldom has much pay to call for.

It is poor system where each piece of work is given out with instructions how each detail has to be done, as it leaves no chance for improvement or for getting the ideas of the workman. It is a foreman's place to help his men when he finds that they need assistance, and give them instructions when necessary.

To keep track of the different kinds of tools for lathes, planers, etc., which are usually forged and marked in the blacksmith shop, it would be well to have the different brands of steel of which they are made numbered instead of being marked with the initial of the brand. Quite often two or more brands have the same initial, and are liable to get mixed. If marked with numbers, there would practically be no limit to different brands which could be handled without confusion. The blacksmith who forges the tools should have a list of the brands of steel used with the numbers representing them, together with the working instructions which the makers of high-speed steel usually send out to their customers. The system here outlined may be added to or changed to suit circumstances. On the whole, it would take but little time to handle, would increase the efficiency of the blacksmith-shop, would save time and worry, and be an advantage to all concerned.

[In the course of his article, our contributor states that it is poor policy to have each piece of work given out with

* Address: 916 West Third St., Plainfield, N. J

† James Cran was born on a farm in Aberdeenshire, Scotland, in 1868. At the age of eighteen he commenced to serve an apprenticeship in a small country blacksmith shop in Scotland, where he remained for two years after having finished his apprenticeship. After that he was employed by two Scottish makers of iron golf clubs, until he arrived in the United States in 1896, where he was at first employed with A. G. Spalding & Bros. for about four years, the greater part of the time as foreman of the blacksmith shop. He was one of the first, if not the first man, in the United States engaged in making forged iron golf clubs. Later he has been engaged with the Moore Drop Forging Co., Springfield, Mass., the Holt Mfg. Co., Stockton, Cal., and the Electric Vehicle Co., Hartford, Conn. At present he is foreman of the blacksmith shop at the Pond's Works of the Niles-Bement-Pond Co., Plainfield, N. J. Mr. Cran's specialty is machine blacksmithing, but he has had wide experience in almost all branches of forge shop work.

instructions as to how each detail is to be done. This seems to be diametrically opposed to the principle of the Taylor system of shop management. Examining the conditions and the subject our contributor deals with, however, we will find that his statement is not referring to shops having an actual planning department, such as is required by the Taylor system, but the ordinary shop organization is referred to. In such a case it is very seldom that the foreman has the time and the detailed information required to give instructions of such a character as would insure the highest efficiency; and, then, it would be better that no attempt be made to give detailed information unless the workman is likely to fail to carry out the work entrusted to him satisfactorily if not instructed.—EDITOR.]

* * *

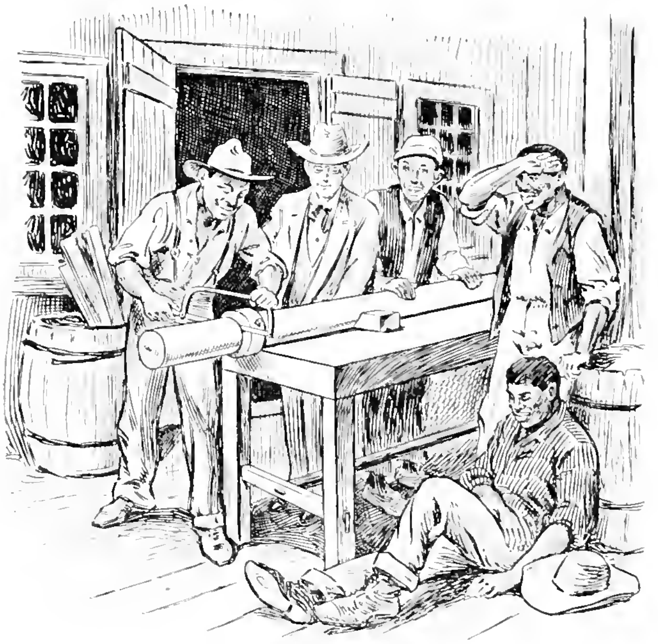
SAM AND HIS HACK-SAW MACHINE.

A. P. PRESS.

When I was working at the old Mason Machine Co. we had a man named Sam Graw, Sunny Sam, we used to call him. He was a rough-and-ready sort of a fellow, a good mechanic, and he could always crawl out of a cavity all right. He could use a micrometer as well as the best of them, but if he didn't have one handy a two-foot rule would do as well.

The firm used to do a lot of cotton work down South, and Sam was the "setter up," that is, he used to go for the firm with the first shipment to lay out the mill, set up the looms, and other machinery, as fast as they came along, and stay until everything was in good order.

Sam has just got back from a trip, and he told me this yarn. He had got most through on the job and one day about five o'clock they came over from the next mill and wanted him to come over at once. They had got into a mess. It seems they



"He worked them all night."

had ordered a 6-inch shaft 8 feet 10 inches long, and it had come 10 feet 8 inches long, and they could not use it without cutting it off. There was no shop within thirty miles that could handle a 6-inch shaft that could help them out anyway. Sam thought a minute and said: "Sure thing." "How long will it take?" "Ten hours or less." "What help do you want?" "Just four good darkies" (all the cheap help were negroes), said Sam, "and it will be ready at 7 o'clock to-morrow morning." "Well, that is easy,' said the superintendent, and he sent in the men.

Sam put a collar on the shaft, and started the first man at work with a 10-inch hack saw he had in his kit. He ran him fifteen minutes, and then took No. 2 and so on through the four; he worked them all night, while he sat on a keg and urged them on. When that 10-inch saw got in the center of the 6-inch shaft it was a pretty short pull, but Sam kept them at it, and at 6.30 A. M. the shaft came off.

The superintendent was a pleased man when he saw it. He gave the darkies all a day off, and Sam an X, and the whole gang was happy.

USING A SLIDE RULE FOR OBTAINING ANY ROOT OF NUMBERS.

HJALMAR FAGERSTROM.

Some years ago the writer found a convenient way for figuring out on a regular slide rule any root of any number, using for this means the scale of centimeters commonly found on the vertical edge of the slide rule. An example will best show how this is done. Suppose that it is required to find $\sqrt[5]{87}$. If there are no logarithmic tables at hand, it may be difficult to find the root, but it can be figured near enough for most cases with the slide rule, even without employing the logarithmic scale of the rule. Before, however, the root can be determined by the means the writer is about to explain, an improvement must be made on the slide rule runner in order to insure fair accuracy. The runner must be marked with an index line in line with what would be the zero line on the centimeter scale, the index line on the glass of runner being over the graduation 1 on the rule when this line is marked, as is plainly indicated in the accompanying

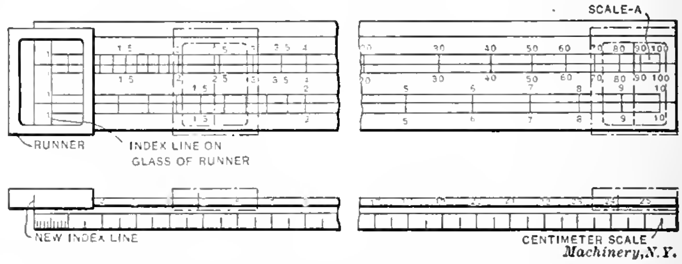


Illustration showing the Method of obtaining the Roots of Numbers.

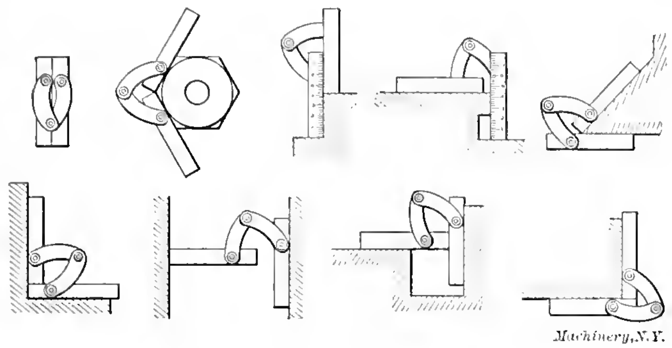
engraving. Now, if it is required to figure out $\sqrt[5]{87}$, move the runner until the index line comes over 87 on the scale A (see engraving). When this is done, turn the rule and read off on the centimeter scale the graduation in centimeters opposite that index line which has just been marked on the side of the runner. The graduation opposite this index line would be 24.25. Now assume that 24.25 is the logarithm for 87, then divide 24.25 by 5, in which case we obtain 4.85. Now move the runner until the index mark on its side points to 4.85 on the centimeter scale. On the scale *A* under the index line of the runner we can now read off the figure 2.44, which is equal to $\sqrt[5]{87}$.

[It may be interesting to point out the reason why the method employed by our correspondent will give the correct root of any number as indicated. The slide rule is so graduated that the various distances along the scales from the first graduation represent the logarithms of the various numbers marked on the slide rule. Consequently, when we move the slide from the figure 1 up to the figure 87, we move a distance corresponding to the logarithm of 87. To find the logarithm for $\sqrt[5]{87}$, we divide this distance in 5 equal parts, and one of these parts represents the logarithm for $\sqrt[5]{87}$. The distance we have moved the slide, when we moved from 1 to 87, is represented by the length of the centimeter scale from the end of the rule up to 24.25. Therefore, we divide this distance in 5 equal parts, which gives us 4.85, which corresponds to the position where the slide will have to stand in order to get the logarithm for $\sqrt[5]{87}$. It is clear that powers of certain numbers can be obtained in a similar way. Some improved slide rules would not permit this method to be used, however, with the ordinary runner, as the distance which the rule projects outside of the graduation 1 on the top of the rule is so long that the runner does not extend over the end of the rule when indicating 1; the graduations on the centimeter scale, however, commence at the end of the rule, and it is not possible to get an index line on the side of the runner, opposite the zero line in the centimeter scale. For numbers over 100 this method becomes rather complex, as it necessitates adding one full length of the scale, or 25 centimeters, to the figure read off on the centimeter scale, for each two additional figures in the original number given. It is rather unprofitable to discuss this complication of operations at length, as it is far easier to use the logarithmic scale of the slide rule, and obtain the actual logarithm required itself.—EDITOR.]

ITEMS OF MECHANICAL INTEREST.

A SIMPLE TOOL FOR MEASURING ANGLES.

The accompanying illustration shows a very simple, but at the same time, a very ingenious tool for measuring angles. Strictly speaking, the tool is not intended for measuring angles, but rather for comparing angles of the same size. The illustration shows so plainly both the construction and the application of the tool, that an explanation would be superfluous. It will be noticed that any angle conceivable can be obtained in an instant, and the tool can be clamped at this angle by means of screws passing through the joints between the straight and curved parts of which the tool consists. Linear measurements can also be taken conveniently,

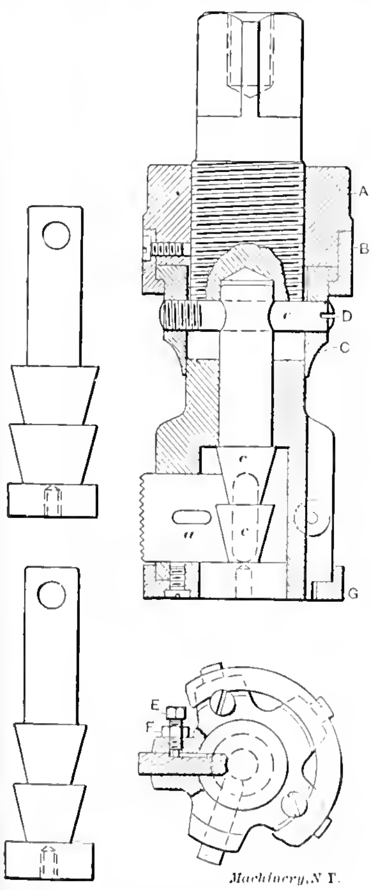


A German Tool for Comparing Angles

one of the straight arms of the tool being graduated. As both of the arms which constitute the actual angle comparator are in the same plane, it is all the easier to make accurate comparisons. This tool is of German design, and is manufactured by Carl Mahr, Esslingen a. N.

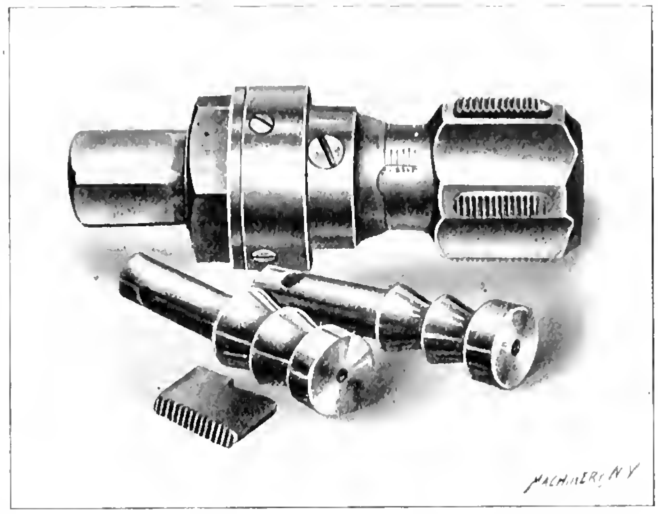
GERMAN DESIGN OF ADJUSTABLE TAP.

An interesting adjustable tap has been brought out by the Präzisions-Werkzeug und Maschinen-Fabrik Richard Weber & Co., Berlin, Germany, and has been illustrated and described by the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*. The general appearance and construction of this trap is illustrated in the accompanying halftone and line engraving. The principle of the tap is plainly shown in the line engraving, Fig. 2. The special feature of this tap is the use made of stems or spindles, having different sized steps, against which the back of the threaded chasers, which enter into slots in the tap, are placed. The taps are provided with five chasers or inserted blades. With simply a single set of chasers and a number of different stems or spindles, various sizes of tapped holes can be taken care of. The tap can also be adjusted within certain limits, using the same spindle, by turning the nut *A* on the shank of the tap, whereby,



Section and Elevation of the Tap.

through the action of the intermediate parts *B*, *C*, and *D*, the stem can be moved so as to force the chasers outward the required distance. The chasers are clamped in place, when adjusted, by screws *E*, provided with a check nut *F*. The ring *G* at the lower end of the tap, which may be provided in special cases, serves the purpose of guiding the tap concentric in the drilled hole. The neck of the tap is provided with graduations, so that the amount of adjustment can be read off directly, when made. While the principle of this tap merits

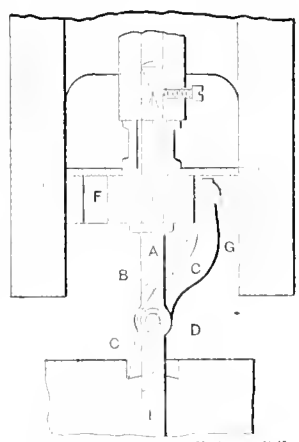


The Adjustable Tap, and Stepped Stems for Varying the Size.

attention and has certain points in its favor, it seems, however, that the design is rather complicated and that the expense of making taps of this type would be so high as to prevent them from coming into general use. No doubt, however, the principles could be employed to advantage in a simplified design, and in such a case it would not be impossible that a tap of this type would have a successful future.

DEVICE FOR DRILLING SQUARE OR IRREGULARLY SHAPED HOLES.

The accompanying illustration shows an interesting little device, described in the May 25, 1908, issue of the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*. The device, as shown, is attached to the spindle of a drilling machine, and consists, in main, of a cam *G*, a lever *C*, and a stiff guide bar *A* through which a slot *B* is cut. In this slot the lever *C* is inserted and held in place by the screw *D*. The lower end of this lever is ground so as present a cutting edge to the work, while the upper end is provided with a ball-shaped projection, which slides in the groove *F*, in cam *G*, this groove being a form corresponding to the outline of the hole to be machined, only on a larger scale. The cam is stationary, while the lever *C* is rotated by the arbor *A*. It is evident that when rotating, the upper end follows the path of the cam-groove *F*, thereby causing the lower end with its cutting edge, to follow a path similar to that of the cam-groove, and thereby producing a hole of the required form and of the size determined by the proportion between the lengths of the upper and lower lever arms. While the cam *G* is stationary as far as rotating motion is concerned, it follows, of course, the motion of the tool in an axial direction. A circular hole is first drilled in the piece where the irregular shaped hole is to be formed, in order to provide for the guiding of the bar *A* which enters into the hole *I* as indicated, and acts as a pilot.



Attachment for Drilling Holes, the Shape of which Depends upon the Shape of the Cam-groove F.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

AUGUST, 1908.

PAID CIRCULATION FOR JULY, 1908, 21,145 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE ECONOMICAL LIMIT OF INCREASED PRODUCTION.

In a letter published in the present number, a correspondent relates an experience intended to indicate that increased output at the expense of the tools employed is not always profitable to a manufacturing concern. The problem of increased output, and its economical relation to the best use of the machines and tools employed, is one of the most important in any successfully conducted shop; and, at the same time, it is one for which it is difficult to lay down absolute rules on account of the many different conditions involved. A case similar to the one referred to by the correspondent occurred in one of our largest manufacturing concerns. A new foreman was engaged to take charge of a certain department, who was known as a "hustler," and no doubt he well deserved the title. After having taken charge of his department, his first efforts were directed to increasing the output, as he received a certain percentage on the savings effected. There was no doubt that he did greatly increase the output, and that the labor cost of the articles manufactured was placed on the company's books in figures considerably smaller than before, but at the same time the "unproductive" labor cost of the shop increased materially. The number of tool-makers employed making tools and repairing machinery and fixtures for this particular department, had to be increased, and as they were paid considerably higher than the cheap help engaged directly in manufacturing, a considerable part of the profits of the increased output were required to pay the increased expense for tool-makers. It may also be surmised that the machines in the department had to be replaced with new ones several years earlier than would have been the case if they had not been worked somewhat beyond the limit of their normal capacity. Although machines are inanimate and not affected by fatigue, as is a human being, every machine seems to have a definite capacity limit, beyond which the expense of upkeep and loss of time because of breakdowns make the swifter pace unprofitable. The most successful shop foreman is not he who can increase the output indefinitely, but the one who understands when this economical limit has been reached, and possesses sense and independence enough to stop at that limit.

MAKERS OF SMALL TOOLS SHOULD KEEP IN CLOSE TOUCH WITH USERS.

We recently received a contribution on the construction of brass threading dies in which numerous points were brought out of practical value to tool makers and users of such dies. In the course of the contribution the writer stated that the company with which he was connected, although a large user of dies, had been unable to buy chasers which answered its requirements, and was forced to make its own chasers in order to get satisfactory results. The conditions affecting the action of brass threading dies are much different from those affecting dies used on steel or iron, which are of fairly uniform texture; for a die that will cut a smooth thread on a piece of machinery steel will, nine times out of ten, answer the requirements of most users of dies on steel or iron. This, however, is not the case with brass work. "Brass" is a term roughly covering a multitude of alloys. Its constituents are almost infinitely varied, and it runs in hardness from material so soft that it can be almost dented with the finger nail, to grades which can scarcely be touched with the best steel tools, so that a set of chasers which cut the soft grades easily and smoothly will not work well on other grades.

It is therefore advisable for manufacturers of thread-cutting tools to study carefully the actual conditions affecting the manufacture of brass goods. It is not sufficient to test their chasers on a piece of brass tubing of the best free-working stock, as that is a grade of metal seldom found in commercial brass work. The makers of standard small tools are apt to think they possess nearly all the knowledge on the construction of thread tools that is required for various shop conditions; but in some cases small-tool makers can perhaps obtain valuable information by keeping more closely in touch with the requirements of their customers. Instead of putting a customer down as a mere "kicker" because he complains that a tap or die does not work well, investigate his complaint and find out what the actual conditions are, so that the product can be improved to meet the requirements of all users.

* * *

DRAFTING AS PRODUCTIVE LABOR.

In the April issue of the engineering edition of MACHINERY, an editorial appeared entitled "Economy of Non-Productive Labor," and a specific case was cited to illustrate the argument advanced. There is one phase of machine shop work where we find that greater economy doubtless could be arrived at by introducing a slightly greater amount of non-productive labor, and eliminating a great deal of time wasted by the productive labor in the shop. The writer's experience in some large drafting-rooms, as well as information obtained in regard to others, indicates that it is quite common practice to make jig drawings in assembled views only, and to put all the dimensions directly on the assembly drawing, making no detail drawings whatever; and the argument advanced in favor of this practice is that experienced pattern-makers and tool-makers, who are, as a rule, the only mechanics who will work on the tools, will find no difficulty in reading the assembly drawing, and that, as the drawing is used but once, it would be a waste of time to have the draftsman detail the parts.

In the case of a very simple jig this is undoubtedly true, but in more complicated ones there can be little doubt that the comparatively small expense required for the draftsman to detail the jig will be many times saved in the shop, for the pattern-maker or tool-maker will not have to spend a number of hours puzzling over the drawing, and even then being liable to make a mistake. This is another case where a slight extra amount of non-productive labor, judiciously expended, will save a large amount of outlay for so-called productive labor.

In two large shops within the writer's own experience, the recent practice in one was to detail all jigs, and in the other to make assembly drawings only, and the difference was surprising in the number of questions asked by the shop regarding the design of the jig in cases when they were detailed and when they were not. When assembly drawings were sent directly into the shop, hardly a jig passed through its regular course through the shop without the foreman of the tool making department, or some of his men, coming into the drafting-room to ask half a dozen questions. When the drawings were detailed, hardly a question was ever asked.

SIMPLICITY IN MACHINE TOOL DESIGN.

W. T. SEARS *

Nearly every type of machine tool seems to have to go through at intervals, a period of extreme complication, in which it becomes loaded down with automatic trips, complicated devices for movements in various directions and numerous other mechanisms, the utility of which, in actual practice, is questionable, although for the time being, and in a great many cases, they undoubtedly make for the salesman good "talking points."

These devices, if inexpensive and not liable to get out of order, are oftentimes useful, and this may be particularly true where a great deal of duplicate work is to be done, especially if these devices are properly fitted for this repetition work. The fitting up of the machine in this manner is perhaps a good thing also, in that it may tend to advance the general usefulness or efficiency of the tool, even if, later, the complicated parts are omitted. It has at least helped to show how far to go, through having gone too far.

Unfortunately, however, in this last case the knowledge has been arrived at, at the expense of the purchaser of the machine, who, in place of getting a machine equipped with many improvements, receives on the contrary, one that is not as good as if the "improvements" had been omitted entirely. They thus represent additional money that has been spent to a disadvantage instead of to advantage, and have actually handicapped the more simple original machine that could have been obtained by a smaller investment. It is safe to say that no machine tool builder knowingly gives a purchaser something for nothing, and the improvements must be paid for. If the price is the same for the new machine with the new features, as for the old machine without them, the probabilities are that the former has been altered and cheapened in some other direction.

There are several points having considerable bearing on this subject which, I believe, have often been overlooked: for instance, when purchasing a machine costing say $2,000, the buyer may be convinced by salesmen that for $200 more he can get a machine which will more than pay for the additional investment. While this, of course, may be true, at the same time attention should be called to what is often the case, which is that it may be a device which would practically never be used, and therefore the $200 is virtually thrown away, in that no reasonable return is obtained for the investment.

Considering this along a little different line again, the purchaser may be convinced that it is a good device or be willing to take a chance, and the machine is ordered with the idea in the purchaser's mind that in case this $200 device did not work satisfactorily, it would simply be a loss of that amount and that would end it.

This is, perhaps, the view most commonly taken and is a very wrong one, for as a matter of fact, the $200 investment may have put a device on the machine which interferes with the regular movements, either by making them unhandy to get at or weakening them through change of design which the new device necessitates.

Another point is that by getting out of order it may lay up the whole machine. It may get out of order through use or abuse, but if this occurs at all frequently, it can readily be seen that the total efficiency has been reduced in place of being increased, unless the saving effected by it while in working order is very great indeed. It often takes considerable time for the testing or proving of the above statements, but that they are correct is proved every day in the history of machine tool design, if in no other way than by the returning of the tool designer to simple forms.

A number of concrete instances can easily be quoted from the writer's experience. For instance, take a planer design with a greatly increased speed on the idle part of the stroke which is obtained by changing from a moderately fast to a very fast speed shortly after the reciprocating part has been reversed. This, by figures, will show a saving for a long stroke, but it was found in actual practice, in the case in mind, that the work requiring a long stroke where this saving could be made, was the exception, and as a result the machine was returned at a moderately fast speed all the time, and the high speed not used at all.

In other words, the money invested for the high return was not only thrown away, but the return actually used was less than on a standard machine with a single return speed. The above is a case where additional money spent proved to be in actual practice, a handicap on what should have been the original investment.

On another machine which the writer has knowledge of, a fast power traverse was called for, for doing a certain class of work. In order to put this fast traverse on, it was absolutely necessary to change the design of the machine quite materially and add considerably to the cost. The machine itself was a simple one. It had gone through years of improving and testing, and its parts were all well proportioned and well designed. The additional parts required for the power traverse were also well designed, but from the nature of the machine they had to be somewhat complicated. The machine was small, and the advisability of the power traverse was much questioned. However, it was put on and worked very satisfactorily.

After the machine was put to work the operations were timed and it was found by actual experiment that the time saved by having this power traverse was about half a minute on a half hour's job. The amount saved in energy was, of course, also very slight, and while the impression conveyed to a casual observer was favorable, it is extremely doubtful if the fast traverse of this tool will prove economical in any way. Taking it in actual figures, and along one of the lines attention has been called to, if this additional mechanism lays up the machine for a day, as is quite possible, it will more than counter-balance the time saved in four months by the use of the power traverse.

Of course, if the machine were a large one and the amount of distance of travel of parts required, considerable, these figures would be entirely changed and the investment would unquestionably be a good one; but it is extremely doubtful if on the small machine it is either economical or advisable, and it is pretty safe to say that on such a machine it is a mistake. These are exceptional cases, but not by far as uncommon as many suppose, and these exceptional cases are the very ones that bring out the weaknesses of many so-called labor- and time-saving devices, and should act as warnings to any one about to purchase machinery and lead him to investigate such devices carefully and thoroughly.

A real improvement, one that actually saves time or labor and is neat and simple in design and operation, is one that can be easily recognized as such by any man capable of intelligently purchasing a machine tool. Such a device ought to command its proper price, and will pay good interest on such price.

Summarizing the above objections to new special features, we have: First, that a special device may be used but seldom; second, that it may break down and hold up the entire machine; and third, that its installation may be detrimental to the design of movements now on the machine, which are already recognized as good.

An arrangement which appears to come under any of the objections in the above summary should be bought with caution and only after very careful consideration.

* Address: 21st and Callowhill Sts., Philadelphia, Pa.

* * *

A quick installation of a steam heating equipment was recently made in a building at Trowbridge, England, in which some public meetings were to be held. As stated by the *Engineering Record*, the order for the work was given on Saturday at 9.45 A. M. and at 7.30 A. M. the following day the work was completed, including the installation of a steam boiler with an independent pump for the return of condensation, all necessary fittings, reducing valves, steam traps, etc., 1,080 feet of cast iron feed pipes with 40 fittings, and 1,140 feet of wrought iron pipe with 176 fittings. The work was accomplished by 30 men working continuously all the time, and involved the making of 159 joints in cast iron pipe, over 500 joints in wrought iron pipe, and the handling of 12 tons of material.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

The Cape Town to Cairo Railroad in Africa, which, when completed, will be one of the important Trans-Continental railways of the world, at the present time requires the completion of less than 700 miles to enable travelers to make the journey from Cairo to Cape Town by rail.

The Controller-General of Patents in Great Britain states that the great inventive activity in connection with the motor car industry which has produced such a large number of applications for patents in recent years, now shows signs of falling off. The decrease in the number of patents relating to automobile construction was not less than 35 per cent during last year.

New York City is spending $161,000,000 to increase its water supply. A great aqueduct will be built from the Catskills, and the water shed of a large area will be made available for the city water supply. In the matter of length, the aqueduct building for Los Angeles, Cal., is greater, however. It is to be 215 miles long and will tap the snow-fed Owens River and its tributaries. Its capacity will be 400 cubic feet of water per second.

As an example of the present realization of the value of the enormous water powers of the streams in northern Europe, it is stated by *Engineering* that the building of a large power station in Lapland, in the north of Sweden, is likely to be started during this summer. The power available at the falls near Brännland, which are to be utilized, is estimated at 81,000 H.P. It is not stated for what purpose the power is intended to be used.

An indication of the expense of repairs attending the running of motor cars and motor omnibuses is given by the report of the General Omnibus Company of Berlin, Germany, which is the largest transport undertaking of its kind in Germany, and which carries about 134,000,000 passengers a year. According to this report, the cost of maintenance and repairs of motor omnibuses reaches yearly nearly 50 per cent of the original purchase price.

A news dispatch states that the Southern Pacific R. R. is contemplating the boring of a long tunnel through the Sierra Nevadas, and that the surveys and estimates have been completed for some time. This tunnel will be between Truckee and Blue Canyon. It will be about 7 miles long and the total cost will aggregate $11,000,000, at least three years being required to complete the work. This will be the longest tunnel in the United States, and, with three exceptions, the longest tunnel in the world.

The Holland-American liner *Rotterdam* reached the port of New York City on June 22 on her maiden trip. This vessel is one of the largest that has ever been built, being 24,170 gross registered tons. The principal feature of the ship is the large amount of space placed at the convenience of the passengers. The state-rooms are said to be larger than those of any steamer that has entered New York harbor, and the promenade deck makes a record for size with 12,000 square feet of walking space. The total accommodations provided for are 525 first-class, 515 second-class, and 2,500 third-class passengers.

A very peculiar accident occurred on the Long Island R. R. June 22. A passenger train was approaching the Long Island City terminal when a brake-rod broke and the end falling down caught on the ties, doubled up, and twisted the handle of the train pipe valve around and closed it. When the engineer attempted to apply the brake he found that he had lost control of the train. Vigorous whistling alarmed the conductor and trainmen, who applied the emergency brakes, but too late to prevent disaster. The train crashed into the station, knocking down the bumping post, derailed the engine and demolished the side of the station. Fortunately no one was seriously injured.

The Singer Building tower, 612 feet high, and the Metropolitan Life Building tower, 693 feet high, are soon to be put in the shade by a building to be constructed on the site of the Equitable Life Assurance Society Building on the block bounded by Broadway, Nassau, Pine and Cedar Sts., New York. This building is to be 909 feet from the sidewalk, exclusive of the flagstaff. The flagstaff will be 150 feet higher, making the total height of the building from the sidewalk to the top of the flagstaff 1,059 feet. The main building will be thirty-four stories high. Superimposed on the main structure will be another with smaller base about fourteen stories high, and springing from the center will be a tower of another fourteen stories, making the total height in stories sixty-two. Thirty-eight passenger elevators will be provided.

Small producer power plants are growing in favor, especially in the Middle West. They have the merit of producing power at low cost for fuel and requiring a minimum of attention. An example is the plant driving the shop of the Mechanics Machine Tool Co., Rockford, Ill. A Fairbanks-Morse 50 horse-power motor was installed, and one of the mechanics working in the tool-room is paid 50 cents a day extra for running the machine. He comes to the shop half an hour before starting time and spends about another half hour during the day attending to the plant. Otherwise he works in the tool-room all day long. A car-load of anthracite pea-coal costing $163.24 was put in November 1, 1907, and lasted until June 1, 1908. Since January 1 the plant has run only five days a week. The cost for power in labor and fuel thus figures only about $260 for seven months power.

A Milan correspondent to the *Times Engineering Supplement* states that official trials of the De Forest wireless apparatus for telephonic service have recently been made in the presence of officers of the Italian navy. The apparatus was installed on one vessel, and the vessel put to sea, while communication was entered into with another vessel remaining at anchor in the harbor. Communication was maintained constantly, even when the vessel passed a chain of mountains enclosing the gulf where the harbor is situated. At intervals, several cannons were fired to ascertain if atmospheric disturbances had any influence on the working of the system. At a distance of 20 miles—the greatest distance tried—telephonic communication was regularly maintained. The results were satisfactory, and wireless telephone apparatus will be installed in some of the vessels of the Italian navy.

A hydro-electric power station, using the highest head of water in the world, has lately been designed by Aktiebolaget Vattenbyggnadsbyran, Stockholm, Sweden, for a large factory in Norway. The water is taken from a large mountain lake 3,536 feet over sea level, from which the water is brought by a tunnel 7 miles long, supplying six turbines of from 12,200 to 14,600 H.P. each. The total head is 3,287 feet, which is 72 feet more than the highest head hitherto used for power purposes. The largest diameter of pipe used for conducting the water will be 4 feet 6 inches, and the pipes will be of seamless tubing. The undertaking is one of the most remarkable engineering feats of our time. Norway is rapidly making use of its enormous natural resources in water power, another power station to supply 70,000 H.P. being built, the head here used, however, being only 84 feet.

Experiments carried on by the National Physical Laboratory, in Great Britain, indicate that steel imbedded in concrete is not influenced on its surface either by moisture or by the concrete itself. Specimens of both finished and rough steel were imbedded in concrete in December, 1906, and in

April this year one of the concrete blocks was broken up. On examination, the specimens of steel showed no trace of action by the cement or otherwise. The finished specimen was practically as bright as when put in, and the scale on the rough specimen was undisturbed. To test the possibility of any slight action, the surface of the turned specimen was polished and etched, and examined under a microscope side by side with the specimen of the same metal cut from the center of the bar, but no difference could be detected, and the conclusion is that in sixteen months, at least, no action takes place on steel when imbedded in concrete.

Some interesting experiments regarding the effect of artificial light on vegetation are related in the June issue of the *Electrical Magazine*. A French scientist has for the last two years made repeated experiments regarding the effect of various lights on the growth of plants which were subjected to red, green, blue, and white lights, the conditions otherwise being similar. Under the effect of red light it was found that certain vegetables grew fifteen times as fast as under blue light. On the other hand, the experiments proved that blue light has a remarkable preservative power on growing vegetation. It is recorded that an oak tree planted two years ago has kept its first leaves, which are now as fresh and vigorous as when they first appeared. In the same way, ripe fruit, it is declared, can be kept fresh under a blue screen for several weeks without decay. The facts disclosed by these experiments are expected to find a wide application, and to be of industrial importance.

Statistics collected by the United States government show that the nation has consumed about 7,000,000,000 tons of coal up to the present time. In 1908 the consumption was more than 400,000,000 tons. During the past ten years nearly as much coal was used as had been used during the preceding century. In view of the limitation of our coal resources and the enormous waste in the utilization of the heat energy of coal, there is no greater problem to-day than that of increasing the efficiency of coal utilization. As used at the present for heat, light and power, the losses are so great that less than 5 per cent of the total heat value of coal is converted into useful work in the manufacturing plant. The best and largest power plants utilize only about 10 per cent of the energy, while in railroad operation only from 3 to 5 per cent of the coal value is realized for hauling trains. It is estimated that only one-seventh of 1 per cent of the fuel value is actually converted into light in an electric incandescent lamp. Nearly 2,000,000 horse-power in the form of gas is allowed to escape from the blast furnaces of the country. This waste, however, is being rapidly checked by the installation of gas engines.

Comparatively little has been published in the United States regarding the Renard road train, intended for use on ordinary highways. Consul-General Robert P. Skinner, of Marseilles, states that Renard trains have been run from Paris to Marseilles over ordinary highways in order to supply the public with a demonstration of their efficiency. Each car receives the power necessary for its locomotion from the first vehicle or "locomotor" through a flexible transmission shaft, extending from one end of the train to the other, so that each car utilizes its own adhesion to the road surface as a means of advancement. Trains of this type, completely loaded, are able to maintain a speed of 13 miles per hour in the case of passenger trains, and 9 to 10 miles per hour in the case of freight trains, on a level road. It is also stated that freight trains of this type are able to maintain an average of from 6 to 7½ miles, fully loaded, in any kind of country. It should, however, be understood that the highways in Europe, in general, where these trains can be profitably used, are of a character that is only found in exceptional instances in the eastern part of the United States, and practically unknown all over the rest of the country. It seems possible that, in regions where railways would not prove profitable, this kind of transportation will have an important future ahead, but, of course, an extensive system of high grade, well-kept highways is a primary condition for its success.

FRICTION BRAKES.

H. D. James, in *The Electrical Journal*, May, 1908.

Although, at first thought, the brake may seem to be but a small detail in the construction of a crane, a hoist, or other device, a closer examination will show that it is a very important item, and one that may cause a great deal of trouble if improperly designed. The brake consumes mechanical energy in its friction surfaces and develops heat which must be radiated. Mr. H. D. James, and Mr. W. A. Paris, of the Westinghouse Electric & Mfg. Co., recently conducted a series of experiments extending over eighteen months to determine the best material to use for the friction surfaces in brakes. Endurance runs were made with cast iron shoes, and with shoes lined with wood, fiber, lignumvita, etc., on both cast iron and steel wheels. The best combination proved to be a cast iron shoe bearing on a cast iron wheel. Under heavy pressure the coefficient of friction was 0.3, and the wear on the brake wheel about one-sixteenth of the wear on the shoe. Cast iron shoes on cast iron wheels have been used for many years on freight cars and for street railway work, where the service is more severe and continuous than for most industrial applications. One advantage of using metal shoes bearing against a metal wheel is the increased radiating surface obtained. If an insulated lining is used, the heat from the rim of the wheel is not conducted directly to the brake shoe. This makes it necessary for the wheel to radiate most of the energy dissipated. Or, if a combustible lining is used, the permissible heating is limited, and a much larger brake wheel must be used to absorb a given amount of energy. These limiting conditions are obviated when a cast iron shoe is employed. Radiation may be improved by using a brake wheel ribbed on the inner side of the rim, and provided with fans for driving the heated air away from the motor bearings. The brake shoes should be provided with deep ribs to assist in radiation as well as to make them very stiff. Such a brake can be operated at a temperature which will turn cast iron to a blue color without in any way injuring the parts.

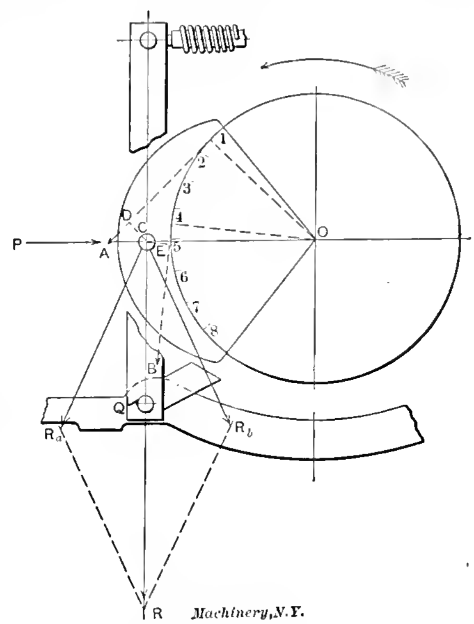

Fig. 1. Arrangement of Brake Rigging.

The usual method of suspending brake shoes causes them to exert an unequal pressure upon the brake wheel, because the resultant pressure produces a turning moment around the point of suspension, the shoes wear unequally, and the ends have a tendency to dig into the wheel when the brake is first applied, thus causing a severe strain on the motor shaft. This defect has been overcome by making the brake shoe stiff, so that the static pressure is uniform, and by selecting a point of suspension such as to eliminate the turning moment on the brake shoe. If the pressure is uniform and the surface of the shoe is considered as divided into a number of equal strips, the retarding force of each strip is the same, and may be considered as concentrated at the center of the strip, provided the number of strips is large. Selecting two strips, 1 and 4, Fig 1, the retarding force may be represented in amount and direction by the lines 1-*A* and 4-*B*, each at right angles with a line drawn from the center of the wheel to the center of the strip. Using a point of suspension, *C*, it may be seen that force 1-*A* tends to turn the shoe counter-clockwise around the point *C*, having a turning moment

equal to 1-*A* times *CD*, while the force 4-*B*, having a moment equal to 4-*B* times *CE*, tends to turn the shoe clockwise about point *C*. It is evident that point *C* may be so located that the sum of the moments for all the strips tending to produce counter-clockwise rotation is exactly balanced by the sum of the moments of those tending to produce clockwise rotation, and that the resultant pressure on the point of suspension due to the upper part of the shoe will be represented by a line such as R_a. In the same way the turning moments about point *C* for the lower part of the shoe will balance each other and produce a resultant pressure on *C* represented by a line R_b. The total resultant pressure of the shoe on the point of suspension *C* is represented by *R*, which acts directly along the hanger and through its pivot. There is, therefore, no tendency for the hanger to turn about its pivot, thus increasing or decreasing the pressure of the shoe as a whole against the wheel. If the point *C* is located in the manner described, it insures a uniform pressure per square inch on all parts of the brake surface, and freedom from any turning tendency about points *C* or the hanger pivot, and this is true for rotation in either direction. The results of this method of suspension are as follows:

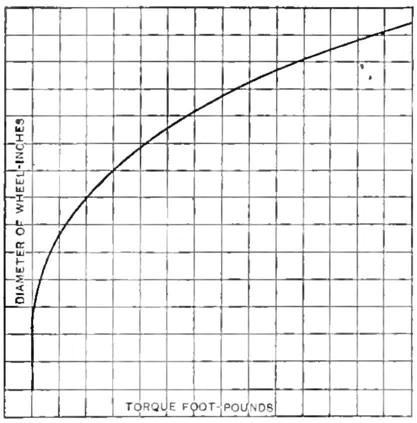

Fig. 2. Diagram showing Relation between Diameter of Wheel and Torque exerted by Brake.

a. The shoe is free to turn and find a true seat on the wheel.

b. The pressure of the shoe against the wheel is uniformly distributed.

c. The retarding force acts directly along the line of the brake hammer.

There is no tendency for the ends of the shoes to press harder against the wheel and thus wear away faster, and there is no tendency or possibility of one shoe pressing harder than the other, thus producing a side thrust on the shaft bearings. This insures an even wear on the shoe and wheel and long life for both.

The relation between the diameter of the wheel and the torque exerted by the brake is expressed by the following formula:

$$D = 24\sqrt[3]{\frac{1}{144\,B\,C\,f\,p}} \times \sqrt[3]{\text{torque}}$$

where *D* equals diameter of wheel in inches; *B* equals angle (in radians) covered by two shoes; *C* equals width of wheel divided by the radius; *f* equals coefficient of friction; and *p* equals pressure in pounds per square inch.

By assuming fixed values for *B*, *f* and *p*, the curve shown in Fig. 2 was plotted. This shows that for small wheels the torque increases very slowly with the diameter of the wheel. As the size of the wheel approaches eighteen or twenty inches, the torque increases more rapidly than the size of the wheel, so that large brakes are more compact than small ones.

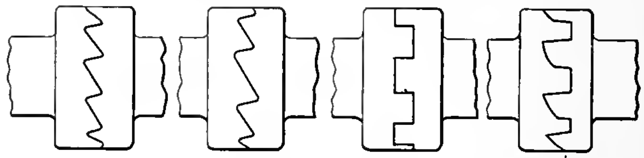
CLUTCHES.

Abstract of paper by Mr. Henry Souther before the Detroit Meeting of the American Society of Mechanical Engineers.

Clutches, in one form or another, have always constituted an important detail of machine construction. In general, however, engineers have not given clutches very great attention until recently, but now, when these devices have been called upon to do the delicate work required in connection with them in cotton mill machinery, printing presses, electric cranes, and automobiles, the real importance of clutch design has become apparent.

Positive Clutches.

The positive, or jaw clutch, is necessarily used only where a sudden starting action is immaterial, and where the inertia of the originally stationary or driven parts is relatively small. The different forms of positive clutches are modified merely in the angle of the engaging surfaces. The least positive form is one where the planes of engagement are inclined backward, as regards the direction of motion. The tendency of such a clutch is to disengage under load, and it must be held up to its work by axial pressure. This pressure may be regulated to perform normal duty, permitting the clutch to slip and disengage when overloaded. Positive clutches with the engaging planes parallel to the axis of rotation, must be held up to their work in order to prevent their natural tendency to jar out of engagement, but they present no safety features against overload. So called undercut clutches will engage tighter when loaded, and can be disengaged only when absolutely free from load, and in a condition permitting them to be rotated in a reverse direction sufficiently so that the undercut angular surfaces can clear each other. Some simple forms of positive clutches, embodying the fundamental principles, are shown in Figs. 1 to 4.



Figs. 1 to 4. Examples of Positive Clutches.

Friction Clutches.

While there is an infinite variety of detail in construction and manipulation of friction clutches, they might all be classified as belonging to one of the following four types: contracting band friction clutches, friction cone clutches, friction sector clutches, and friction disk clutches.

The most simple form of clutch is, perhaps, the Ramsbottom clutch, used for rolling mill work. It is, in reality, a friction coupling in which one flange is squeezed in between two other flanges, tightly bolted together. This clutch is shown in Fig. 5. The flange *A* is firmly clamped between the wood-lined surfaces of *B*, the bolts clamping these parts together, so that the friction will resist normal torque, but yield to abnormal torque.

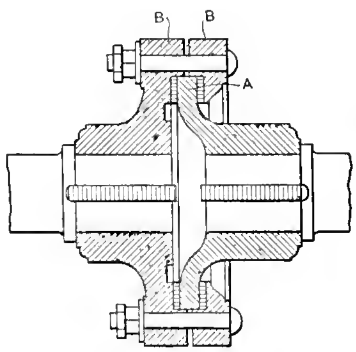


Fig. 5. Ramsbottom Clutch.

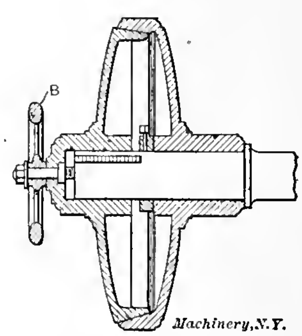

Fig. 6. Simple Form of Cone Clutch.

In Fig. 6 is shown the simplest form of cone coupling, where the two parts are being forced into engagement by a screw and a hand-wheel *B*. The angle of the cone should not be less than 10 degrees. The coefficient of friction for two iron surfaces in a clutch of this character is about 0.15. The mean radius of the cone should be kept within 3 to 6 times the diameter of the shaft, in order to keep the axial pressure within reasonable limits.

A further development of the friction cone clutch is shown in Fig. 7. This clutch may be termed the multi-cone friction clutch, being provided, as it is, with a series of concentric cone-shaped rings, of 20 degrees included angle. The design shown in the engraving requires that the collar on the shaft and the yoke in the engaging sleeve resist the pressure due to the axial pressure necessary for proper engagement, which causes serious wear. Such wear, however, is avoided in heavy or high speed machines by making the axial pressure

self-contained on the rotating members. A modification intended for this purpose is shown in Fig. 8. The pressure required for engaging the two clutch halves *A* and *B* is obtained by tightening hand-wheel *C*, the thrust being taken by collars on the respective shafts in such a manner that the ends of the shafts are forced together.

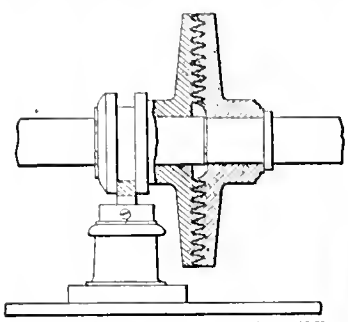

Fig. 7. Multi-cone Clutch of Objectionable Design for Heavy Work.

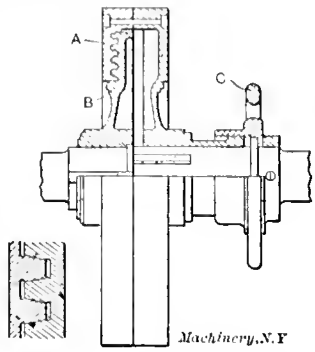

Fig. 8. Principle of Self-contained Multi-cone Clutch.

Another fundamental type of clutch is shown in Fig. 9. This is of the internal expanding type, three internal clamping pieces *A*, fitted with bronze shoes, being thrust out against the enclosing cylindrical drum *B*, by means of lever and screw action. There is no danger of wedging in this clutch, as exists in connection with the cone clutch.

In Fig. 10 is shown the well-known Weston clutch, which is based on the fourth fundamental principle mentioned above, that of multiple plate friction. The plates are alternately wood and iron, the wooden ones engaging with the outside cylindrical case *A*, and the iron ones with the shaft *B*. In the form shown, the plates are pressed together by springs *D* and disengaged by drawing back a collar-sleeve *C*, which releases the spring pressure.

Machine Shop Clutches.

The clutches shown so far have been intended simply to indicate basic types. The following examples will illustrate

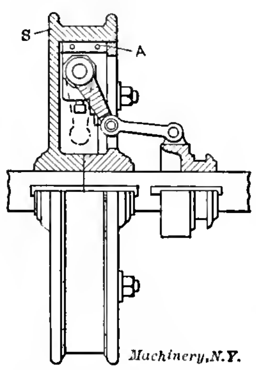

Fig. 9. Internal Expanding Type of Clutch.

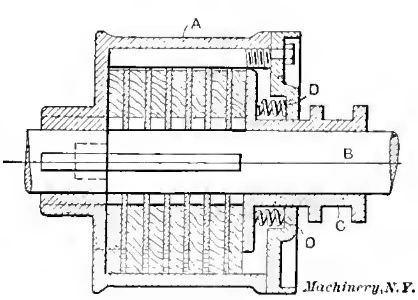

Fig. 10. Disk Clutch, Weston Type.

the development of present practical machine shop clutches. The simplest type is one in which one flat disk presses against another, the surfaces being either leather against iron, bronze against iron, or wood against iron. Such a type is shown in Fig. 11. The wooden disk *A*, attached to the casing *B*, is gripped between two iron surfaces *C*, keyed to the driving shaft. In order to prevent a drag when disengaged, separating springs *D* are placed between the iron disks. An interesting clutch, formerly known as the Frisby clutch, was designed many years ago. This clutch is shown in Fig. 12, and in this one flat surface *A* and the cone surface *B* are used in combination. The gripping of the surfaces is accomplished in a manner similar to that of the clutch in Fig. 11. It is apparent that this clutch would require less axial pressure for any given horse-power transmitted than the foregoing type, because of the cone; or, in other words, for a given axial pressure it would transmit more power and therefore would be smaller and more compact, all other things being equal. But here we meet with the uncertainty of the coefficient of friction. This clutch, for example, might throw its oil to the frictional surfaces more than the previous example, which oil would more than offset the effect of the cone engagement.

Very little information is obtainable in regard to the frictional capacity of this class of clutches and the knowledge at hand is of an empirical character. The Dodge Manufacturing Co., Mishawaka, Ind., gives some experimental data on the capacity of this class of clutches. The results are obtained from clutches fitted with maple blocks, and calculations are based on a coefficient of friction of 0.37 and a speed of 100 R.P.M.

TABLE OF HORSE-POWER TRANSMITTED BY FRICTION CLUTCHES.

Horse-power.	Block Area.	Diameter at Block, inches	Circumferential Pull at Block Center.	Total Pressure.	Total Pressure per sq. in.
25	120	16	1960	5300	44
32	141	18	2240	6000	44½
50	208	21½	2900	7800	37½
98	280	27½	4500	12200	43½

A modern development of the expanding ring clutch is shown in Fig. 13. These clutches are largely used for heavy work and are made by the A. & F. Brown Co., Elizabethport, N. J., in sizes up to 48 inches in diameter, capable of transmitting 320 H.P., at 100 R.P.M. The frictional surfaces are of wood, especially prepared for the purpose, the casing being of iron.

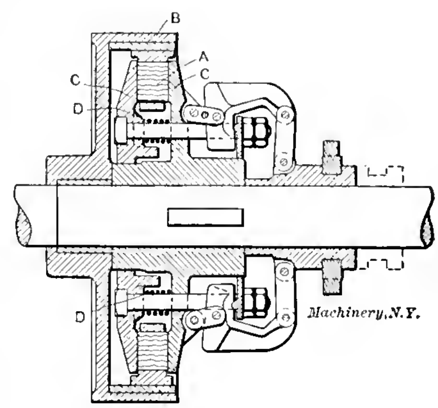

Fig. 11. Simple Form of Single Disk Clutch.

One of the oldest usages made of clutches is in wire drawing manufacture. The iron drum, around which the wire is wrapped, as a rule contains some form of clutch within it. A recent development of this class of clutch is shown in Fig. 14, being a clutch made by the Morgan Construction Co., Worcester, Mass. This clutch is working on the compound principle, the main driving effort being furnished by a wrapping coil on a chilled iron surface, the initial engagement of the coil being brought about by a modified cone or ring, slipping down onto a cone which drags the free end of the coil into engagement. When once seized, the wrapping continues until tight. In Fig. 14, *A* is the tapered friction surface of the chilled drum on which the friction ring bears, and below this is the coil, which is submerged in oil in an annular oil chamber. The drum is 12 inches in diameter by 7 inches high, and the coil, made of soft steel, is 1½ inch square at the large end and ⅜ by ⅝ inch at the small end.

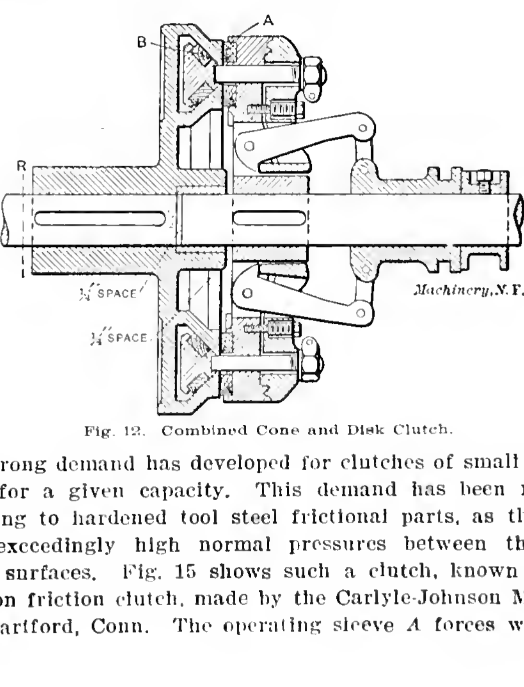

Fig. 12. Combined Cone and Disk Clutch.

A strong demand has developed for clutches of small dimensions for a given capacity. This demand has been met by resorting to hardened tool steel frictional parts, as this permits exceedingly high normal pressures between the frictional surfaces. Fig. 15 shows such a clutch, known as the Johnson friction clutch, made by the Carlyle-Johnson Machine Co., Hartford, Conn. The operating sleeve *A* forces wedge *B*

between the two long arms of the levers *C*, thereby spreading them in such a manner that they expand the friction ring *D* against the hardened drum *E*, enclosing the friction ring. This enclosing ring is an integral part of, or connected with, the driven pulley or shaft. As much as 100 H.P. has been transmitted, at 1,000 R.P.M., with a clutch of this type, having friction rings 5¼ inches in diameter and 1½ inch wide.

Clutches with Cork Inserts in the Frictional Surfaces.

Commercial clutches of the form now discussed have recently been designed with cork friction surfaces, with considerable success. Cork has a high coefficient of friction, probably double that of wood or leather on iron. As a rule the cork is forced into suitable cavities formed in one of the

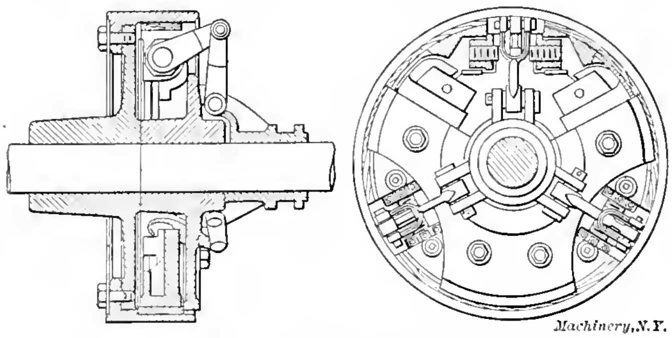

Fig. 13. Modern Application of Expanding Clutch.

metallic frictional surfaces. The cork is previously boiled, and thereby softened, before being pressed into the cavities. When so inserted in a metal surface, it normally protrudes above the surrounding surface, and engages first when the surfaces are brought together. If sufficient pressure is applied to the clutch, the cork is forced down flush with the metal surface and acts with it in carrying the load. When the clutch is released, the cork will again protrude beyond the surrounding metal surface.

Two forms of cork are used, one being the cork in its natural condition, the other prepared as follows: Small pieces are compressed into sheets and blocks of any desired shape under very great pressure and under enough heat to cause the natural gums of the cork to exude and act as a binder. This form of prepared cork is really more enduring than the natural, being stronger, firmer and yet possessing much elasticity, but it is expensive and has not had wide use for this reason. Nevertheless, it has been most successful in performing service beyond the capacity of other materials.

As an example of this, it may be mentioned that a Dodge friction clutch carrying 500 H.P. gave much trouble on account

COMPARATIVE TESTS OF LOOM CLUTCHES.

Average results of eight positions.
Torque measured in pounds-feet.

Pressure on Clutch, pounds.	Torque.	
	"Compo" Clutch with Cork Inserts.	Leather-faced Clutch.
89.5	19.50	16.95
151.5	34.20	17.66
213.0	46.43	23.09
275.0	57.05	29.46
337.0	73 33	36.09
398.0	82.24	41.31
460.0	96.48	47.56

of being overloaded. This clutch was strained up as tight as possible, and it was all a man could do to throw it. The maple blocks used were replaced with compressed cork. It was then possible to loosen the adjustment of the clutch to such an extent that the operator could throw it with little effort. Following this change it was found that a set of cork blocks outlasted the maple ones five to one.

Prof. I. N. Hollis of Harvard University has determined the coefficient of friction of cork on metal. He found that the coefficient of friction for plain cast iron on cast iron is about 0.16; similarly, for plain bronze on cast iron the coefficient of friction is 0.14. The coefficient of friction of the cork on the cast iron, however, was found to be from 0.33 to 0.37, the former, 0.33, being the value for the heavier loads.

It is apparent that the coefficient of cork on iron or steel is about double that of iron on iron. It is further claimed that the coefficient of friction is not very much less when the cork is lubricated. Cork has much advantage in a moist atmosphere, being very slightly affected by moisture, as compared with maple blocks ordinarily used.

Tests have been made by Prof. C. M. Allen of the Worcester Polytechnic Institute in connection with loom clutches, showing that for a given dimension of clutch the torque for cork inserts is nearly double that of a leather-faced clutch.

Automobile Clutches.

The latest development in clutches has been due to the development of the automobile. In clutches for this purpose, the matter of absolute disengagement is perhaps the most important. An important feature in the clutch is also the question of its weight, especially as affecting its inertia. A clutch having high fly-wheel effect spins to such an extent as to cause violent clashing of idle gears. Consequently, clutches are made as light as possible, and the smaller in diameter the better. Aluminum enters largely into clutch construction for this reason.

One of the simplest forms of clutch, which is commonly used for small machines, and in connection with the planetary system of change gearing, has one disk covered with leather, bronze, or copper, and is pressed against another, of iron or steel. The engagement of this clutch is soft and gradual, but it is open to the objection that a small amount of oil coming in between the surfaces renders it absolutely useless. Such a clutch, when reasonably dry, will drive a car up a grade

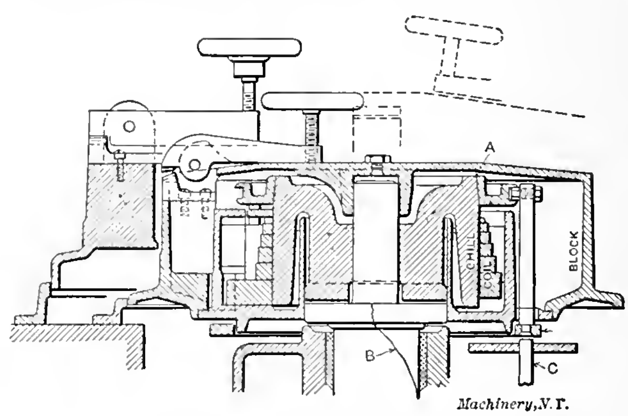

Fig. 14. Clutch for Wire Drawing, permitting Gradual Application.

sufficient to stall the engine. The same clutch, with too much oil between the friction surfaces, will not drive a car up a half per cent grade on asphalt. This is a good illustration of the uncertainty in clutch design, as far as frictional capacity is concerned.

For automobile clutches, all things considered, the best form when properly designed and mounted is the cone clutch. It has the advantage of engaging and disengaging with very small axial motion. The axial pressure may be low, because the normal pressure between frictional surfaces is multiplied by the angularity of the cone. This clutch may also be small, and the disengagement may be made perfect. Proper engagement, however, has proved to be a very difficult problem, and the cone clutch must therefore be absolutely free to center itself and seat itself uniformly.

Leather riveted onto an aluminum cone usually forms one of the rubbing surfaces and gray cast iron the other. It is desirable that the leather shall be kept soft by neatsfoot or castor oil. Some builders boil the leather in tallow before applying to the clutch surface; others do not, but this matter is of minor importance. With leather ¼ inch to ⅜ inch thick, properly softened, engagement may be sufficiently mild, but an improvement is obtained by placing under the leather at six or eight points on the periphery of the cone, flat or spiral springs that cause the leather to engage at these points a little bit before engaging elsewhere.

It is obvious that the construction surrounding the clutch must be such that, by no means, can an unusual supply of

lubricant find its way to the frictional surfaces of the clutch. With proper usage, cone clutches with leather faces seem to last indefinitely.

There has been a considerable variety of opinion as to the proper cone angle. Various authorities have placed it all the way from 7 degrees to 20 degrees. The French have settled down on an 8-degree to 9-degree angle as being about right

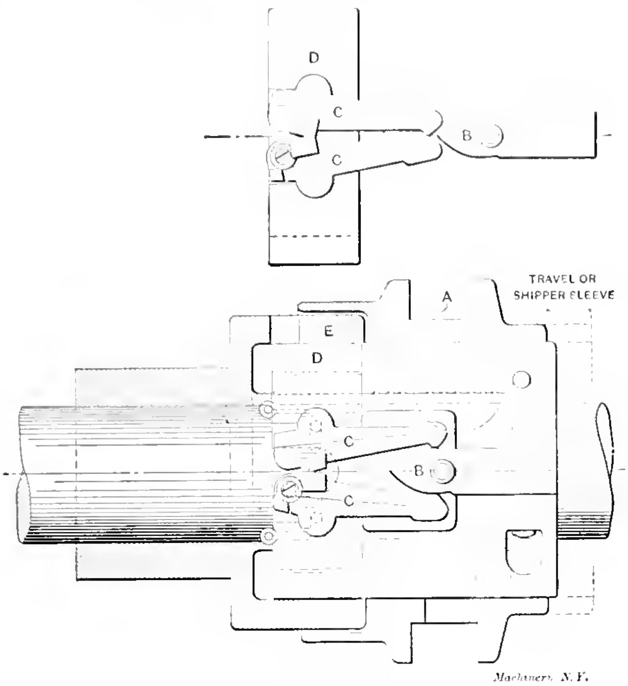

Fig. 15. The Johnson Clutch, used largely on Machine Tools and on Counter-shafts.

for a leather-faced cone. Several important American makers are using 12 degrees to 13 degrees, several 10 degrees, and others 8 degrees.

In general, these clutches present no difference in design from the types already illustrated. Some clutches have been brought out, however, of rather novel construction. An interesting form is shown in Fig. 16. This may be called a multi-cone clutch. When the clutch engages, the smallest cone seizes first and commences to revolve, and subjects thereby the spiral spring between the next two clutches to a torsional movement, which draws the springs together and brings the two outside clutches into action. The principle of the clutch is that the small clutch shall slip when the car starts and that the medium clutch shall behave in a similar manner when engaged, and that finally, the large clutch, when it

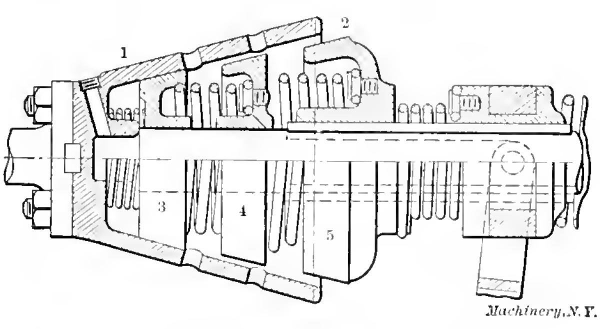

Fig. 16. Multi-cone Clutch of Novel Design.

comes into play, shall present sufficient frictional resistance to take up the full load in combination with the other clutches. It does not appear that this clutch has been tried out sufficiently to say whether it is a practical success, but the idea is a rather ingenious one.

Theory has not entered largely in clutch design, but in Fig. 17 is shown a simple clutch embodying the tractrix curve. This curve is adopted, because it is of such a form that by the calculated relation of pressures and peripheral speed, the wear ought to take place uniformly at all points, regardless of the distance of the point from the center. On account of this it is claimed that the clearance required is very small; that there is no wedging action between the two members of the clutch; and that there is no chance for it to bind.

A simple formula for calculating the ordinary cone clutch is the following:

$$\text{H.P.} = \frac{PfrR}{63{,}000 \sin \theta}$$

P = assumed pressure of engaging spring in pounds,
f = coefficient of friction, which in ordinary practice is about 0.25,
r = mean radius of the cone in inches,
R = revolutions of the motor per minute,
$\sin \theta$ = sine of the angle of the clutch.

To obtain the size of spring when the horse-power is known, the following formula may be used with good results:

$$P = \frac{\text{H.P. } 63{,}000 \sin \theta}{frR}$$

the same symbols being used as in the preceding formula. It will be noted that the coefficient of friction used is 0.25. This is probably near enough for a properly lubricated leather-iron clutch.

Expanding and contracting band clutches are used to some extent in automobile construction. The principle involved in all these is that a friction ring with sufficient flexibility either expands on the inside of a drum, or casing, or contracts on the outside of a drum, transmitting power by the friction between the expanding or contracting band and the drum. The mechanical designs to accomplish this have been greatly varied, but the designs are rather complicated. Clutches of this type are not greatly in favor in successful automobile designs.

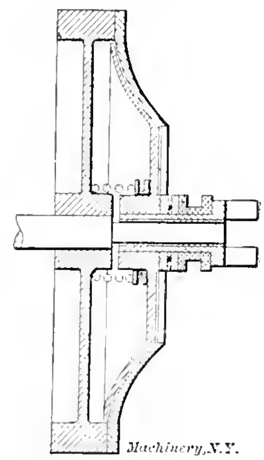

Fig 17. Clutch Designed for Uniform Wear.

Disk clutches on the other hand, are widely used. The principle involved in these clutches is a simple one, and has already been referred to in connection with our general classification of clutches. Cork inserts may be used in these clutches to considerable advantage. The question of lubrication is very important in these clutches, and in fact, it would seem that the principal problem in connection with the multi-disk clutch in particular is proper lubrication.

A modification of the multi-disk clutch, in which the cone and the disk are combined, is attracting much attention. This clutch is known as the Hele-Shaw clutch and has previously been described in these columns (see MACHINERY, October, 1903, engineering edition, and May, 1908, engineering and shop edition). With this clutch, 1,000 H.P. is being transmitted at 700 or 800 R.P.M., the clutch being 18 inches in diameter. The following table gives the dimensions and number of plates used for clutches transmitting different H.P.

	Bronze.	Steel
25 H.P., 27 plates of 6½ in.	14 outer	13 inner
40 H.P., 25 plates of 8¼ in.	13 outer	12 inner
60 H.P., 21 plates of 11 in.	11 outer	10 inner

Pneumatic clutches have been developed, but have not been widely used, because of their cost. In these a plain, leather-faced disk is pressed against a metal plate. The air deflects the leather, and causes it to bear against the metal disk, which is given a slight, endwise motion. Hydraulic clutches have also been used, but are not very popular.

Magnetic clutches are in use and are fairly successful. One complication in magnetic clutches arises in the fact that one of the parts of the magnet must rotate continuously, the gears being always in mesh; consequently the exciting current must be carried to it by a brush. These clutches usually seize rather abruptly unless carefully controlled. A considerable current is also necessary on the car for the operation of the clutch. These complications rather interfere with its extended usage.

DIMENSIONS OF SCREW HEADS AND NUTS.

A great many attempts have been made to standardize the dimensions of screw heads and nuts, but none so far has been undertaken under the auspices of any sufficiently recognized agency to command, for the particular standard in question, universal recognition. Strictly speaking, therefore, there are no standard dimensions for screw heads or nuts. The most prominent firms in this country, however, have adopted for their own use standards which do not materially differ from one another. In the following, dimensions are given for a number of different types of screw heads and nuts, these dimensions agreeing, in most particulars, with those in use at the Pratt & Whitney Co., Hartford, Conn.

In the tables in the Supplement, giving the sizes, no dimension has been given for the length of the screw itself, nor for the length of the thread, because these dimensions depend, of course, entirely upon the conditions for which the screws are to be used. In order to give a convenient rule to follow, however, for the length of the thread, it may be said that the length of the thread should equal two times its diameter, whenever the total length of the screw below the head is more than two times the diameter. When the total length of the screw is less than two times the diameter, the screw is threaded practically all the way up to the head.

In Table I in the Supplement, dimensions for the heads of screws with fillister heads are given. Two styles are shown; in the one it will be noted that the upper end of the head is rounded, whereas in the other the corner is sharp. The one kind of head is used when the screw head is permitted to project slightly above the surface of the work, which is common, particularly when the surface of the work is not finished. The other style shown, having a sharp corner at the upper edge, is intended for use where the screw comes flush with the surface of the work, which, in this case, always is finished. All dimensions for both types of heads are the same, excepting those which are influenced by the slight rounding of the corner. Dimensions are given for the width and depth of the slot for the screw-driver. It will be noticed that in order to prevent getting too many different widths of slots, several sizes are provided with the same dimensions for the slot.

In cases where the screw heads are not standard, it is a good rule to make the width of the slot according to the formula

$W = 0.135 \times D$,

where W = width of slot for screw-driver, and

D = diameter of bolt or screw.

A mistake which is often committed is to make the screw slot in proportion to the diameter of the head, irrespective of the diameter of the screw. This, however, is not correct, and often results in screws being twisted off by too large a screw-driver inserted in the slot in a special large head, the slot being proportioned according to the head, and not according to the screw to be tightened. While this would have no reference to screws with standard heads, it may not be out of place to mention it in this connection.

In Table II in the Supplement are given dimensions for the heads of standard square head screws. These screws are most commonly provided with a flat point as shown in the upper view, the screws being used for binding or set-screws; but not infrequently these binding screws are made with an angular point, as shown in the lower right-hand view in Table II, the included angle of the point being 90 degrees. At the left is shown still another form of point frequently used.

In Table III dimensions are given for headless set-screws. The dimension D is for the slight round at the upper end of the screw. Of course, the dimensions given in this case refer practically only to the size of the slot for the screw-driver. Three different types are indicated, one having a flat point and the two others being pointed, one to a 120-degree included angle, and the other to a 90-degree included angle.

In Table IV is shown a kind of screw known as a collar-head screw, having a square head and circular collar, which latter binds up against a surface of the work. These are commonly made with different sized heads for the same size bolt, in order to permit different sized bolts to be used, all of which would have the same size head, so that the same wrench may be employed for the different screws. These screws are usually threaded as near to the shoulder as possible, when the total length below the shoulder or collar is one inch or less; for screws longer than one inch, and up to 1½ inch, one inch length of thread is sufficient. For longer screws five-eighths of the length under the shoulder is usually threaded.

In Table V standard hexagon head screws are shown and dimensioned. These are used, as a rule, only in sizes larger than ¾ inch, the smaller sizes of screws for similar purpose being of the collar-head type. In the former, when the length under the head is longer than two times the diameter of the bolt, the length of the threaded portion should equal two times the diameter.

In Table VI dimensions are given for regular hexagon nuts, and in Table VII for hexagon nuts having less than the standard number of threads per inch, in this case 16 threads. These nuts, of course, can be made considerably thinner than the standard nuts. The thickness of these nuts is purely arbitrary, and there is no really good reason why a ¾ nut, for instance, should be only 5/16 inch thick, and a 2-inch nut 5/8 inch thick, if both are provided with 16 threads per inch. The figures given, however, embody common practice. In Table VIII are given dimensions for hexagon check nuts with regular standard threads. These check nuts are rounded on both sides, and are considerably thinner than the standard nut.

In Table IX dimensions are given for washers used in connection with standard bolts and nuts. It will be noted, upon examination of the table, that these are proportioned according to certain definite rules, and these rules are embodied in the following formulas:

$B = 2A + \frac{1}{8}$ inch, for A less than one inch.

$B = 2A$, for A equal to one inch or over.

$C = \frac{A}{4} + 1/32$, for A less than one inch.

$C = \frac{A}{4}$, for A equal to one inch or over.

In these formulas

A = hole through washer,

B = diameter of washer, and

C = thickness of washer.

While the nominal size of the hole through the washer is A, the hole should be made from 0.002 to 0.005 inch larger than the nominal sizes of the bolt for which they are intended.

Square heads for bolts intended for standard T-slots should be made to dimensions given in Table X. This table also gives the dimensions of the T-slots, in accordance with the dimensions of standard T-slot cutters, as manufactured by the Pratt & Whitney Company and the Brown & Sharpe Mfg. Co. The dimensions for nuts used in standard T-slots are given in Table XI.

* * *

A convenient rule for calculating the weight of cold-rolled shafting has been expressed in formula by Mr. H. E. Roush, Marion, Ohio, as follows: Weight per foot $= \frac{(\text{diameter} \times 4)^2}{6}$, or $\frac{8\,d^2}{3}$, in which d is the diameter, in inches. For example, the weight of a 3-inch shaft is $\frac{8 \times 3 \times 3}{3} = 24$ pounds. A rule of some value in certain cases for calculating the weight of steel plates is: The continued product of the length (in feet), the breadth (in inches), the thickness (in inches) and 3.4 is the weight in pounds. For example, what is the weight of a steel plate 5 feet long, 40 inches wide and ¾ inch thick? $5 \times 40 \times \frac{3}{4} \times 3.4 = 510$ pounds, answer. In both cases the weight of rolled steel is assumed to be 489.6 pounds per cubic foot, which agrees closely with standard authorities.

HOW TO OBTAIN APPROXIMATE FRACTIONS BY THE METHOD OF CONTINUED FRACTIONS.

MITCHELL DAWES *

Mitchell Dawes.†

Having exceptional opportunities for observation, I think it would not be untruthful to say that not more than 2 per cent of the men hired as being capable machinists and operatives on general work, understand the subject of continued fractions well enough to use them in obtaining approximate fractions. And having been repeatedly requested to put the subject in such shape that the ordinary man might understand it, I send herewith an article which I trust will be helpful to that extent.

In a work published by the Brown & Sharpe Mfg. Co., entitled "Practical Treatise on Gearing," the subject of continued fractions is taken up and explained in detail, and yet many machinists and apprenticed machinists are not well enough posted in mathematics to apply these rules in their regular shop practice. The reason for my sending this article is more for their enlightenment than any other purpose.

Now, I do not propose to enter into an explanation of what continued fractions are, as that is fully explained in the treatise above mentioned. When we have a fraction that cannot be factored and we resolve it into other fractions by the process of continued fractions, these fractions are called approximate fractions.

An Example for Illustration.

As an illustration, I will work out an example and show each successive step in its solution. If the reader will follow this explanation and apply it to like problems that he desires to solve, I think he will have very little trouble in obtaining satisfactory results in the future. Suppose, for example, that it is required to cut a spiral worm by means of a B. & S. milling machine, and the lead of said worm is to be 7.29 inches; find the necessary gears.

The required lead being 7.29 inches, then expressed as a fraction, it will read $\frac{7.29}{10}$ (the 10 being the ratio between the spiral head spindle and the table feed-screw of the milling machine, when the driving and driven gears are alike). For every decimal place in the numerator, add one cipher to the denominator and remove the decimal point from the numerator, thus making it a common fraction; it will then read $\frac{729}{1000}$. Reduce this fraction by the process of "continued fractions as follows:

$\frac{729}{1000}$

```
729)1000(1
     729
     ---
     271)729(2
         542
         ---
         187)271(1
             187
             ---
              84)187(2
                 168
                 ---
                  19)84(4
                     76
                     --
                      8)19(2
                        16
                        --
                         3)8(2
                           6
                           -
                           2)3(1
                             2
                             -
                             1)2(2
                               2
                               -
                               0
```

(In solving this example, it will be noticed that each divisor is divided in its turn by the last remainder.)

Now take the several partial quotients and arrange them in a line,

```
      + — + — + — + — 0
thus: 1 2 1 2 4 2 2 1 2.
```

Starting with the first one on the left, we call it plus (+) because when formed into its fraction it will be more than the original fraction $\frac{729}{1000}$ and the second will be minus (—) because it will be less than the $\frac{729}{1000}$ and so on, alternately plus and minus, each successive fraction being a little nearer the exact fraction $\frac{729}{1000}$ as it approaches the last one which is 0, or the fraction itself.

The Approximate Fractions.

To obtain the first fraction:

Take (1) the first partial quotient for a denominator and 1 or unity for its numerator, thus $\frac{1}{1}$. In relation to this first partial quotient and its connection with the first approximate fraction, I would state that no matter what the first partial quotient was found to be, say 1 or 5 or 7 or 10, in *all* cases it is taken for the first denominator, and 1 placed over it for a numerator, making it $\frac{1}{1}$ or $\frac{1}{5}$ or $\frac{1}{7}$ or $\frac{1}{10}$ as the case might be.

To obtain the second fraction:

Multiply (1) the numerator of the first fraction by (2) the second partial quotient, thus $2 \times 1 = 2$, which is the numerator of the second fraction, then multiply (1) the denominator of the first fraction by (2) the second partial quotient, thus $2 \times 1 = 2$, and to this product add (1) the numerator of the first fraction, thus $2 \times 1 + 1 = 3$, the result being the denominator of the second fraction; complete, it is $\frac{2}{3}$.

To obtain the third fraction:

Multiply (2) the numerator of the second fraction by (1) the third partial quotient and to the product add (1) the numerator of first fraction. Thus $2 \times 1 + 1 = 3$, which will be its numerator; then multiply (3) the denominator of the second fraction by (1) the third partial quotient and to the product add (1) the denominator of first fraction, thus $3 \times 1 + 1 = 4$, which will be its denominator; complete, it is $\frac{3}{4}$.

To obtain the fourth fraction:

Multiply (3) the third numerator by (2) the fourth partial quotient and to the product add (2) the second numerator, thus $3 \times 2 + 2 = 8$, which will be its numerator; then multiply (4) the denominator of the third fraction by (2) the fourth partial quotient and to product add (3) the second denominator, thus $4 \times 2 + 3 = 11$, which will be its denominator; complete, it is $\frac{8}{11}$.

The remaining fractions are found, as were the third and fourth, thus:

To obtain the fifth fraction $8 \times 4 + 3 = 35$, its numerator, and $11 \times 4 + 4 = 48$, its denominator.

To obtain the sixth fraction $35 \times 2 + 8 = 78$, its numerator, and $48 \times 2 + 11 = 107$, its denominator.

* Address: Brown & Sharpe Mfg. Co., Providence, R. I.

† Mitchell Dawes was born in Saugerties, Ulster County, N. Y., and was educated at the Saugerties Academy. He served an apprenticeship with the Brown & Sharpe Mfg. Co., Providence, R. I., and has worked for Laflin & Rand Powder Co., Hendrie Bros. & Holthoff, Union Paper Box Co. and Sheffield Paper Co. He was appointed instructor of apprentices of Brown & Sharpe Mfg. Co., January, 1897, which position he still holds. Mr. Dawes' specialty is apprenticeship instruction. He has delivered addresses on apprenticeship system before the New England Association of Teachers of Metal Work and to the students of the Rhode Island College of Agriculture and Mechanic Arts. Since he has had charge of the apprentices at Brown & Sharpe Mfg. Co., two hundred and forty-five have completed their apprenticeship course and one hundred and twenty-five are still under instruction.

To obtain the seventh fraction $78 \times 2 + 35 = 191$, its numerator, and $107 \times 2 + 48 = 262$, its denominator.

To obtain the eighth fraction $191 \times 1 + 78 = 269$, its numerator, and $262 \times 1 + 107 = 369$, its denominator.

To obtain the ninth and last fraction $269 \times 2 + 191 = 729$, its numerator, and $369 \times 2 + 262 = 1000$, its denominator.

The following are the approximate fractions as they have worked out in this example:

1	2	1	2	4	2	2	1	2	= partial quotients.
+	—	+	—	+	—	+	—	0	
$\frac{1}{1}$	$\frac{2}{3}$	$\frac{3}{4}$	$\frac{8}{11}$	$\frac{35}{48}$	$\frac{78}{107}$	$\frac{191}{262}$	$\frac{269}{369}$	$\frac{729}{1000}$	= the approximate fractions.

After the first and second approximate fractions have been found, the remaining fractions can be obtained by working according to the following rule. Multiply the numerator of the last fraction found, by the next partial quotient, and to this product add the numerator of the preceding fraction; the sum will be the numerator for the next fraction. Take a similar course for the denominator, that is, multiply the denominator of the last fraction found, by the same partial quotient as was used to obtain the numerator just found and to this product add the denominator of the preceding fraction; the sum will be the denominator for the uncompleted fraction. Continue in this manner until all the partial quotients have been used, and fractions obtained. The last fraction will be the original fraction, or a fraction of equal value. In this case, it is 729/1000.

The fraction 35/48 derived from the fifth partial quotient in the continued fractions, has been selected as the one which can best be used, and being factored and raised to higher terms, thus:

$$\frac{35}{48} = \frac{7 \times 5}{6 \times 8} = \frac{56 \times 40}{48 \times 64} = \text{the gears chosen.}$$

Proof: $56 \times 40 \times 10 \div 48 \times 64 = 7.2916 +$ inches, an error of 0.0016 inch, which is near enough for all practical purposes.

Proving an Approximation.

By continued fractions you may be in doubt whether or not a chosen approximate fraction will be near enough to the required one to allow its use. Then prove it.

Example:

Suppose you should desire to cut a screw of 2.243 turns per inch, and being unable to factor it, you obtain approximate fractions, thus:

```
243)1000(4
     972
     ---
      28)243(8
         224
         ---
          19)28(1
             19
             --
              9)19(2
                18
                --
                 1)9(9
                   9
                   -
                   0
```

+	—	+	—	0
4	8	1	2	9
$\frac{1}{4}$	$\frac{8}{33}$	$\frac{9}{37}$	$\frac{26}{107}$	$\frac{243}{1000}$

Selecting 9/37 you decide to cut 2.9/37 turns per inch, instead of 2.243/1000 turns per inch. Then to find how near this selected fraction is to what was first wanted, you reduce it to thirty-sevenths, thus, $2.9/37 = 83/37$ and dividing the numerator by the denominator, the quotient will show how near this selected approximate fraction is to the required thread, thus:

$$83 \div 37 = 2.243243 +$$

What we obtain by this selection is....	2.243243
What we wanted was..................	2.243000
	0.000243

This error is so slight that for all practical purposes it may be used.

Supposing your lathe has a lead of 4 turns per inch, your ratio would be thus expressed: $\dfrac{4}{\frac{83}{37}}$. Reducing the lead of the lathe to the same terms (*viz.*, thirty-sevenths) you obtain $\frac{148}{37}$, then $\dfrac{\frac{148}{37}}{\frac{83}{37}} = \dfrac{148}{83}$ which being factored equals

$$\frac{74 \times 2}{83 \times 1} = \frac{74 \times 70}{83 \times 35} = \frac{\text{Drivers.}}{\text{Driven.}}$$

General Proof.

Product of driven gears by lead of lathe, thus, $83 \times 35 \times 4 = 11620$.

Product of driving gears $74 \times 70 = 5180$, and $11620 \div 5180 = 2.243243 +$ or the turns per inch this combination will cut.

It will be noticed that one example is for the lead, while the other is for the turns per inch.

No doubt some of your readers will say that this article is entirely too elementary, and enters too much into detail. Should that be the case, my reply would be that it was written for those who needed just such details.

* * *

MACHINE SHOP PRACTICE.*

RE-PLANING A LOCOMOTIVE DRIVING-BOX.

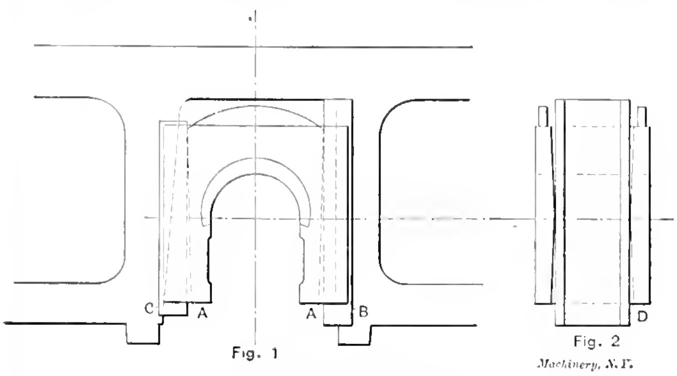
When a locomotive is being repaired, particular attention should be given to the driving-boxes, for if this part of the work is slighted and the boxes overhauled improperly, the result will be manifest, after the engine goes into service, in the shape of pounds which are difficult to overcome. As is well known, each driving-box is held in its place by a shoe and wedge which are fitted to the jaws of the locomotive frame. The usual construction is to have one of these jaws tapering, as shown in the illustration, Fig. 1, with a corresponding taper on the back of the wedge so that as the wedge is raised or lowered the distance between the faces of the shoe and wedge can be varied. When the box is in its place, the wedge is adjusted until the box is just free enough so that it can be moved up and down, for when the engine is in motion there is more or less of this vertical movement which would be impossible if the wedge were set up too tightly. This continual movement of the box results in more or less wear on its shoe and wedge bearing faces, and, consequently, it finally becomes necessary to replane these faces in order that the boxes may have a free movement with a minimum amount of lost motion.

When the brasses are considerably worn and need to be renewed, the new ones should be put in the boxes and bored before the shoe and wedge bearing faces are planed. The brasses are usually forced into place under considerable pressure, the ultimate pressure ranging from 10 to 18 or 20 tons, depending upon the sizes of the boxes, and the result is that the bottoms of the boxes generally spread apart, sometimes as much as 1/16 inch. Obviously, if the shoe and wedge faces of the box had been planed previously, the insertion of a new brass would render them unparallel. The boring of the brass for the journal should also be done prior to the planing operation, as the removal of the metal when boring has a tendency to cause the sides of the box to spring inward or toward its original shape. The dotted lines *A* in Fig. 1 show in an exaggerated manner the shape of a box planed prior to boring. It will be seen that if the faces of the shoe *B* and wedge *C* are parallel with each other, the bearing between them and the box will be at the top, leaving the bottom of the box free to move back and forth. This lost motion will result in a pound when the engine is in service, and this will increase as the springs weaken, causing the frame with the shoe and wedge to lower. Trouble of this kind, however, is not always

* With Shop Operation Sheet Supplement.

due to improperly planed boxes, for, as the brass wears, the sides of the box tend to close in, especially if equipped with poorly-fitting cellars.

When a locomotive is to be equipped with a new set of boxes, it is the usual practice to do the planing work on all of them at the same time, which is, of course, the most economical way. When re-planing, however, it is often impracticable to plane more than one or two boxes at a time because of variations in their size, unless it is desired that there be no such variations. Of course a set of boxes of different sizes might be lined up to prevent removing too much metal from the larger ones, but this would require considerable time, and



Figs. 1 and 2. Views showing Effect of planing Box prior to Boring, and Box with Tapered Flanges.

it is doubtful if the work could be accomplished as quickly in this way as when planing the boxes in pairs, taking care to select those most evenly matched.

In Shop Operation Sheet No. 70, accompanying this issue, the method of laying out a box preparatory to planing has been described. It is the common practice on railways to bore the brasses of all boxes central with the shoe and wedge bearing faces. Therefore, when planing these faces, the boxes are laid out from the bore or, from what is practically the same thing, the surfaces t and u. The points J and K should be located so that the minimum amount of metal required to make the shoe and wedge bearing faces central and parallel, is removed. In setting the box on the planer the sides which come next to the wheel hub should be set at right angles to the platen, or the bore may be set parallel with it by testing the side of the bearing with a surface gage. The finishing cuts should leave the faces smooth and flat to insure a good bearing, thus reducing the wear of the box to a minimum.

Frequently, locomotives are equipped with boxes having flanges which taper from the center toward each end, as shown in Fig. 2. When planing boxes of this kind, it will often be necessary to shift them in order to plane out the tapered portion D of the faces, which the tool could not reach on the first cut. It is necessary that these corners be removed so that when the shoe or wedge is placed between the flanges, as shown in the illustration, it can be given a rotary movement, the centers of the flanges acting as a pivot. The reason why box flanges are tapered for the purpose of giving this play between the box and the shoe and wedge, is to prevent the flanges from breaking, and the tapering flange is especially desirable on rough roads. When a locomotive running at a high rate of speed strikes a curve, the relative positions of the wheels and the engine frame are momentarily changed. This change is caused by the elevated track and the inertia of the mass supported upon the springs and the flexibility of the springs. When the wheels come to a curve, the outer ones ascend the elevated outer rail so quickly that the driving-boxes are forced upward against the tension of the springs. If the box flanges were not tapered, permitting this movement, there would be danger of their being broken. Therefore, in re-planing the shoe and wedge bearing faces of a box, the importance of planing out the tapered portions of the faces will be understood.

* * *

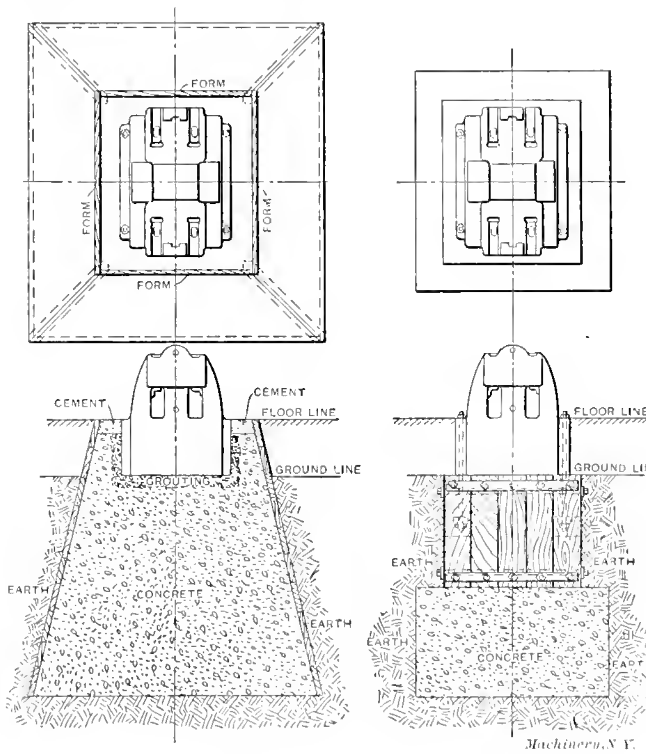
The motor car trade of Germany in 1907 is stated in the British Consular report to be somewhat less than was expected. The supply greatly exceeded the demand, and the heavy cost of repairs is stated to have contributed largely to the bad condition of the trade.

DROP-HAMMER FOUNDATIONS.

The E. W. Bliss Co., Brooklyn, N. Y., builder of drop forge hammers, contributed the following information regarding the construction of drop-hammer foundations.

The endurance and effectiveness of drop-hammers depend in no small degree upon the proper ratio between the weight of the base and the weight of the hammer. It has been demonstrated that 12 to 1 is decidedly better than a smaller ratio, and that the best results are obtained with a ratio of 15 to 1 or 16 to 1 with all parts made in proportion; the extra cost of the heavier machine being more than compensated for by the larger quantity and better quality of the finished product and by the comparative freedom from breakdowns.

For the successful operation of drop-hammers, it is very essential to have a good foundation. Both of the types here illustrated have been found to give good results. The wood cushion foundation, as shown in Fig. 2, is used where the bottom is not good and where the jarring of the surrounding buildings is objectionable. The solid concrete foundation shown in Fig. 1 is recommended as best when it can be used, as it is like a continuation of the base on the hammer, and therefore makes the drop more efficient. In deciding the depth of foundation of either of the above types, care should be taken to determine the best point to stop the excavation. Bed rock is the best bottom, cement gravel next best, and a strata of sand or clay, say 4 feet thick, and in its original



Figs. 1 and 2. Drop-hammer Foundations of Solid Concrete, and with Wood Cushion.

and undisturbed condition, also makes a good bottom. The trouble with sand or clay is that on account of the heat of a drop forge shop drying the soil and a continual jar, they are apt to shift provided they get an outlet in the shape of other near excavations. By spreading the bottom of the foundation the desired result is sometimes obtained without going very deep, but for any size of drop-hammer the concrete should not be less than 4 feet thick, whether the wood cushion is used or not.

* * *

In an interesting little pamphlet, published by a German investigator, Mr. Hermann Nelkes, regarding the unit of measurement and the system according to which the Cheops pyramid in Egypt was built, the author mentions that he finds that the dimensions of the pyramid and its integral parts are in such proportions as to indicate that the unit of measurement employed was identical with the English foot or, in other words, that the standard length of the English foot has its origin in, and came down to our time from, the standard of length in Egypt about six thousand years ago.

COMPARATIVE TEST OF ABRASIVE DISKS ON CAST IRON.

This test was made at the shops of the Gardner Machine Co., Beloit, Wis., to determine the comparative efficiency for grinding cast iron, of different kinds and makes of disks, such as are commonly used in connection with disk grinders. In the following table the different kinds of disks are indicated by figures:

No. 1 indicates the Gardner improved abrasive disk No. 126, which is further described in this article. No. 5 is the regular No. 24 commercial emery cloth. No. 6 is the same in emery paper. Nos. 2, 3 and 4 are proprietary articles of excellent quality as compared to commercial emery cloth, and all are well known by trade names, being extensively used.

The disks tested were all 20 inches in diameter and all excepting Nos. 5 and 6 were No. 16 grain. The grinding was done on the ends of hollow blocks of cast iron as shown in Figs. 1 and 2. The area ground at the end of blocks was 5 square inches. Reducing the blocks one inch in length, indicated the removal of 5 cubic inches of metal. The grinding was all done on the same machine by the same operator. Fig. 3 shows the method of handling the work, and twelve blocks which have been considerably reduced from original length. Usually twelve blocks were operated on together.

TEST OF EFFICIENCY OF ABRASIVE DISKS.

Disk Number.	Time Used in Minutes.	Stock Removed in cubic inches.	Number of Times Dressed.	Average Cutting Rate, cubic inches per min.	Cutting Rate, First Half of Time Used.	Cutting Rate, Second Half of Time Used.	Life of Disk, Based on Disk No. 1.	Stock Removed, Based on Disk No. 1.
1	754	349.85	0	0.464	0.442	0.486	100. %	100.0%
2	137	42.13	6	0.307	0.344	0.270	18.1%	12.4%
3	540	113.95	0	0.211	0.238	0.184	71.6%	32.3%
4	68	27.97	2	0.411	0.546	0.276	9 0%	8.0%
5	71	2.41	4	0.034	0.062	0.006	9.4%	0.7%
6	73	12.48	2	0.171	0.273	0 069	9.7%	3.5%

The micrometer stop at the back of the table was set to grind off a fixed amount, usually 0.050 inch, and the twelve blocks ground to the stop. The stop was then moved back 0.050 inch and the operation repeated until the blocks became too warm for efficient grinding, when they were cooled, and the time of grinding and the amount of metal removed, noted. This was repeated until the disk was worn out or the blocks all ground up. In the latter case, new blocks were substituted and the operation continued until the disk was worn out. By reversing the blocks they were ground down until the wheel touched the handles on both sides. During this test several hundred pounds of these blocks were converted into cast iron chips.

In the table given above it will be noted that it was necessary to use a Huntington emery wheel dresser on all disks tested except Nos. 1 and 3. The dresser was used whenever

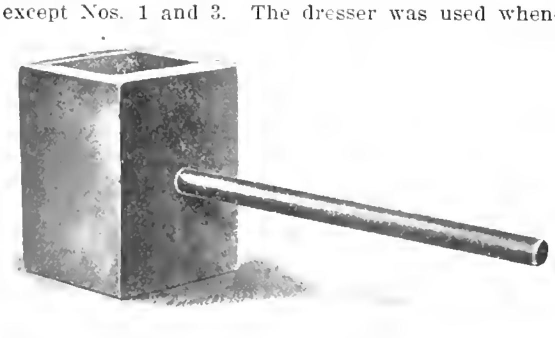


Fig. 1 Form of Hollow Cast Iron Block used for Test.

the surface of the disk became dull and glazed so that it would not cut cast iron readily. The use of a dresser shortens the life of the disk, but it was absolutely necessary. The results obtained are given in the foregoing table.

The disk called No. 1 in the table is made by an entirely new process. The abrasive grains are mixed with required bond and the mixture is cemented to a cloth backing. While in a plastic condition the abrasive grains are *mechanically* tilted to an efficient cutting angle. Careful examination of a disk treated by the tilting process will fail to show any large grains with large flat faces fixed parallel to the plane of rotation. On the other hand, before being subjected to this tilting process a great majority of the grains present their largest flat surfaces parallel to the plane of rotation, *i. e.*, the surface of the work being ground. It is obvious that the flat side of a grain will not cut so freely as a

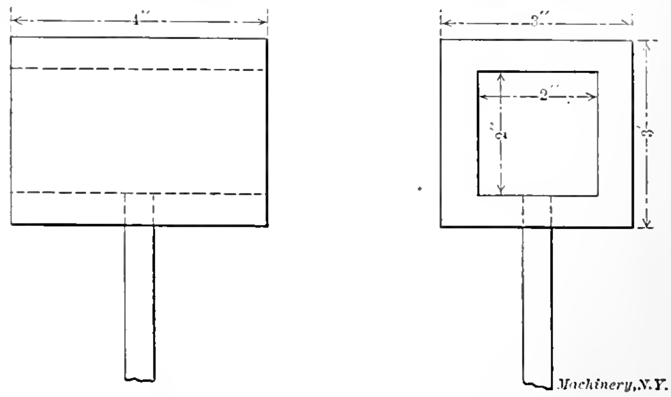

Fig. 2. Hollow Cast Iron Block used for Test.

sharp edge. The truth of this is evident from results shown in the table.

Another very noticeable feature of the No. 1 disk is the uniformity of its cutting efficiency from start to finish. As shown in the table, the disk removed stock just as fast during the last six hours as it did the first six.

All the other disks tested are made by depositing a heavy coating of glue on the backing sheet and then spreading a quantity of dry abrasive grains onto the glue. The abrasive grains settle into the glue and so become firmly attached to the backing sheet. By this process the grains and glue are

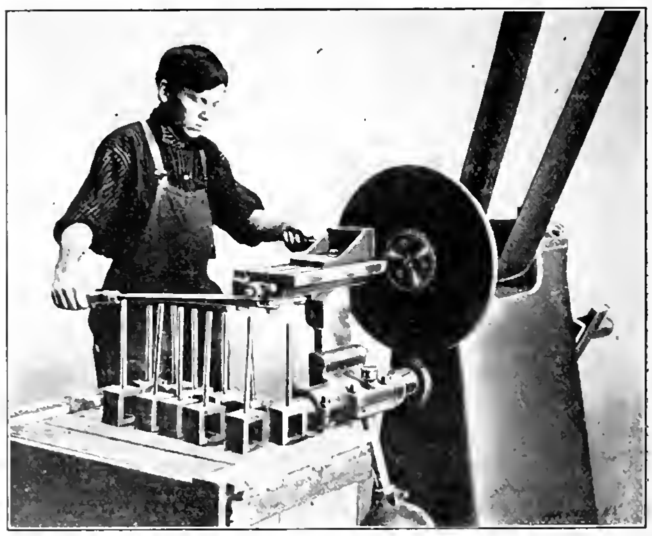

Fig. 3. Method of Grinding Blocks in Test.

not evenly mixed from face to back. Disks made in this way cut freely and rapidly at first, but soon wear down to a point where there is too much glue and not enough of the abrasive grains. This fact is plainly evidenced by record of disk No. 5, in the columns giving average cutting speed for first and second half of the time used.

The illustrations Figs. 4 and 5 show operations on work done with disk No. 1. Fig. 4 shows grinding of impellers for centrifugal pumps. These are gray iron castings and are very rough and hard in places, making them difficult to machine in a lathe. The diameter is 26 inches, and the area of surface ground is about 50 square inches on each side. It was necessary to remove ¼ inch thickness of metal at some points. The rate of grinding these impellers on both sides was fifteen minutes for each impeller. The former time for turning in a lathe was three hours and thirty minutes for each impeller. The pieces are ground at an angle of seven degrees to the axis, and the surface of the blades being curved and not radial, necessitates their being revolved while grinding. This develops the surface of a cone. The impellers are mounted on a spindle driven by a worm gear and worm connected with a hand-wheel, as shown. This fixture is mounted

on a lever feed table set at the required angle with the face of the disk wheel, and the impeller is slowly revolved by means of a hand-wheel while the lever is used to bring it against the disk wheel.

Fig. 5 shows a rather interesting job of disk grinding of special cast iron latticed plates. These plates are used in the manufacturing of the grinding disks No. 1 in the foregoing table, and are required to be accurately flat and of uniform thickness. They are 23 inches diameter by 7/8 inch deep. The rings and spokes that go to make up the plates are 5/32 inch thick. The castings being so thin, it was found to be impracticable to machine them in a lathe or boring mill, but results obtained with a disk grinder are entirely satisfactory.

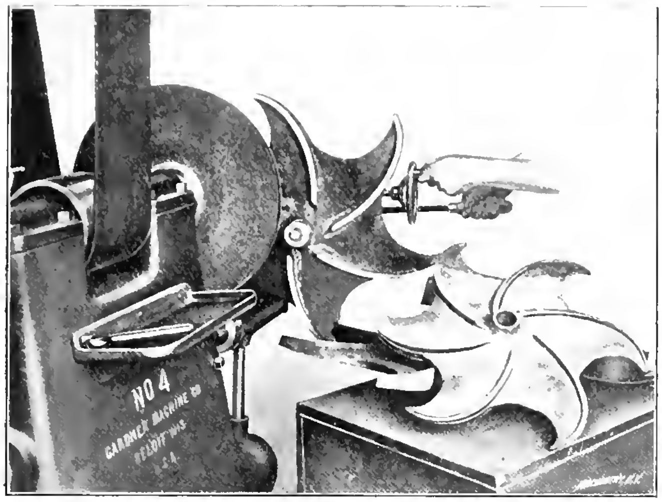

Fig. 4. Grinding Vanes of Cast Iron Impellers.

The plates are chucked at the inner circle, which is about 6 inches diameter, on a metal disk having heads of set-screws projecting from its periphery. This disk has a 3/4 inch hole in the center, fitting a stud in the angle plate which is bolted to the top of the lever table, as shown. The latticed plates are hung on this stud, bearing against the angle plate, and are pressed against the disk wheel by the lever. They are, of course, free to revolve with the wheel, but the speed of this revolution is easily controlled by changing the relative position of the stud to the axis of the machine spindle, and also by the hand of the operator, as shown. By changing pressure on the lever and by swinging the table on the rocker shaft the revolution of the plates can be increased, stopped entirely or reversed at the will of the operator.

The castings for the plates are made in a stove foundry and are quite accurate to pattern, but too hard to turn. The amount of metal to be removed to make them accurately flat, is small, averaging less than 1/32 inch each side. By the method shown, they are finished to the required size and made flat on both sides in about fifteen minutes.

Figs. 6 and 7 are reproduced from a photograph of Gardner's improved abrasive disks. Fig. 6 shows No. 1 disk used in the grinding test. Fig. 7 is the same kind of disk, but made of a much finer abrasive and being lighter in color, shows very plainly the corrugated surface which produces the mechanical tilting of the abrasive grains.

* * *

A correspondent of the *Engineering News* says that the greatest inventor and engineer of the nineteenth century, whose inventions have spread over the civilized world, once said to him: "If people knew how little I know, they wouldn't come to me for advice." Think of a lawyer or doctor or a "man of affairs," whatever that may mean, making such an admission to a client. Does the experience and training of the engineer, which constantly forces him to honestly deal with the laws of nature which underlie all his work, produce a type of man that is more honest, simply on account of his technical training and the influence of the work to which he devotes himself?

* * *

Tracings and drawings that have been rolled up can be flattened by rolling them in the reverse direction from that in which they have been kept, forming the roll into a conical funnel shape, and holding the wide end over the flame of a lamp, so that the hot air can circulate over the surface of the drawing. When unrolled, the drawing will be found to lie flat.

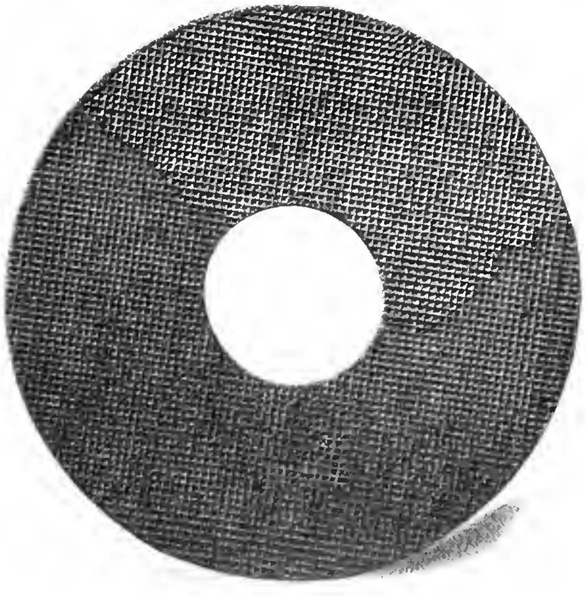

Fig. 7. Same Type of Grinding Disk as shown in Fig. 6, but with Finer Abrasive.

LETTERS UPON PRACTICAL SUBJECTS.

SHEET METAL DRAWING.

Only those who have made a specialty of drawing sheet metal know just how to proceed to lay out a die so that the desired result will be a certainty the first time it is tried. Recently the writer has had quite a little experience on this class of work and a few of the kinks that I discovered and some which I had explained to me by others, follow.

First, we are confronted with finding the diameter of the blank. There are several methods by which we can determine the size of the blank. One way is to cut out a blank of the same thickness as the stock of which the model shell is made, and then keep reducing the diameter until the blank balances the model. Another way is to multiply the circumference by the height and add the area of the bottom, which gives the area of the blank, then find the diameter of a circle whose area is equal to the area found. This latter rule applies to blanks that must be of a uniform thickness on the sides and bottom. But if the article should be an ordinary box or something allowing a variation of thickness, the size of the blanking die can be much smaller. By this, I mean that a shell 3 inches long can be drawn from a blank 3 inches diameter, or from a 2-inch blank. The sides and bottom will, of course, be thinner. A good rule to follow is to make the height of the shell at first draw, one-third the diameter of the blank, that is, a 3-inch blank, for best results, should produce a shell 1 inch long at first draw. The shells should be annealed if drawn to any length.

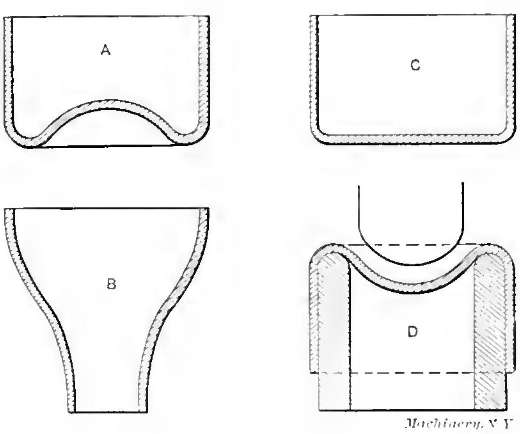

Fig 1. Method of Drawing Shells which gives a Minimum Variation in Wall Thickness and a More Even Distribution of Stretch

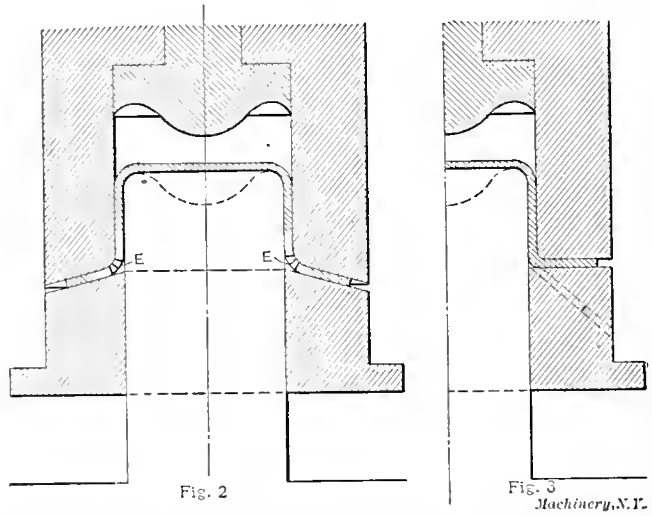
Fig. 1 shows a novel kink when the blank is to be drawn into a shell of length or into a shape as shown at *B*. The first operation leaves the shell as shown at *A*, and this will save at least one drawing operation. It will be noted that the indented end in the shell bottom presents surplus stock, so to speak, whereas, if it is drawn at the first operation in the ordinary way as shown at *C*, the succeeding operations must be gentle to prevent a greater reduction in the thickness of the walls on the angular sides of the shell. Another advantage in shaping the first shell as shown at *A*, is that when drawing it to the angular shape, the stretch or draw of metal is more evenly distributed over the entire surface and the strain on the metal is not as great as if the draw commenced at the corner. Another novel feature (to the writer) is to shape the blank as at *A* (if the shell is to be a long one) and then use a die for the second operation, as illustrated at *D*. The blank, when forced through, is actually turned inside out. This operation presents two good points to the writer. First, we are enabled to get a suitable amount of stock in the shell in such a shape as to draw to the best advantage. Second, if the shell is to be a long one, the diameter of the blank must of necessity be large, therefore the stock is distorted considerably in changing from a flat blank to a shell of much smaller diameter, and if we could see the grain of the stock as it passes over the die, it would present an appearance similar to that shown by the lines *E* in Fig. 2. That is, the inside of the stock stretches and the outside compresses. Therefore, by turning the shell inside out, the stock is apparently restored somewhat to its original texture of close grain, which will allow further stretching.

A very important point which must not be overlooked is the angle on the face of the stripper and blanking punch. I have found that in making long, small diameter shells, that if the angle on the stripper and blanking punch is, say 8 degrees, every shell would break out at the corner; but by changing the angle to 10 or 12 degrees, that they would come out without breaking. This point can be better understood by referring to the half section, Fig. 3. It would be almost impossible to draw the shell when the edges of the blank were at right angles to the shell, but by making the angle of the punch and stripper as shown, exaggerated by the dotted lines, the shell is practically drawn by the blanking punch, and leaves very little work for the drawing punch.

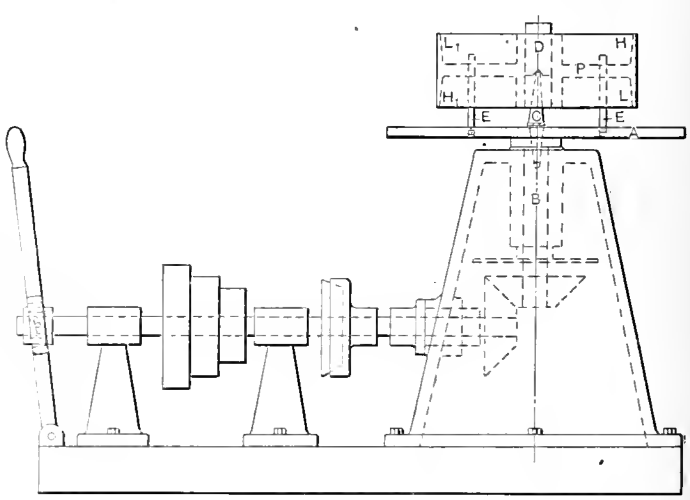


Figs. 2 and 3. Diagrammatical Views illustrating the Stretch of the Metal and the Effect of Angular Punch and Stripper Faces.

Pittsfield, Mass. FRANK E. SHAILOR.

PULLEY BALANCING DEVICE.

Most machinists have, at some time or other, met with problems in balancing which have been difficult to solve. It is easy to obtain a fairly accurate static balance on a pair of parallel ways, in the ordinary manner, but if the pulley or other part to be balanced is wide, and runs at a high speed, this method is not altogether satisfactory, as one edge may be heavy on one side of the pulley, and the other edge on the opposite side. When this condition is present, there is a vibration when the pulley is running at high speed, which causes unnecessary strain on the shaft on which the pulley is mounted, and on the adjacent bearings. The writer lately saw an old machine designed for obtaining a running balance, which may be of interest to some of the readers of MACHINERY.



Device for the Dynamic Balancing of Pulleys.

An outline of this machine is shown in the accompanying line engraving.

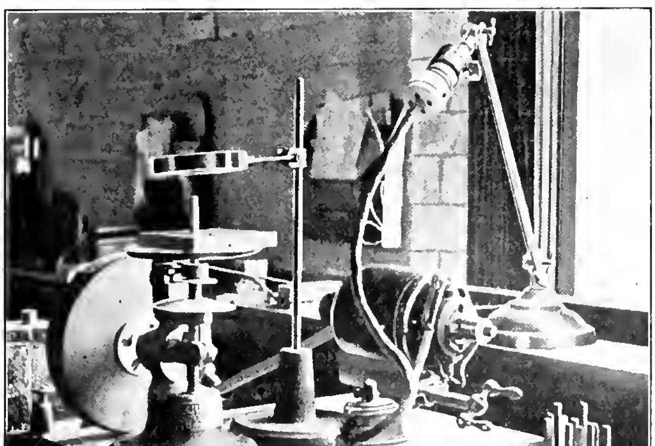
The lower part of the illustration shows the frame and the driving details. At the right-hand end is a stand on which is mounted a plate A, which is, by suitable means, fastened solidly to the shaft B, and revolves with it. Into this plate and shaft is inserted a taper pin C, having a round point at its upper end. In the plate are further inserted two rods or pins E, which are screwed into holes about half-way between the center and the outside periphery of the disk A. These pins serve to drive the pulley P being balanced.

In balancing a pulley, the static balance is first approximated by the usual methods. A plug D with a large center is then driven into the bore in the pulley, so as to extend about half way through the hole, and the work is then placed on the machine in the position shown in the engraving, the center of D resting on the round point of C, so as to bring the latter approximately to the center of gravity of the pulley. If we now assume that the points H and H_1 are the heavy points, then, when the machine is started, these points will throw outward, on account of centrifugal force, and the pulley will assume a tilted position, H moving downward, and H_1 rising until a state of equilibrium is reached. The pulley can then be marked by a piece of chalk. After marking the pulley, the machine is stopped, and weights added in equal quantities on opposite sides at L and L_1, or metal may be removed at H and H_1, whichever is most convenient. If either H or H_1 comes in line with the weights used for static balance, these weights can be moved up or down, whichever is required, producing the same results. Now the machine is started, and the pulley is tried again, and the balancing process repeated until it will run truly balanced at full speed.

ALLAN.

A HANDY FILING MACHINE.

The engraving illustrates a very convenient filing machine which is in use in the Remington-Sholes typewriter factory, for filing dies. It consists of a small filing machine to which an old center grinder has been attached by means of a couple of wood pulleys and a belt. The whole thing is mounted on



The Filing Machine with a Reading Glass mounted above it.

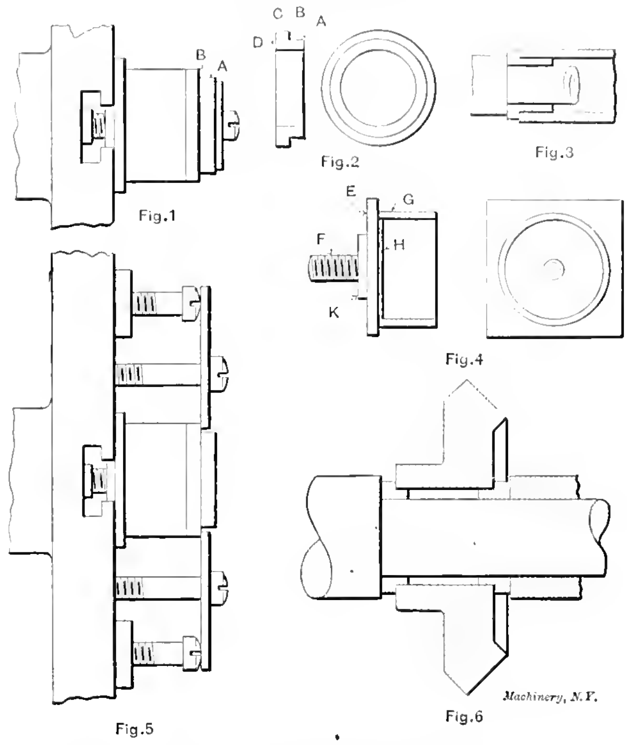
a cast-iron base and may be moved anywhere and attached to an electric light socket, and it is ready for use. The engraving also shows a very good way of using a large reading glass. The mount for this, of course, being movable.

Decatur, Ill. ETHAN VIALL.

SMALL ACCURATE FACE-PLATE WORK.

Not long ago I had some soft steel bushings to make, as shown in Fig. 2, where the part A was to be concentric with the hole, and the faces B and D flat and parallel, and square with the hole. The part C was not particular, and was left with the finish of the original surface of the cold rolled shafting of which they were made. There were four sizes of these bushings, and only two of each size to be made. They were to be put on milling machine arbors used for holding bevel gear blanks when cutting the teeth, as shown in Fig. 6, thus making each size of arbor do for more than one size of hole. I wanted to make a rather accurate job of them, and not let an error of over 0.0002 inch creep in, if I could help it. As this is not an unusual type of job, I thought a few simple fixtures could be made that might afterwards be used on similar jobs where considerable accuracy was required.

For ordinary work these bushings would be turned on an arbor between centers, as the holes were standard sizes, but I thought a more accurate job could be done on the face-plate of a bench lathe, so that was the way I adopted. My draw-in chuck for the bench lathe was fitted some time ago with a



Miscellaneous Views showing Piece to be machined, its Use, and Method of holding to Face-plate.

reducer and auxiliary draw-spindle to take the smaller sized chucks of a watchmaker's lathe, and I found that by taking out the main draw-spindle and putting in the auxiliary draw-spindle alone, the front end of it fell a little short of coming through to the front of the face-plate, so I made a bushing as shown in Fig. 3, making the hole to fit over the auxiliary draw-spindle, and the outside of the bushing to fit the back end of the hole in the lathe spindle. This bushing kept the auxiliary draw-spindle central, and gave it a shoulder to work against. The piece shown in Fig. 4 I have called a false face-plate, for want of a better name, and of these I have three different diameters at present. E is made of square brass rod for the small sizes, and thick sheet brass for the larger sizes. It has a round hub K turned on the back that is an easy fit in the regular face-plate. There is a hole tapped all the way through E the same size as the threaded part of the auxiliary draw-spindle. The steel stud F is threaded its entire length, screwed through E, and sweated and riveted tightly into it. The front end of F has a small hole tapped in it, while the front end of E has a boss turned on it which is an easy fit in the bore of the short piece of seamless brass tubing G which is sweated fast to E. In use, the false face-plate is held tightly against the regular face-plate by the auxiliary draw-spindle taking hold of the stud F, and a light cut is taken over the outer face of G just before clamping the work on it. This gives a face-plate that is easily trued up just before using, and on which work may be clamped either by four clamps on the outside or by a large washer and screw inside. The bushing shown in Fig. 2 was first held in a cast iron step chuck, bored to size with a slide rest tool, and D was faced, after which the shoulder was roughed out on an arbor between centers. The bushing was then lightly held against one of the false face-plates by a screw and washer, as shown in Fig. 1, and shifted about until it ran

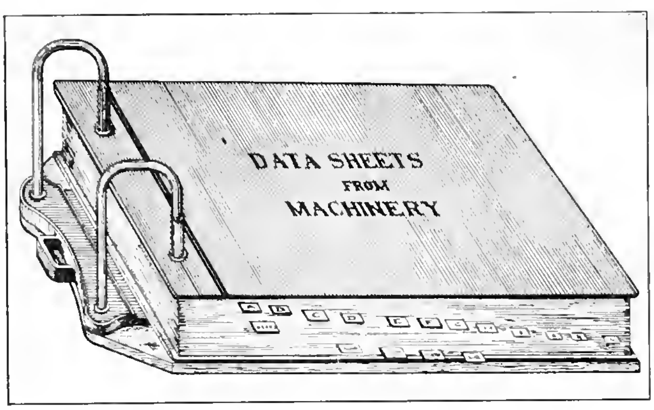
approximately true, after which four clamps were arranged around the outside, one for each T-slot; two of these clamps are shown in Fig. 5. The central screw and washer were now removed. This gave free access to the hole, and a dial indicator applied to the bore told when that ran true. Then the outer clamps were tightened and another look was taken at the indicator to make sure that nothing had shifted during the final tightening of the clamps, after which the central screw and washer were replaced, screwed home tightly, and the outer clamps removed, which gave free access to the outside, so the diameter *A* and face *B* (Fig. 2) could be turned.

Of course, in doing work in this way, only light cuts can be taken, for a heavy cut might cause the work to shift. The brass tube *G*, Fig. 4, is a piece generally taken from the scrap box. After considerable use, tube *G* will be gradually turned off until the outer end is about flush with the front of *H*. When this occurs, the remains of *G* can be "soldered off," as a Teutonic friend of mine used to say, and another piece of tubing soldered on in its place, thus giving the device a new lease of life. *G* is made of brass because it solders easier than steel, and also because a more accurate cut can be taken from brass, as less pressure is required to keep the tool to the work. The lack of durability is of no importance, as the working face of *G* is supposed to be trued up immediately before using. WALTER GRIBBEN.

Brooklyn, N. Y.

FILE FOR MACHINERY'S DATA SHEETS.

The accompanying engraving illustrates a scheme which I have found very useful for filing and indexing, in a systematic manner, MACHINERY'S data sheets. An ordinary arch file is used, small, rectangular pieces of paper pasted at the edge of the data sheets being used for indexing purposes. In the



Convenient Method of filing Machinery's Data Sheets.

front of the file is placed the alphabetical index of contents supplied with the data sheets, and in addition to this index I have a supplementary alphabetical index for the sheets that arrive from month to month. This gives all the advantages of a loose-leaf notebook, permitting new sheets to be conveniently added and indexed. SAMUEL G. ARONSON.

Philadelphia, Pa.

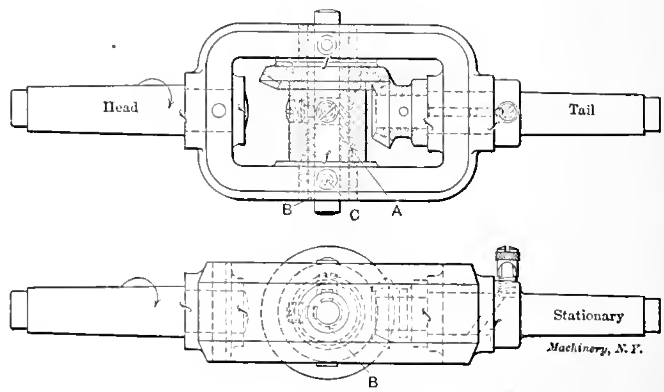
DOES PREMIUM WORK ALWAYS PAY?

The writer asks the question, Does premium work always pay? because of a case which recently occurred in the factory where he is employed. One of the articles manufactured consists of drawn steel pieces from which the bottom end is cut off after the drawing process. The shape of the drawn part or cup is elliptical, the long axis 3½ inches, the short axis 2 inches, and the thickness of the metal 0.109 inch. The operation of cutting off the bottoms from these cups is performed on a plain milling machine, using saws made from Novo high-speed steel, the saws being about 8 inches in diameter and ¼ inch thick. While being cut off, the pieces are held in a fixture, and a single movement of the lever locks or releases them, so that very little time is consumed in putting them in the machine and taking them out.

The rate fixed for the cutting off of these pieces was 50 per hour, and a bonus was offered at the rate of ¼ of a cent for each additional piece. Recently one operator cut off 2,050 pieces in a day of 10 hours. This, of course, looks all right on the face of it, but in doing so he dulled three saws, and it takes four hours' work for the tool-maker to recut one of them. Therefore, the point I raise is this: Is it profitable to allow a man to work the tools beyond their limit of endurance in this way? It is actually costing more to do the work at this speed than it would working at the speed at which the saws would stand up to the work for a longer time. W. ALTON.

GRINDING FIXTURE FOR END MEASURE RODS.

The fixture shown in the illustration was made to grind spherical end measuring rods 3 inches long, and over. There were three diameters of these rods, ⅜, ½ and ⅝ inch, and three sizes of fixtures were also made to suit. Steel sleeves *B* were made of various lengths for each fixture, to stiffen the rods near the end when grinding. These sleeves had a bearing at each end in hardened bushings which were driven



Fixture for Grinding Spherical End Measuring Rods.

into the fixture body. The sleeves were kept from turning and from sliding endways, independently of the gear, by the tit-screws shown. These screws, in addition, held the rod being ground. Member *A* was a tight fit in the large bevel gear, being made separate to allow of cutting the gear teeth. The flush oilers *C* were placed on opposite sides of the body, so the tendency to throw oil would be done away with as much as possible.

A feature apt to be overlooked is that the numbers of teeth in the two gears must be prime to each other. If not, every certain number of revolutions, depending on the gears used, the wheel will grind into one of the previous cuts. The fixtures were arranged to be used on a bench-lathe, with a tool-post grinding fixture.

Brooklyn, N. Y. G. R. RICHARDS.

VALUE OF COOPERATION.

In a drafting-room in which I have been employed, there were five draftsmen, including myself, and being interested in many technical magazines and in the habit of subscribing for them, I thought of a method by which I could benefit my fellow draftsmen as well as myself. I proposed that we each give 25 cents a month, and, when a sufficient amount was obtained, subscribe for one of the many technical magazines. In this way, at the end of a year, we had a total of $15 worth of magazines at a cost of only $3 a person. The magazines that we subscribed for were: MACHINERY, *American Machinist*, *Industrial Magazine*, *Popular Mechanics*, and *Engineering News*. We made the agreement that if any of us left at any time we should waive all claim on the magazines and leave them as the property of the office, the inference being that we received our money value in the number of magazines we each had an option on for the time we were employed, and for the money expended. If this cooperation was instituted in large drafting-rooms where there are from ten to twenty-five or more draftsmen, one can readily see how much could be collected and how many magazines could be subscribed for. There would soon be established a small library of magazines, which, if kept properly indexed, would form the foundation of a valuable information bureau, which I think the employers would not object to providing a space for, and they might even

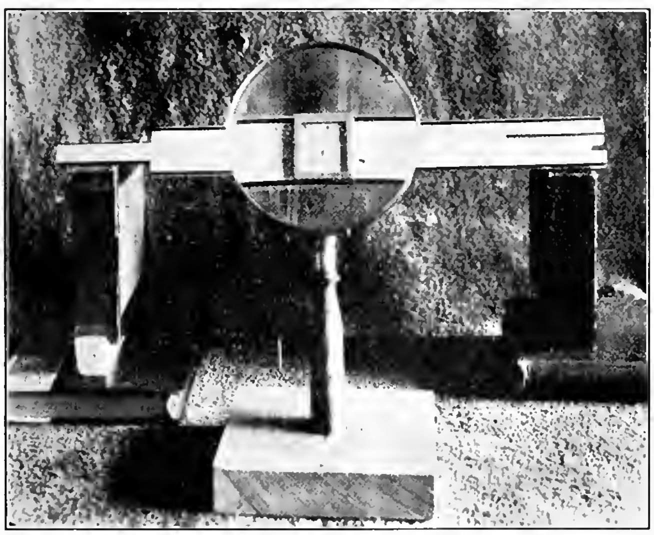
cooperate in the matter. This method could also be instituted in the machine shop, and where there are from one to two or three hundred men they would only be required to give 10 cents a month. The management could be placed in charge of a committee who would take care of all money and the necessary details. It is surprising to see how this idea will develop, and the enthusiasm felt among the men. I have never seen this method in operation except in the drafting-room where I was employed. It is a case where an investment is repaid many fold, and shows the value of cooperation.

Roxbury, Mass. WALTER J. BITTERLICH.

[It is quite evident that the cooperative scheme which has been suggested is not as valuable as it might appear on the surface. Of course, a number of publications can in this way be secured at a low cost per capita, and, in time, there would be a valuable collection of technical literature which would be useful for reference purposes, but, unfortunately, draftsmen and mechanics are not in the habit of staying in one place a lifetime, and consequently the firm alone would be permanently benefited. The man who does not file a technical publication for which he subscribes loses a large part of its value, and while the cooperative method enables him to see a number of good magazines, he is deprived of their use as soon as he goes to work elsewhere. For this reason we believe that it is better to subscribe outright for one first-class technical paper than to have a part interest in half a dozen.—EDITOR.]

READING THE SLIDE RULE ACCURATELY.

A simple device for reading the slide rule more accurately than can be done with the naked eye is shown in the accompanying photograph. The magnifying glass is set in a base,



Stand with Magnifying Glass for Reading the Slide Rule accurately.

as shown, at an angle of 60 degrees. The base is of wood 4¼ inches square and ⅞ inch thick. I have found this a very convenient method for getting closer readings.

Lockport, N. Y. C. H. CORNES.

METHOD OF LEVELING A LINE SHAFT.

We once had a job of putting up a line shaft in a long building, and it was quite necessary that the bearings should be level. There were no engineering instruments about the plant with which to level the shaft, and it was thought that a long wooden straight-edge with an ordinary level was not accurate enough. We were about 400 miles from home and in a small town where we could not get an engineer's level, and were at our wits' end to know what to do without sending to our factory for, or renting one from the nearest city, about 25 miles distant.

We finally got a length of ½-inch hose about 20 feet long, and fastened a regular boiler gage glass to each end. Then we poured in water until it showed about half way up in either gage. One gage glass was then held with the water level at the required height of the center of the shaft and the next hanger set with its center even with the level of water in the other glass. This gave us a very accurate way of setting our brackets, as we had practically a U-tube 20 feet between glasses. When our line shaft was put up, it worked splendidly, and we never heard any complaints.

This was the first time I had ever heard of such an apparatus being used, but there is no reason why it could not be used for getting levels for setting new machinery, piping, or, in fact, anything where the distances are at all long between supports. It can also be used to set shafting at the same level in different rooms, around a corner where the view directly across is obstructed, or in almost any place imaginable. JULIAN D. PAGE.

Youngstown, O.

METHOD OF ACCURATE DRILLING.

Although much time can be saved by the use of drill sockets so constructed that drills can be slipped in while the spindle is revolving, the work does not always come out satisfactorily accurate unless the bushing in the jig is exactly central with the drill spindle. In the shop where the

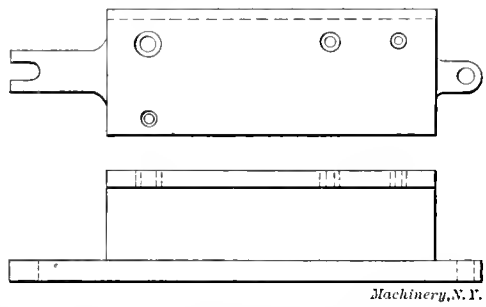


Fig. 1. Outline of Jig for which Jig Plate in Fig. 2 is used.

writer is employed, such sockets are used almost exclusively, but trouble has been experienced with the holes not always being in alignment.

To overcome this trouble, a jig plate, such as is shown in Fig. 2, was made for the jigs, and the work comes out much better, and fewer drills and reamers are broken, because this jig plate makes it possible to have the bushings for each hole, when drilled, in perfect alignment with the spindle. Fig. 1 shows a lay-out of a jig used in drilling exhaust rockers for small gas engines. All the holes are reamed, removable bushings being used for this purpose. The jig is cast with an extension at each end on the bottom side. One of these extensions is slotted, and fits over short pins, shown at A, A_1, A_2 and A_3, Fig. 2. The other end has a hole, to take a taper pin, which enters into the holes A',

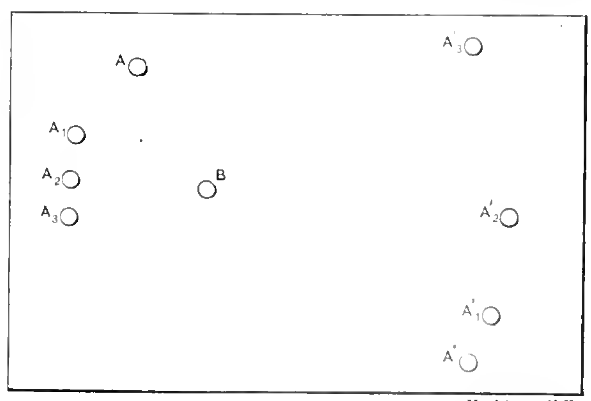

Fig. 2. Jig Plate used for Locating Jig in Fig. 1 on Drill Press Table.

A'_1, A'_2 and A'_3 in the plate, when the slotted end has been placed with the corresponding pin on the other side of the jig plate.

These pins and holes are so located that the jig, when placed between correspondingly located pins and pin holes, will be held in such a position that one of the bushings in the jig will be exactly in line with the drill spindle, provided the plate is originally clamped on the drill table correctly, so that the position of the small hole B is exactly in line with the center of the spindle. When this plate is in use, the jig is first put on the plate with the pin A en-

tering the slot, and the hole in the other lug of the jig is placed over hole A', and the taper pin put in to hold the jig in position. The corresponding hole in the work is then drilled and reamed. The jig is then changed so that the slot in the lug fits over pin A_1, and the taper pin in the other end of the jig is changed to the location A_1', the second hole then being drilled and reamed. In the same manner, any number of holes may be drilled. Jigs with holes at right angles to each other must, of course, have lugs cast on two sides. In the engraving, no binding devices have been shown, as it is not necessary to indicate the design of the jig itself in order to explain the principles of this jig plate.

Y. ZIEGLER.

RACK FOR CHANGE GEARS.

The way we mount change gears in our lathe legs is illustrated in the half-tone and line engraving. There are two lugs cast in the leg, and the change gears are held on a steel rod

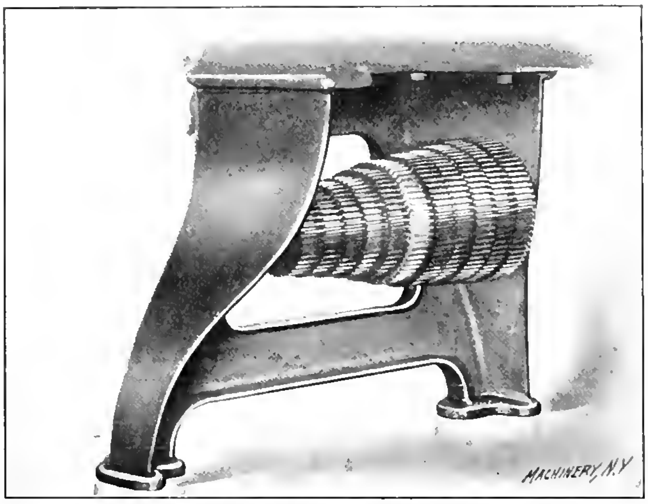

Fig. 1. View showing the Change Gears stored beneath the Lathe.

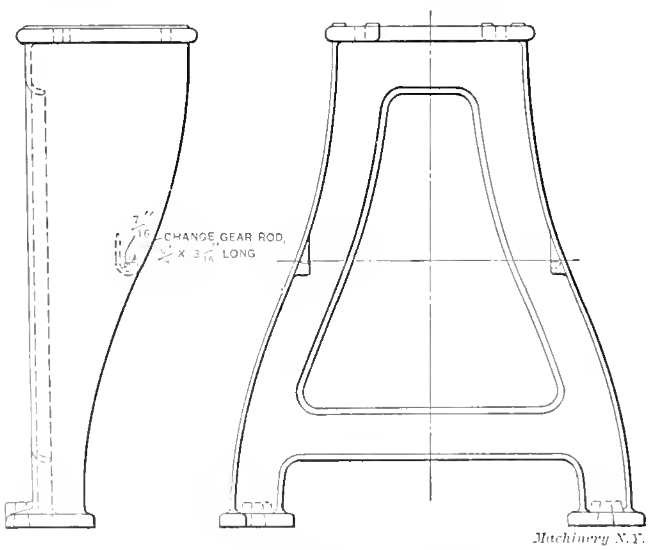
which hangs on these lugs. This makes a very convenient method of keeping the gears clean and at the same time in position where they can be quickly taken off for use. This scheme is new to me, and I thought that perhaps some of the



Lugs for Holding the Rack in Place.

readers of MACHINERY might use this device on their lathes. Of course, they could bolt little hooks to the legs instead of casting lugs on them as we have.

WM. F. GROENE.

Cincinnati, O. R. K. Le Blond Machine Tool Co.

OBTAINING THE HEIGHT OF THE MIDDLE ORDINATE OF AN ARC.

In the March issue F. M. S. gave a method for finding the length of the middle ordinate of a circular arc, given the chord and the central angle. The Editor's note remarked the fact that there are three operations in the solution, of which two are divisions. It was also, and very justly, stated that it is generally easier to multiply numbers than to divide them. By a slightly different method it is possible to reduce the operations to two, of which one is still a subtraction, and the other is a multiplication. The rule given by F. M. S., written as a formula, says:

$$h = \frac{C}{2 \sin x/2} - \frac{C}{2 \tan x/2} \quad \text{where}$$

C = length of chord,

h = length of middle ordinate,

x = central angle.

Substituting for $\sin x/2$ its equal $1/\operatorname{cosec} x/2$ and for $\tan x/2$, $1/\cot x/2$, the equation becomes

$h = C/2 \operatorname{cosec} x/2 - C/2 \cot x/2$, or putting $C/2$ outside a parenthesis,

$h = C/2 (\operatorname{cosec} x/2 - \cot x/2)$, or, expressed in words, the height of the middle ordinate equals the difference between the cosecant and the cotangent of half the central angle, multiplied by half the chord length.

New York. H. S. QUACKENBUSH, JR.

SELF-OILING MACHINERY.

It is always somewhat dangerous to differ with an editor, but to go against an editor and against self-oiling machinery at the same time is a piece of pure devilish recklessness. However, human nature is such that recklessness appeals occasionally even to the most timid, and this, in short, is the reason why I am trying to lift my voice in protest to your editorial under the above heading in the July issue.

Self-oiling machinery is very nice. There is hardly anything in the whole machinery line which can so easily be talked up, and for that reason alone it deserves the appreciation of machinery salesmen if of nobody else. Like a great many other things, the trouble comes afterwards. If I had a shop of my own and a lot of self-oiling machinery in that shop and also an oil-can, I would send the first man I hired for that oil-can and have him go carefully over the self-oiling machinery. Of course, I know that a great many of the most improved steam engines, air-compressors, pumps, and other machines, are made self-oiling. But one should not forget that there is a man in charge of this machinery whose main duty it is to inspect the machinery, practically speaking, constantly, and if anything goes wrong with the self-oiling system, the man is there with an oil-can ready to take the place of the automatic device. If things were arranged in the same way in the machine shop, I would not object so strongly, but this would mean that there must be a man going constantly from machine to machine, inspecting not only the self-oiling device, but especially the gears, bearings, shafts, and so forth, and who must be ready to oil the machines or any parts of the machine if the oiling mechanism has broken down.

Of course, the salesman may tell you that there is really no possibility of the self-oiling system breaking down, but you and I who have been "up against it" know better. We know that there is nothing in this world, and especially in a machine, that will not break down occasionally. The oil-pump may break, or may wear, or spring a leak, the oil pipe may get clogged up, a bug may be forced in one of the pipes, and a thousand other things may happen which temporarily throw the oiling system out of commission, and there is no way of finding it out except when the machine stalls on account of a hot bearing.

From the above, it may seem that I am in favor of having every machine operator hover all the time over his machine, looking to the left and squirting oil to the right, but this is not the case. Personally I am in favor of having the system of oiling machines well regulated; and employing a man whose sole duty it is to look after the oiling of the machines, and to see that the man actually oils the machine and not the floor space around it. And I would have one or two or three men according to the size of the shop, doing this work, become expert at it, and be held responsible for every hot bearing in the place, and as I said before, if I had self-oiling machinery I would have the man just the same.

There are certain advantages connected with self-oiling machines in a power plant, which recommend this arrangement,

but if the engineer in charge of the plant ever gets into the habit of thinking that the automatic oiling arrangement will do the work and that he can read his newspaper in peace, he will soon find out in which corner trouble brews, and it will not be very long before his name will be known no more in that power plant. The main advantages are: saving of oil, uniform, constant, and abundant lubrication. In fact, the main advantage is the flooded lubrication which cannot possibly be given by means of the oil-can. As far as machine tools are concerned, these same advantages would be worth a great deal, but they would be as nothing compared with the trouble of the machine stalling, even once, on account of some little defect in the oiling system.

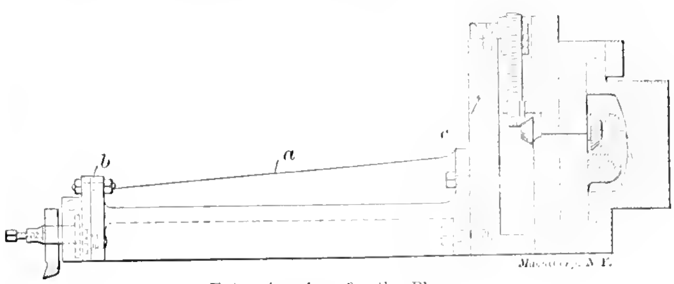
I am not much of a mind reader, but I am willing any time to bet five cents against a nickel that in writing the editorial, the editor had in mind a certain machine advertised in the technical papers mainly for its self-oiling features. The advertisement states that this machine needs to be oiled only once or twice a year, and I presume that the advertisement meant to express the idea that once a year is a good deal better than twice. Now I am of the opinion that to oil a machine only twice a year is bad enough, but to oil it only once is simply horrid. It seems to me that the oil must be so badly deteriorated at the end of a few months that it is absolutely worthless for lubrication, though it may still be good for advertising. Just think of how well bearing No. 6 is lubricated by oil which has been pumped over a lot of bearing surfaces for nearly a year and which carried with it all the grit and dirt and general unrighteousness of the five bearings situated above. And apropos of this machine I notice that the "ad" called the machine self-oiling, whereas in fact, the greater part of the machine must be still treated with homeopathic doses of oil administered by Dr. Oil-Can. I wonder if this same thing would not be the case with practically all machine tools if the so-called self-oiling system were applied to them.

I would like to go into this matter more thoroughly, but this would require more space than I can expect MACHINERY to give when I am hammering at an editorial, and I prefer to call this matter to the attention of the reader and get his opinion. This much I am prepared to say without hesitation: "No self-oiling arrangement for me, except where all the parts to the self-oiling system are constantly and absolutely accessible, and are located in such a way as to be readily inspected and repaired; simple means provided for frequent renewals of the oil, and further, no self-oiling arrangement unless there are also the old-fashioned means for oiling in the old-fashioned way with the old-fashioned oil-can.

Cincinnati, Ohio. A. L. DELEEUW.

EXTENSION ARMS FOR PLANING WIDE WORK.

The article in January issue of MACHINERY entitled, "How a Large Casting was Planed on a Small Planer" recalls to the writer's mind his experience in planing a somewhat similar casting on a 24 x 24-inch Gray planer a few years ago. The



Extension Arm for the Planer.

overhanging end of the casting was guided by rollers in the same manner as was the casting referred to in the January issue, but the length of the surface to be planed in the direction of the planer travel was so great as to necessitate the use of an extension arm on the planer cross-head. The accompanying engraving shows the design of the arm. This design is not original, but is merely one of those old ideas which need to be resurrected occasionally, in order that the rising generation may have the benefit of past experience. These arms, or extension heads, as some mechanics would call them, may be constructed with so little expense that there is small excuse for the bent forgings that are sometimes used instead. The writer found use for two, one about 10 inches long, and the other 20 inches long. The pattern may be produced very quickly as follows: Glue together three boards in the form of an inverted rectangular trough, using boards about ⅜ to ⅝ inch thick, and of suitable length to answer for the job in hand, or any prospective job of reasonable dimensions. The width of the trough should be about equal to the width of the rectangular part of the clapper-box, and its depth may be about the same as the depth (vertical dimension) of the latter. The trough should be closed at the two ends with rectangular pieces about ⅞ to 1⅛ inch thick, and of such width and length as will give ample room for the bolts, as indicated in the engraving. If the pattern be parted in the plane of the top surface of the trough, a light rib *a* will hold the loose pieces *b* and *c* together, and at the same time add strength to the casting. But if the upper portion be given plenty of taper, the cope may be lifted without making the pattern in two parts.

The work of machining the casting is as simple as that of making the pattern. The two ends may be faced in the lathe, on centers, and they should be marked for drilling by the holes in the clapper-box. The bolts which are ordinarily used to hold the clapper-box to the vertical slide will serve to hold it to the outer end of the arm, other bolts being used to secure the arm to the slide. W. S. LEONARD.

PATENT RIGHTS IN TECHNICAL DESCRIPTIONS.

I wish to say a few words regarding a practice which seems to be increasing in the technical press, and that is the growing custom among writers of illustrating and describing patented tools or other articles without mentioning the name of the patentee or maker, or without referring in any way to the fact that they are patented. Not only is this practice an injustice to the inventor or manufacturer because of not giving credit for what he has done—corresponding to plagiarism in literature—but it tends to break down the little protection now afforded by the patent laws. It carries to the mind of the reader the impression that there is no patent on the article described. This is not fair to those who have spent time and money in developing an article and placing it on the market.

An illustration of this practice is found in the July issue of MACHINERY in the article "Special and Adjustable Taps" by your associate editor, Mr. Erik Oberg. Fig. 9 shows the Pratt & Whitney method of securing the blades in its expanding reamers, and Fig. 10 shows the way the inserted blades are held in its large milling cutters. Both of these constructions, I understand, are covered by unexpired patents.

Cleveland, Ohio. J. G. MATTHEWS, Cleveland Twist Drill Co.

[It is not practicable for the editor of MACHINERY to investigate the status of patent rights on all the tools and devices illustrated in its columns. In fact, it is difficult enough for a court of law to decide these perplexing matters, oftentimes. To avoid complications we generally ignore patent rights, leaving them to the investigation of parties interested in the manufacture and sale of the device shown. Scrupulous and prudent manufacturers would not engage in the making of any tool or device without knowing its status in the patent office, while the unscrupulous are not likely to take much heed of the warning "Patented ———" if they think an infringement can be successfully made and sold without prosecution. In the case referred to by Mr. Matthews, the fact that the reamer construction is patented was mentioned in the article "Adjustable Reamers and Taps with Inserted Blades," July, 1907, this article being referred to in the July, 1908, issue. Our contributors will confer a favor by always mentioning the status of patent rights on devices described, if known to them.—EDITOR.]

LAPS AND LAPPING.

I sometimes wonder why we do not see more printed matter on laps and lapping, especially on rotary laps, how to charge them, and their construction. Some time ago I spoke to a very competent tool-maker who was a fellow workman in the tool-room, in regard to laps, and when I mentioned a rotary lap he wouldn't believe that accurate work could be done on such a contrivance without jabbing the corners into the lap or spoiling the edges of the work; and he also stated that he had not seen any, and had been employed in some of the best shops in the country. Well, he had a knife-edge square

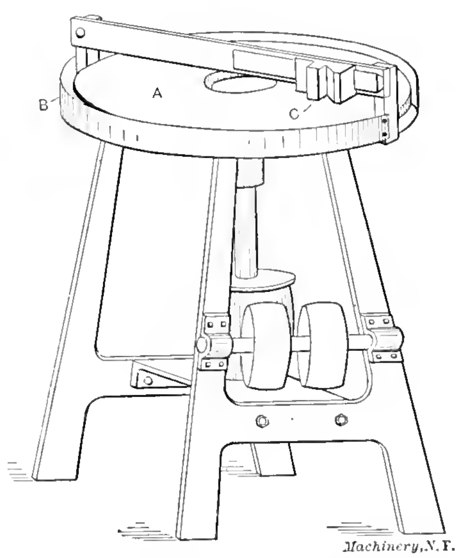

Fig. 1. The Rotary Lap.

that he had lapped on a hand lap, and I had a knife-edge square that I had lapped on a rotary lap, and we found that one was as accurate as the other.

In a small shop where I learned how to use laps, we had a rotary and a hand lap. The rotary was 24 inches in diameter, and the speed about 300 revolutions per minute. The hand lap was about 18 by 20 inches. The engraving, Fig. 1, will give a clear idea as to the construction of the rotary lap. I have found that some men who have used laps have an idea that they should be made with grooves and checks, which I think are fallacies, for I have proved to my own satisfaction that they are not essential for keeping the surfaces from filling with "bird's-eyes." Again, I have noticed that some men think that if the lap has a true, flat surface, anyone can produce true work, but such is not the case; it requires considerable skill, and that skill can be acquired only by trying it yourself. Many machine operations can be shown to another person and the principle grasped readily, but not so with lapping. I know that on many occasions I had the boss show me how he did the lapping, and yet, when I went at it, I could see that there was something that I had to feel and experience for myself. The boss used to say, "You must get in touch with your work." A great deal of skill is required in lapping thin pieces, small straight-edges or long narrow bars. It is possible, and requires no skill at all, to lap a thin piece of steel, convex or concave, by using a little more pressure in one place than another, and if the surface of the lap is not kept sharp it will soon heat and warp the work out of true. I have used soda water, but find that kerosene and gasoline used together give the best results; the hand lap I always used dry. Keeping the surface of the rotary lap straight and true is very important and requires good judgment in using it. The outer edge runs so much faster than the inside that it is obvious that if it is used too much, either in the middle, inside, or outside, hollow places will be worn in the surface, so that it is a good plan to use the lap all over and try the surface frequently with a straight-edge, favoring the high places when using it.

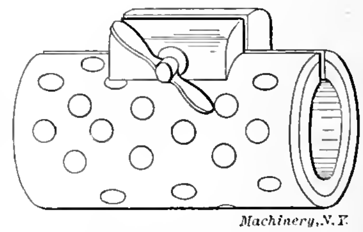

Fig. 2. Lap for Cylindrical Work.

The rotary lap is charged by sprinkling carborundum over the surface when not in motion, and then pressing it in by rubbing with a piece of round iron held in both hands. An old pepper box with a perforated top is just the thing to use for sprinkling the carborundum. The lap I used was made of an ordinary cast iron disk *A* (Fig. 1) with ribs on the bottom and anchor grooves on the top. It is also provided with a hub and a shaft. The end of the shaft supports the whole weight of the lap and runs on a hardened convex disk. A coating of lead is cast over the surface of the lap, and then hammered to make it compact. A galvanized iron pan *B* is provided, the edges of which project above the surface of the lap to prevent the liquid, or whatever is used, from flying off, and onto everything around. Another handy device on this lap is a bar which is provided with ways and a sliding head *C* which can be pushed from the outer edge to the center of the lap. The bar is fastened to lugs which project on opposite sides of the frame, and can readily be removed when not in use. The bar is also provided with adjusting screws to set it parallel with the surface of the lap or to set the sliding head square with the surface. The sliding head has a square corner and an angle groove which can be used for lapping the ends of round or square pieces. I faced the disk by belting it to the slowest speed of the drill press. A piece of self-hardening steel, for a tool, was clamped on the sliding head, and a threaded ¼-inch rod fastened so that it would work through a stationary nut, and by turning the screw slowly, the tool was fed across the disk.

The engraving Fig. 2 shows how I usually make a lap for cylindrical work in the lathe. A piece of wrought iron pipe about 2 inches long, with a number of 5/16-inch holes drilled through will answer the purpose. Face one end of the pipe so that it will stand level on a surface plate; wrap a piece of heavy paper around the outside, using rubber bands to hold it on, then form a square with pasteboard and clamp that on any side of the pipe so that several of the holes open into it; secure a mandrel the same size as the piece to be lapped, twist a piece of string in a spiral around the mandrel, insert it in the center of the pipe, and we are ready to pour the molten lead in. When cool, drive out the mandrel and proceed to drill and tap a hole for a thumb-screw in the center of the lug; then slit one side through the center of the lug with a hack saw, and file off all sharp edges and burrs so that it will not injure the hands. In lapping, the faster the lap is drawn back and forth over the work the more nearly

straight it will be, and as the lap wears and works easy, the thumb-screw is given a slight turn to keep it in contact with the work. I always had considerable trouble with "bird's-eyes" forming on spindles when lapping them, and found that by draw-filing the eyes a little they would disappear, and the frequent scraping of the bright spots in the lap will help immensely. In using flour of emery, I found that by putting a small quantity in a bottle half filled with machine oil, I could get the coarsest emery by dipping a swab down to the bottom, or finer by shaking the bottle a little and using the oil only for finishing, as the coarser particles sink to the bottom while the finest particles are held in suspension in the oil. Taper lapping is very difficult and requires a great

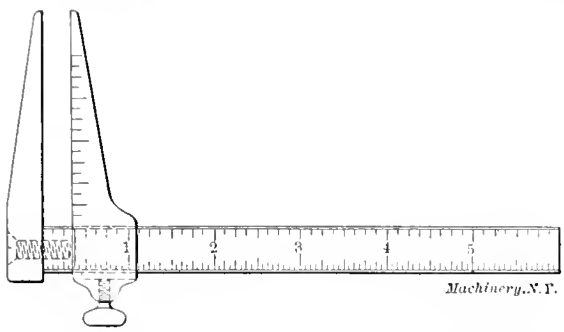

Fig. 3. Tool used when Lapping for Sizing Duplicate Parts.

deal of care. The cast iron lap must be constantly trimmed, kept straight, and the taper the same as the desired taper in the piece being lapped; it must also be kept well lubricated and not be crowded any. A very handy tool, which is shown in Fig. 3, is almost indispensable in doing work with the rotary and hand laps; it is a home-made caliper square. The taper between the hardened jaws is 0.001 inch in the whole length, and a 6-inch flexible scale is inserted in the beam. One jaw is graduated, which enables one to see how far the piece will slide up in the jaws. This caliper is not used so much for accurate measurements as for accurate sizing for parallelism or duplicating sizes.

Minneapolis, Minn. A. J. DeLille.

PATENTS AND INVENTORS.

In an article in the June issue, Mr. E. C. Smith makes some statements to which the writer permits himself to take exception. Mr. Smith seems to think that the inventor has no proprietary right to his own invention, except in as far as the government grants it to him. However, that the right of ownership of an invention exists independently of the government, cannot be questioned; the inventor owns his own invention because it is his; he may or may not be able to enforce his claims. About 1843, Henry Bessemer invented a mechanical process for making bronze powder. His finished powder cost him less than $1.50 per pound, and he sold it for $20 per pound, making over 1,300 per cent profit. He kept the process a secret for thirty-two years, and collected profits at the above rate for that time. Did he own the invention, or did he not? If he did not, who did?

Most inventions are not of such a nature that they can be kept secret, but the question of ownership does not change. Had the Bessemer process been patented, and thrown open to the public at the end of 14 years (length of English term), the users of bronze powders would have been saved expenses amounting to many hundred thousand dollars. From this instance, the enormous value to the country of inventions, the patents of which are expired, may be estimated. Other inventions just as important are thrown open to the public every year.

In my previous article published in the March issue of Machinery, I stated that some of the examiners were incompetent. Mr. Smith says: "To me the showing is not one of incompetency, but of exceptional merit under adverse conditions," but then in the next sentence he says: "The commissioner states that the work of some of his force is frivolous, and otherwise lacking in essential qualities." I certainly believe that the patent office staff is working under exceedingly adverse conditions, and that there is fine work being done by many good men on it, but these good men are so handicapped by the congested state of the work and surrounded by so many men who are not as competent, that the quality of the work in general is far below what it should be. The adverse conditions referred to ought to have been changed long ago.

Large companies, as a rule, do not find much complaint about the conduct in the patent office, for the reason that the present practice suits the corporations quite well. They do not object to long postponed divisions of applications, or continual dropping of old and bringing forward of new references, because the longer the delay the longer is the effective life of the patent, but these things make a great difference to the ordinary applicant. They mean a difference of loss or gain of time of several months.

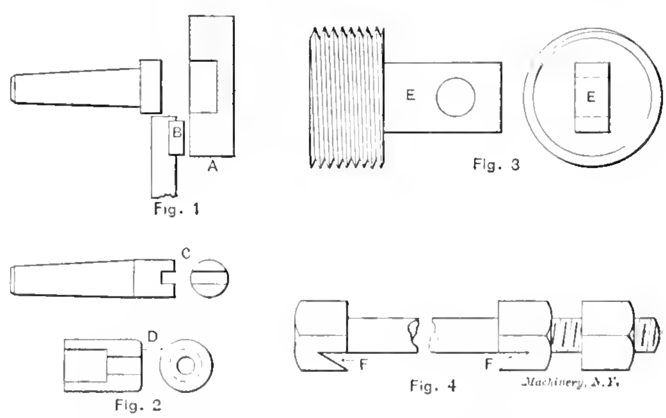
Reasons have been put forth why delay in a patent application would be advantageous to the inventor, due deliberation being preferable to undue haste, but when, as now, each application receives "due deliberation" resting in a pigeonhole in the patent office for several months, it is difficult to see what value it adds to the examiner's action in the case when he eventually reaches the application and is so pushed for time that he cannot go thoroughly into the matter, because he must hurry on to the next case. It is a mistake to suppose that a long delayed application gives the inventor a chance to further develop his invention, and fortify his case if his original claims are inadequate. The patent office rules prohibit the adding of material to a pending application.

The whole underlying cause of complaint against the patent office may be expressed in a few words—lack of money. Without sufficient help, congestion of work and delay in action is inevitable. Were it not for the delays, patentees would not find the mistakes of which complaints are now made, so unbearable. If the office were in such condition that applications would not be delayed more than two or three weeks at each action, it would not be necessary to find fault, but under the present system when actions occur at intervals of from six months to a year, there is entirely too much time wasted.

Toronto, Canada. H. Addison Johnston.

A FEW HANDY KINKS.

A number of pieces, as shown at *A*, in Fig. 1, were to be finished true all over, and, as the hole did not go clear through, an ordinary arbor could not be used, so the following scheme was devised: A piece of machine steel was turned to fit in the lathe spindle and the end made a press fit in the hole in the work. After being pressed on by the



Figs. 1 to 4. Miscellaneous Appliances for the Lathe.

tail-stock and turned up, the piece was taken off as follows: The tool was reversed in the tool-post, and a piece of lead placed between the back of the work and the tool, as at *B*, and the lathe started up. The heat generated by the friction of the lead against the iron caused the latter to expand and drop off in a very short time without marring the work in the least.

The method described in the January issue of Machinery for holding a reamer, calls to mind a handy device for a tap-holder. A piece of machine steel is fitted to the tail spindle and has a slot cut through end *C*, Fig. 2, the width of the tap's square. The piece *D* of cast iron is bored at one end a press fit for the end *C*, and the other end is a loose fit for

the tap's shank. This device prevents the tap from turning, and keeps it in line with the hole, even if the tail-stock is not kept up tight against it.

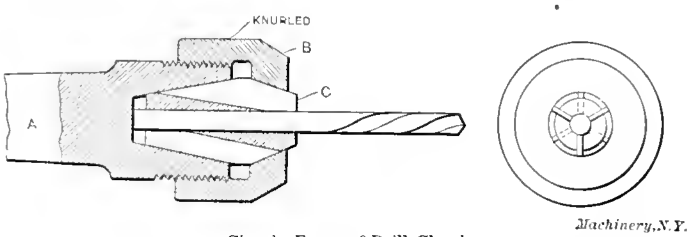
In setting a taper attachment it is very hard to get it exactly right and to get the work perfect. It is a good idea to move the tail-stock over a very small amount, and the screws make a very fine adjustment. If a thin collar is shrunk on the front tail-stock screw and then graduated, it makes a handy micrometer for setting the tail-stock accurately.

Some time ago we had several awkward and heavy jigs to fit to the lathe spindle and in order to make them a good fit without relying on calipers, we laid a face-plate on a block and filled the hole with babbitt, having the flat bar of iron *E*, Fig. 3, in the center to turn it out by. In this way a very satisfactory templet was made.

A stop for the lathe cross-slide can be quickly made of a bolt, and nut with the thread drilled out, by sawing a piece out of the face of each as shown at *F*, Fig. 4. VIM.

A SPECIAL DRILL CHUCK.

The chuck shown in the engraving is not difficult to make and is useful where there is a great deal of drilling to do with drills of one size. It consists of a taper shank *A* having a fine thread on the outside of the large end, and a taper hole bored in the end as shown. The jaws *C* consist of a piece of steel, one end of which is tapered to fit the hole in *A*, and the other end to fit the taper in knurled clamping nut *B*. A

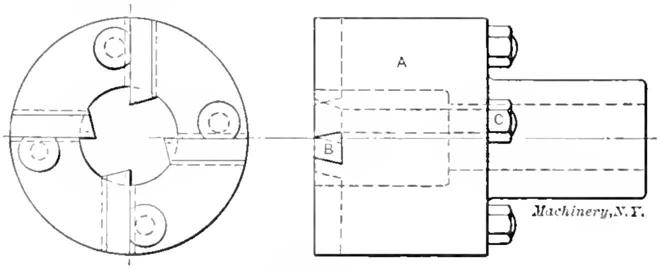


Simple Form of Drill Chuck.

hole is drilled in the jaws *C* the size of the drill the chuck is made for, and from each end three grooves are milled completely splitting the ends of piece *C* into three parts, but the cuts run back on an angle so that metal is left to hold the parts together. The clamping is done by the knurled nut *B*. By making extra jaws *C*, the chuck can be made to take drills of different sizes. W. ALTON.

ADJUSTABLE HOLLOW MILL.

The accompanying engraving shows an adjustable hollow mill which has proved very efficient. This tool consists of a machine steel body *A*, in which four dove-tail slots are cut, into which the four cutters *B* are inserted. These cutters are clamped in place by the taper-headed bolts *C*, which have one side flattened, as shown in the engraving, to permit a rigid



Adjustable Hollow Mill.

hold on the inserted cutter. This tool has stood the test of hard usage very well. It has proved to be practically as rigid as a solid hollow mill, and at the same time, it can be quickly adjusted for different sizes. W. ALTON.

[It will be noticed that the principle of the design of this tool is practically the same as the one employed in the adjustable hollow mills made by the Brown & Sharpe Mfg. Co. In these latter tools, however, there is no dove-tail slot, but the blade is simply bound tightly against the back of a square slot by means of the taper side of the binding bolt, which engages an angular groove in the inserted blade. The hollow mill shown by our correspondent is somewhat more expensive to make, but undoubtedly it permits a firmer grip on the blade, and holds it in position very rigidly.—EDITOR.]

SHERARDIZING OR DRY GALVANIZING.

In the November, 1904, December, 1905, and February, 1908, issues of MACHINERY articles were published descriptive of the dry galvanizing process, discovered and developed by Mr. Sherard Cowper-Coles, London, England. The United States rights for this process have been acquired by the United States Sherardizing Co., New Castle, Pa., and the Globe Machine & Stamping Co., Cleveland, O., has acquired the shop rights. It is to the latter concern that we are indebted for the following description of the process, prepared by Mr. J. Everett Thompson, formerly of the American Steel & Wire Co., and the Jones & Laughlin Steel Co. Mr. Thompson is making a special study of the new process.

The "sherardizing" process of dry galvanizing is applicable not only in all cases where hot or cold galvanizing can be used, but in numberless other cases where they cannot. Briefly, the process consists in packing the articles to be covered with the zinc coating into a closed drum, box or other suitable receptacle in contact with the ordinary zinc dust of commerce. The receptacle is then put into an oven and gradually heated to the required temperature of about 700 degrees F. for a period of four or five hours. The drum is then withdrawn and allowed to cool down to a temperature convenient for handling, when its contents are dumped upon a screen, which allows the zinc dust to fall freely into the chamber below, from which it can be drawn for use again.

The articles are found to be evenly coated with pure zinc, this constituting the entire process. The operation is so simple that the most ordinary class of unskilled labor can be employed without fear of securing poor results. Even the matter of gradually heating up and cooling off is automatically controlled by the fact that zinc dust is a poor conductor of heat. There can be no sudden increase of temperature, as is the case when an article is suddenly plunged into a molten bath of zinc, or the subsequent rapid cooling. Articles do not warp out of shape and even springs are found to retain their temper.

The great superiority of the sherardizing process consists in the fact that in addition to a surface coating of zinc, an infinitesimal quantity of zinc is alloyed into the iron or steel itself and forms a rust-proofing that resists corrosion. This is a very important advantage over the hot galvanizing process. With the latter, in case of a pin-hole, scratch or other abrasion of the coating, a rusting action is set up upon exposure to the elements which in time causes the galvanized coating to peel off. In the case of the sherardizing process, a pin-hole would probably penetrate only to the alloy coating, and no rusting action would take place, but even if the abrasion penetrated through the alloy there could be no possibility of rusting between the zinc coating and the steel.

In many cases, the articles need no special cleaning before being sherardized, but when they do, they are cleaned as is done in ordinary galvanizing. Articles coated with grease or oil take as good, if not better, coating of zinc than those which are free from it.

The extreme evenness of the zinc coating, no matter how thickly it may be applied, preserves sharpness of outline. Screw threads, stamped letters, graduated lines on steel scales are preserved sharp in outline, and if a slight clearance has been given a sherardized nut, it will run onto a sherardized screw as easily and smoothly as if there were no coating; thus no recutting is required. The coating is so smooth and even on parts of fine machinery that they can be assembled after being subjected to the process without requiring filing or fitting.

Numerous other advantages could be mentioned. Articles coated by the process when buffed may be substituted for brass or nickel plated goods; they will retain their color and brightness and can be cleaned more readily than nickel. Since the coating is in the surface and not on it, it does not peel off as the plating is prone to do. It is claimed that sherardized plumbers' fittings are unequaled for finish and durability. Sherardized marine fittings rank next to solid copper and brass in ability to withstand corrosion. A sherardized steel propeller shaft is stronger and will withstand corrosion as well as one made of costly phosphor bronze. Chains treated have remained in sea water continually for nine months without showing any evidence of corrosion.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

HOW ARE HACK-SAW BLADES HARDENED?

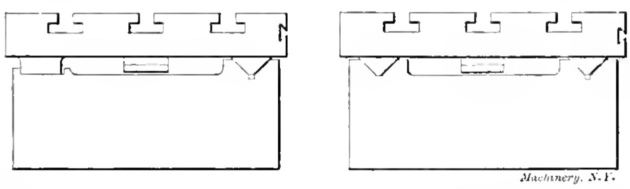
H. G.—How are hack-saw blades hardened in large quantities? Working them one by one as I do now takes too long.

A.—We are unable to give you the desired information. The manufacture of hack-saw blades has been kept pretty well under cover, but inasmuch as there is a number of manufacturers now engaged in making hack-saw blades, it cannot be regarded strictly as a trade secret. We would be pleased to receive a good contribution on the subject from one of our readers.

BEARINGS FOR PLANER PLATENS.

H. U.—What are the advantages or disadvantages in large planers of 8-foot size and larger, having the platen made with two vees, as compared with platens having one vee and one flat way? Which, in general, is considered the preferable construction?

A.—Small planers are built with two vees, not for the reason that two vees are necessarily required for guiding the platen, but largely, we believe, because the weight of a small platen might not be sufficient to hold it down into the vee way when



planing on the extreme edge of a piece located over the flat way. The side and vertical pressures of the tool might be sufficient to lift the opposite side of the platen slightly and push it over, thus causing defective work, whereas if a vee is under the side of the platen where the tool is working, the side pressure effect would be overcome by the vertical pressure, tending to hold the platen in place. On large planers this danger disappears because of the great weight of the platen relative to the pressure of cut and weight of work. The fact that a platen with one vee way and one flat way is easier fitted, and that the combination wears better, naturally causes it to be regarded by many competent designers as the preferable construction for large planers where it can be safely used. We would like the opinions of our readers on the subject.

A PROBLEM IN TRIGONOMETRY.

S. S. Y.—In the accompanying sketch (see Fig. 1) is shown the cross section of a trolley wire, the dimensions and angles being given as shown. I would like to know how to find the dimensions indicated by x and y.

A.—Referring to Fig. 2, we will first solve a problem of this kind having a general application, and will then apply the

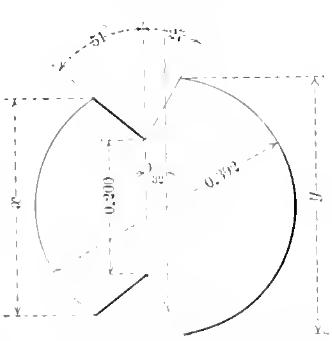


Fig. 1.

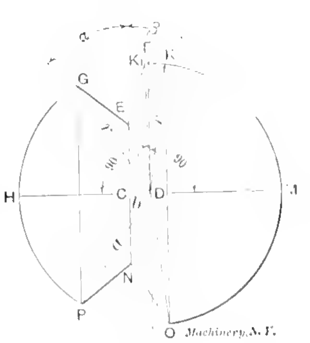

Fig. 2.

formulas we find to the specific case in question. It will be found upon examination, that it is not possible to give a simple general formula, but that it is much easier to solve this problem by taking a step at a time, and finding various dimensions and angles, as we go along. Referring to Fig. 2, it is apparent that to find the distances GP and KO, which are the required distances x and y in Fig. 1, we must find the angles GDH and KDM. When these angles are found, the distances GP and KO are simply the chords corresponding to the angles GDP and KDO, of which the angles GDH and KDM are one-half, respectively. Any handbook will give us the formula for finding the chord when the center angle is given, so that our problem resolves itself into finding this angle.

Let a = the given length EN,

b = the given distance CD, and

r = the radius of the wire = one-half the given diameter.

We have then

$$\tan CED = \frac{b}{\frac{1}{2}a}$$

From this we can find the angle CED, which we will now consider as known. Angle $EDF = CED$, and is therefore also known. Further,

$$ED = \sqrt{\left(\frac{a}{2}\right)^2 + b^2}$$

and angle

$$GED = (180^\circ - \alpha) + CED$$

α, being one of our given angles.

We have now the triangle GED, in which we know two sides ED and GD and the angle GED. The side $GD = r$. We then have

$$\sin EGD = \frac{ED \sin GED}{r}$$

and when we have found the value of angle EGD from this formula, we can find angle GDE from

$$GDE = 180^\circ - (GED + EGD).$$

Furthermore, $GDE + EDF = GDF$, and $GDH = 90^\circ - GDF$. Knowing the angle GDH, we have

$$x = 2r \sin GDH.$$

Applying the same reasoning on the other side of line ED, in order to find the angle KDM, we have:

$$KED = 180^\circ - (\beta + CED)$$

$$\sin EKD = \frac{ED \sin KED}{r}$$

$$EDK = 180^\circ - (EKD + KED)$$

$$FDK = EDK - EDF$$

$$KDM = 90^\circ - FDK$$

$$y = 2r \sin KDM.$$

However, it may happen that the point K does not fall on the right-hand side of the line DF, as shown, but may fall as K_1. In principle, this makes no difference. Only, in calculating the length of the line KO, we use the angle K_1DH instead of the angle KDM. Our numerical calculations will always indicate on which side of the line FD the point K falls, by making angle FDK negative, if K falls as K_1, so that there is no possibility of mistake.

If we apply the formulas, as given above, directly to the case in Fig. 1, our calculations will be as follows:

$$\tan CED = \frac{0.03125}{0.1} = 0.3125;\quad CED = 17^\circ 21' = EDF.$$

$$ED = \sqrt{0.1^2 + 0.03125^2} = 0.1048.$$

$$GED = (180^\circ - 51^\circ) + 17^\circ 21' = 146^\circ 21'.$$

$$\sin EGD = \frac{0.1048 \sin 146^\circ 21'}{0.196} = 0.29629.$$

$$EGD = 17^\circ 14'.$$

$$GDE = 180^\circ - (146^\circ 21' + 17^\circ 14') = 16^\circ 25'.$$

$$16^\circ 25' + 17^\circ 21' = 33^\circ 46' = GDF;\quad 90^\circ - 33^\circ 46' = 56^\circ 14' = GHD.$$

$$x = 0.392 \sin 56^\circ 14' = 0.3259.$$

To find y, we have

$$KED = 180 - (27 + 17^\circ 21') = 135^\circ 39'.$$

$$\sin EKD = \frac{0.1048 \sin 135^\circ 39'}{0.196} = 0.37378.$$

$$EKD = 21^\circ 57'.$$

$$EDK = 180^\circ - (135^\circ 39' + 21^\circ 57') = 22^\circ 24'.$$

$$22^\circ 24' - 17^\circ 21' = 5^\circ 3' = FDK;\quad 90^\circ - 5^\circ 3' = 84^\circ 57' = KDM.$$

$$y = 0.392 \sin 84^\circ 57' = 0.3905.$$

The problem, while requiring some time for working out, is very simple, involving as it does only the first principles of trigonometry.

MODERN GERMAN MILLING MACHINES.

OSKAR KYLIN.*

The accompanying half-tone engravings, Figs. 1 and 2, show two milling machines built by the Wanderer Fahrradwerke, Schoenau bei Chemnitz, Germany. The machines shown represent the highest development of this firm's milling machines, being the last ones of the company's line of machine tools that have been placed on the market. The Wanderer Fahrradwerke originally engaged only in the bicycle business, but, when the demand for accurately made machine tools increased in Germany during the last decade, the company added a department for machine tool manufacture.

Fig. 1 shows what is designated as the Wanderer No. 3 vertical milling machine. An inspection of the engraving will easily convince the careful observer that proper attention has been paid to the matter of giving the machine the rigidity and stiffness required for accurate work of the heavy character for which the machine is intended. It is also in evidence that nothing has been left undone in the way of providing easily adjustable in suitable slots. Twelve different feeds are obtainable, the feed changing device consisting of a gear box placed on the column of the machine as shown. The mechanism is operated by small hand-wheels, the machine being provided with proper scales, giving the table feed per revolution of spindle, for different settings of the hand-wheels. The amount of variation obtainable of the feed per revolution of spindle varies between the limits 0.036 and 7.2 millimeters (0.0014 to 0.29 inch). In order to prevent accidental motion of the table during working, all the hubs of the controlling hand-wheels are provided with clutch devices which enable them to be disengaged as soon as the different adjustments have been made. Suitable covers have been provided over all gearing, and proper care has been taken to prevent the chips from coming into the oiling devices and other vital parts of the machine. The speed change mechanism is placed in an oil and dust-proof cover.

The total horizontal working surface of the machine is 44 × 12 inches, the longitudinal feed of the table is 44 inches, and the cross-feed 12½ inches. The vertical motion of the

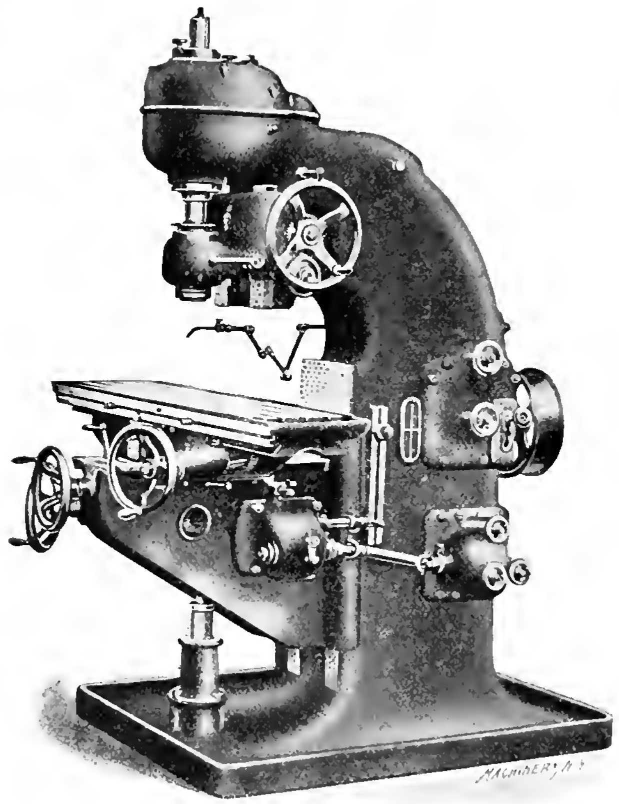

Fig. 1. Wanderer Fahrradwerke No. 3 Vertical Milling Machine.

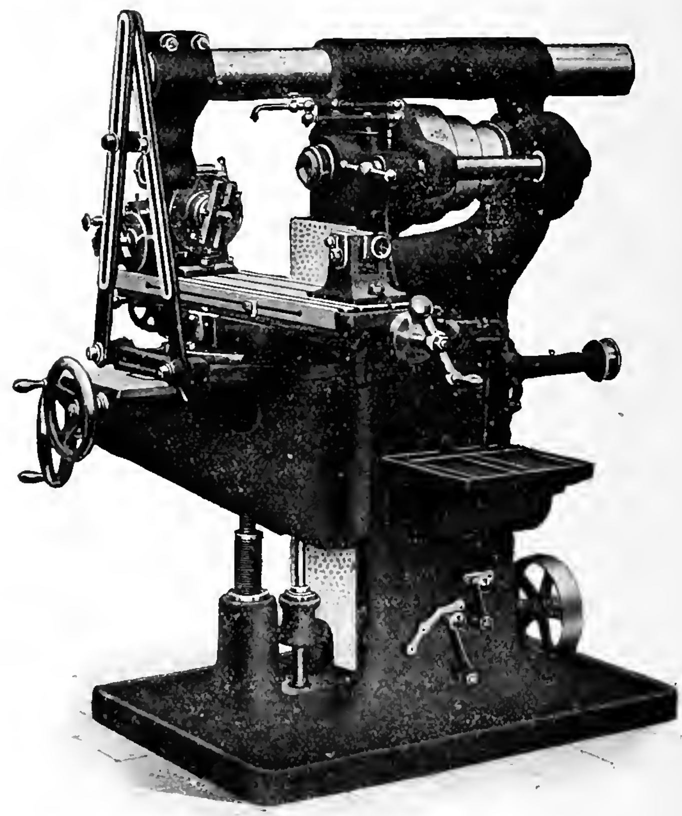

Fig. 2. Universal Milling Machine built by the Wanderer Fahrradwerke.

for easy means of adjustment and handiness of operation, the machine possessing practically the same features as the last model of the Brown & Sharpe Company's vertical milling machine.

The machine is driven from a constant-speed counter-shaft through a single pulley drive, from which all motions of the machine are obtained. By means of a gear box, 16 different speeds are obtainable for the spindle of the machine, varying from 17 to 352 revolutions per minute. The vertical adjustment of the spindle is operated by a hand-wheel provided with a dial graduated to indicate motions of the spindle of 1/20 millimeter (0.002 inch). The table of the milling machine is provided with automatic feed in three directions—vertical, longitudinal, and cross-feed. The longitudinal feed motion is driven by a spiral gear, engaging with a rack on the under side of the table. The mechanisms for engaging and disengaging all the automatic feeds are located on the side of the knee, and may be conveniently reached by the operator, the engaging and disengaging being accomplished by the turning of the respective cranks provided. All the different table feeds can be stopped automatically by dogs provided, spindle is 4 inches, and the total weight of the machine is 4,200 pounds.

In the half-tone, Fig. 2, the universal milling machine built by the Wanderer Fahrradwerke is illustrated. This machine is known as the Wanderer No. 2 universal milling machine. It is apparent from an inspection of the illustration that, in this machine also, proper attention has been paid to the question of the stiffness and rigidity required in order to turn out accurate work under severe working conditions. This machine is driven by a three-step cone pulley, provided with back gears, the three steps of the pulley being 6, 8, and 10 inches in diameter, respectively.

The automatic feed for the work table provides for 16 changes, varying from 0.1 to 5 millimeters (0.004 to 0.20 inch) per revolution of spindle. The gear box for the feed changes is located inside of the column, and is operated by levers, plainly shown in the illustration, the motion for the gear box mechanism being obtained through a belt-driven pulley.

The total table surface is 34 × 8 inches; the longitudinal motion of the table, 20½ inches; the cross-feed, 10 inches; and the vertical adjustment 17½ inches. The weight of this machine is 2,200 pounds.

* Foreign Traveling Representative of MACHINERY.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

KEARNEY & TRECKER UNIVERSAL MILLING MACHINE.

The accompanying illustrations show a new improved milling machine, brought out by the Kearney & Trecker Co., Milwaukee, Wis., and known as No. 3 B Milwaukee universal milling machine. Several interesting features have been introduced in this design, which are not generally found in machines of this type, and while following the general style of previous construction, the design is original and highly interesting in many respects.

Figs. 1 and 2 show two general views of the machine, one taken from the front and one from the side. Fig. 3 shows a rear view of the machine, and gives a clear idea of the manner in which the feed box and pulley bracket are attached, as well as of the arrangement of the levers for the speed and feed changing device. As seen from these illustrations, the tool is a constant drive geared machine, of the advantages of which the firm manufacturing these machines is fully convinced. Tests undertaken have caused the firm to abandon the cone pulley driven milling machines entirely.

Spindle Drive and Speed Changing Device.

The driving pulley is mounted on a shaft carrying on its inner end a pinion which engages with a larger gear, whereby a speed reduction of about $3\frac{1}{2}$ to 1 is accomplished, the pulley itself running at 350 R. P. M. This larger gear runs idle on its shaft and is free to move endwise thereon. On one side of the gear is placed a hardened steel clutch, and on the same shaft is also another gear of the same size, also carrying a clutch. This last gear, in turn, meshes with a gear directly above it on one of the shafts in the gear box, which, in turn, drives the feed and also meshes with pinion *V*, shown in the line engraving, Fig. 4.

The first large gear mentioned, the one which engages with the pinion on the pulley shaft, is moved by the starting lever seen extending upward directly at the right of the head in Fig. 3, until the clutches referred to become engaged, thus starting and stopping the machine without the use of friction clutches. This is permissible by reason of the fact that the clutch referred to always revolves at a constant speed, and this speed is low enough not to produce any noticeable shock, regardless of the speed at which the milling machine spindle itself may be running. The pinion *V*, in Fig. 4, drives the shaft *B*, to which is keyed pinion *W*, which, in turn, drives the idle gear *D*. This idler is carried by the swinging bracket *X*, which has gear teeth cut on its outside at *A*. These gear teeth mesh with a long-faced pinion controlled by the upper index lever shown to the right of the gear box in Fig. 3. The line engraving, Fig. 4, in order to show the construction, shows the segment *X* dropped down further than it actually would come, because in reality it swings in such a way that the pinion *D* engages with the various steps on the cone gear *E*. The endwise location of the swinging bracket *X* is controlled by the handle attached to the spindle speed dial, shown in Fig. 5. This handle operates the lower gear and rack shown in the same illustration, a projecting extension from the rack engaging with the slot *C* in the bracket *X*. The spindle speed plate in Fig. 5 shows 18 speeds, varying by increments of approximately 20 per cent from 13 to 320 R. P. M.

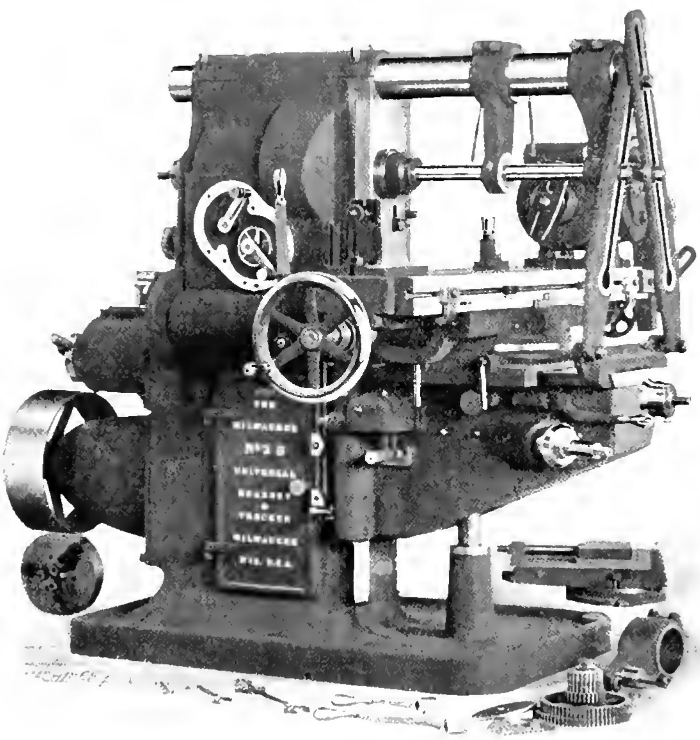

Fig 1. Front View of Kearney & Trecker No. 3B Universal Milling Machine.

Attached to and revolving with the cone *E* in Fig. 4 is the pinion *O*, which engages the gear *N*. This latter gear turns idle on the spindle of the machine and carries a pin *M*. The sleeve gear *F* on the spindle has two gears *I* and *K*, which engage alternately with gears *J* and *L* on the cone *E*, this sleeve being keyed to the spindle *G*. The gear *I*, when moved to the right, thereby bringing *K* out of engagement with *L*, engages the gear *N* through the pin *M*. It will be easily seen that by this arrangement three speeds are obtained directly at the spindle, which, multiplied by the six speeds obtained by the cone *E* and idler *D*, gives 18 speeds in all.

The speed plate in Fig. 5 has three concentric rows of speeds, the inner row being the slowest and the outer the fastest speeds. The inner one of these sets of speeds is obtained when the lever at the left in Fig. 5 is at the position shown in Fig. 1. This lever operates the upper gear and rack in the view to the right in Fig. 5, and a projection on the rack engages with the groove *H* on sleeve *F*, Fig. 4, so that this sleeve can be set easily to any one of the three positions which the lever can occupy. The hand-wheel *U*, in Fig. 4, serves the purpose of turning the spindle by hand, when necessary, or to slightly move the gears, when this is required, in order to bring them into engagement. It will be noticed that the spindle runs in taper bearings, the wear being taken up by the sliding of the cone-shaped bearing *R*, which is accomplished by means of a collar *S*, threaded on the spindle. When the collar has been properly adjusted, it is locked in position by the screw *T*.

Lubrication Arrangement.

Connected with the large gear, driven by the pulley shaft pinion previously mentioned, is a pump of simple construction, consisting of two spur gears running together in a suitable case. This pump raises the oil from the reservoir, shown at the right-hand side at the bottom of the column of the machine in Fig. 2. The oil is raised to the top of the machine above the gears on spindle *G*. Here is a perforated pipe extending from end to end of the frame and delivering oil into the pockets *P* and *Q*, and through the numerous openings in the pipe to the gears between the bearings. The oil is thrown by the gears from one to the other, and falls downward by gravity, the shafts being located approximately in a vertical plane. It also works its way downward by reason of overflow from the pockets *P* and *Q*, cascading into the various pockets and bearings in continuous streams, flowing over the mechanism without interruption. Provision is also made so that a portion of this falling oil finds its way into the feed box at the back end of the machine, lubricating all the shafts and gears contained therein. It also finds its way in a continuous stream through the pulley bracket to the bearing next

to the pulley. The oil is returned through the bottom of the pulley bracket, most clearly shown in Figs. 1 and 2, to the reservoir which extends from the one side of the machine to the other. From this it is again pumped to the discharge pipe above the spindle to continue its circuitous route.

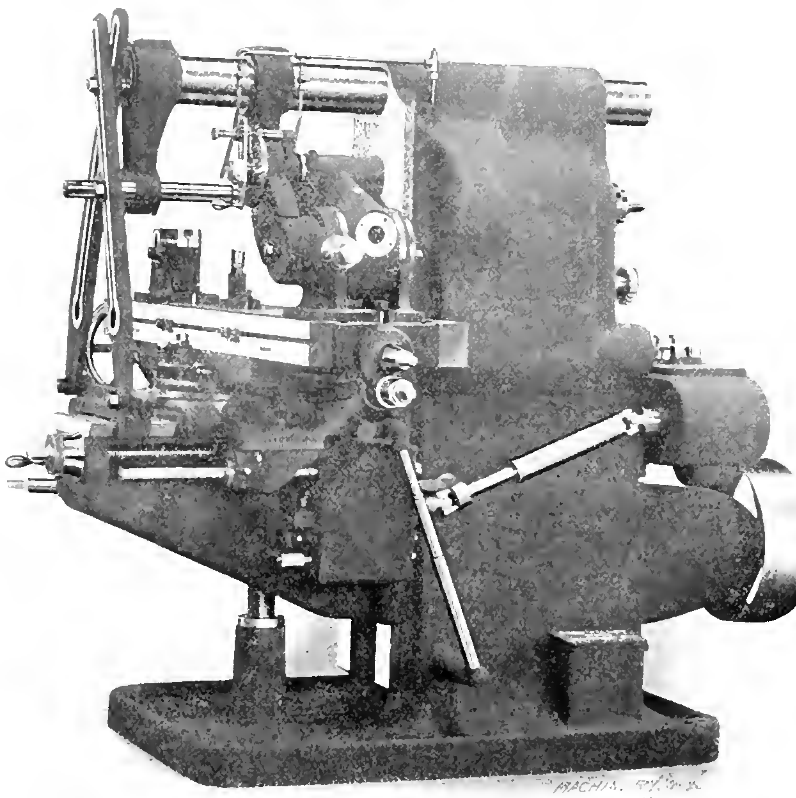

Fig. 2. Side View of Milwaukee Universal Milling Machine.

There is another pump for the oil used for lubricating the cutters, this pump being located in the closet in the inside of the machine frame, behind the door shown in Fig. 1. This pump runs only when the spindle runs, while the pump for lubricating the gears and bearings runs continuously, so that the pulley shaft is flooded with oil, regardless of whether the machine is running or not. The opening covered by the front door, on which the name of the machine and the makers is cast, is not as large as the door would indicate, as there is a wall back of this door, extending from the bottom to about the height of the door knob for the purpose of forming a reservoir for the lubricant used for cooling and lubricating the milling cutters. The pump for this lubrication has a relief and pressure regulating valve, so that the pressure of oil can be regulated to any desired amount. From this pump a pipe extends upward in the interior of the machine, emerging near the top of the frame, as shown in Fig. 2. To the top end of this pipe is attached a swinging connection, and from this a horizontal pipe connection, branching out and connecting with two pieces of flexible oil tubing, carries the oil to the cutters. This arrangement is the standard equipment, which, of course can readily be varied to suit any special case, as many of these flexible tubes being used as found necessary.

One of the great troubles in connection with flooding the cutters and the table with oil has hitherto been the trouble in connection with returning it to the reservoir, the means provided never being adequate. Referring to Fig. 6, which shows part of the table and the swivel carriage of the machine, it will be noted that an oil pocket is provided at the end of the table, there being another pocket at the other end. These pockets are partitioned half way down by the screen shown in the illustration. Connected with the pockets are channels along the sides of the table, which are also divided half way down into two sections by a strip of steel, shown extending up from the groove at the end of the table. The oil falling on the table runs into the T-slots and into the grooves along the edges of the table, which carry the oil to the pockets at one or both ends, where it is strained by the screen mentioned, and then flows to the center of the table through the same grooves along the edges, but under the strip of steel referred to. From the center of the table the oil escapes through a hole into a telescopic slide shown at the extreme top of the swivel carriage in Fig. 6. The parts are so proportioned that the hole in the table will never run beyond the swivel carriage. An opening in the side of the top slide mentioned connects with the long opening in the swivel carriage. This opening terminates in a hole in the bottom of the swivel carriage, which registers with a circular groove in the saddle, and this circular groove, in turn, connects with the swivel joint of the telescopic oil tube, shown at the side of the knee and column in Fig. 2, the oil flowing through this tube to the reservoir, to be again pumped to the cutters. The strip of steel shown lying across the table in Fig. 6 is used to replace the screen when milling cast iron, in order to prevent the dust and chips from this material from finding their way into the channels leading downward to the reservoir.

Feed Mechanism.

The feed change mechanism is contained in the change gear box at the rear of the machine, and the feed changes are effected through gearing quite similar to that shown by the line engraving, Fig. 4, for the spindle drive, these gears also running in oil, as before mentioned. The index plate, giving the amount of feed, shows this in the rates of feed in inches per minute. Twelve feed changes are obtainable, varying from ½ inch to 16 inches per minute, or from about 0.0015 inch per turn of spindle for small cutters, to a little over one inch per turn for finishing cuts with large cutters. From the feed box the power is transmitted directly to the knee, through the universal joint telescopic shaft, shown in Fig. 2. A spur gear reverse is provided at the side of the knee, operated by the push handle, shown in Fig. 2, near the lower edge of the gear box on the side of the knee. This handle slides a clutch between two spur gears running in opposite directions. The feed

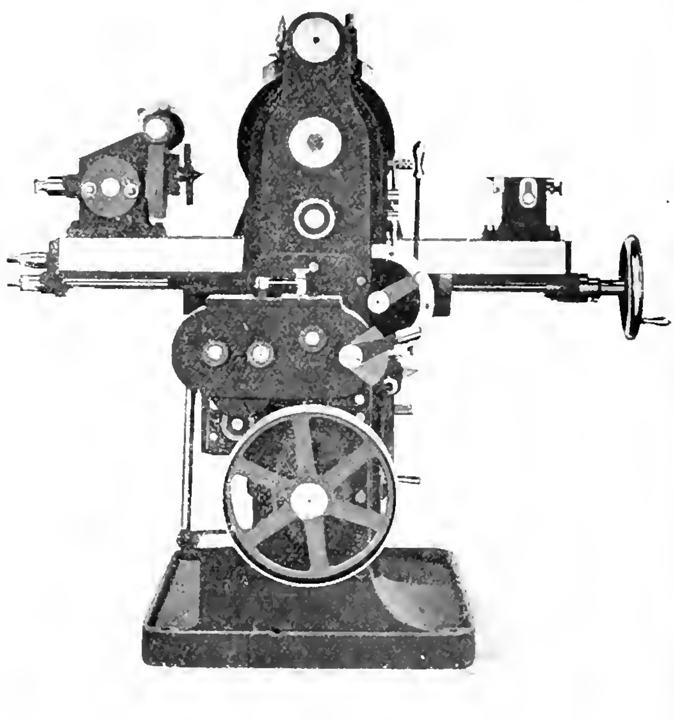

Fig. 3. Rear View of the Milling Machine.

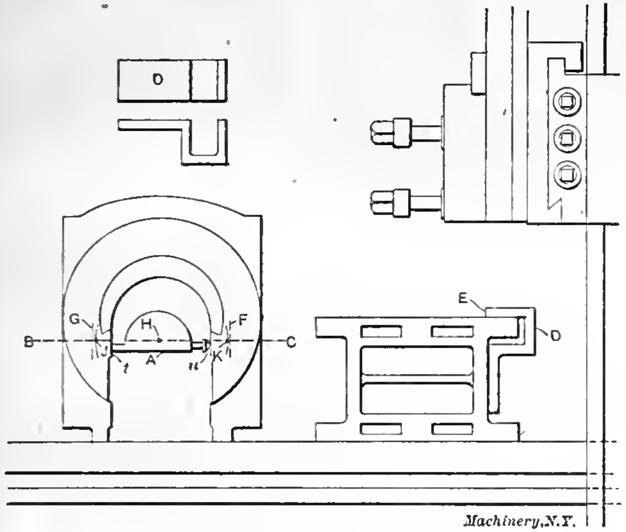
operating handles are shown in Fig. 1. The machine is provided with longitudinal, vertical, and cross feed, for the table, and means are provided to prevent the accidental engagement of more than one of these feeds at a time, and also to make it clear to the operator which feed he is about to use,

Supplement to MACHINERY, August, 1908.

Operations for the Article in this number entitled "Machine Shop Practice—Re-planing a Locomotive Driving-Box."

SHOP OPERATION SHEET NO. 70.

Arthur J. Humphrey. MACHINERY, August, 1908.



To Lay Out a Driving-box for Re-planing the Shoe and Wedge Faces.

1. Place the driving-box on the bed of the planer, as shown, with the inside face toward the operator.

2. Fasten a center-piece A in place, setting it so that it will be flush with the face of the box. With a surface gage draw the line B-C across the center-piece and the flanges of the box. If the crown brass is new, draw this line just below the points of the brass, as shown, but if the brass is worn, the line should be about the same height as the center of the bore of the brass.

NOTE—When the brass is old and is to be re-bored, the line B-C is drawn across the center of the bore so that the center H may be located with reference to the brass, in order that a minimum amount of metal may be removed when re-boring.

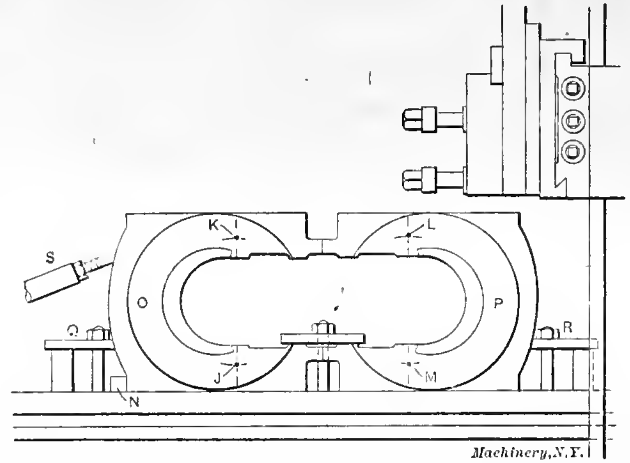
3. Hold the box gage D firmly against the shoe or wedge bearing surface of the driving box, as shown, and using the edge E of the box gage as a guide, draw the line F on the outside of the flange. This line, which is in the same plane as the shoe or wedge bearing surface, intersects the line B-C. Repeat this operation on the opposite side of the box, drawing the line G which also intersects the line B-C.

4. With a pair of hermaphrodite calipers locate a center H midway between the points t and u. With a pair of dividers see if the distance from the lines F and G to the center H are equal. If not, set the dividers 1/16 inch less than the smallest distance, or enough less to allow for planing, and with H as a center, scribe arcs intersecting the line B-C, thus locating the points J and K.

5. Mark the points J and K lightly with a prick-punch, and lay out the other box in the same manner, locating the corresponding points.

SHOP OPERATION SHEET NO. 71.

Arthur J. Humphrey. MACHINERY, August, 1908.



To Set Up a Pair of Driving-boxes for Re-planing the Shoe and Wedge Faces.

NOTE—The driving-boxes are supposed to have been laid out as previously described, and the points J, K, L, and M, located on the outside of the flanges, these points being in the same plane that the shoe or wedge bearing surfaces of the boxes are to be, when planed.

1. Place the boxes on the planer table, with their bottoms together and with a bolt inserted between them, as shown in the illustration.

2. Insert stop plugs N, which are for taking the thrust of the cut, in the table, and place the driving box O against these plugs, and the box P against O.

3. Now place the clamps Q and R in position, with their ends resting in the oil cavities in the tops of the boxes.

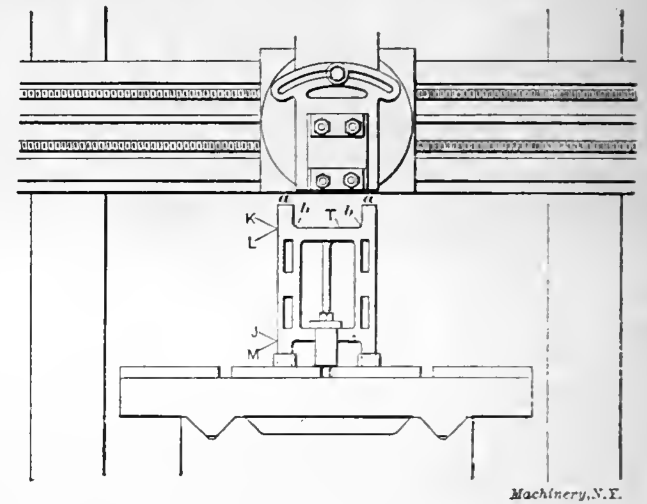
4. With the surface gage test the height of the prick-punch marks K and L, and adjust the box, by placing tin or brass liners beneath the flanges, until these marks are the same height from the table. Using a square, test the face of each driving box, and see if the faces are square with the planer table. If not, they should be set square by again placing liners beneath the box flanges.

5. Place the surface gage on the planer table, with the rear pins of the gage lowered and held firmly against the edge of the table or T-slot, and test the faces of both boxes, adjusting them until they are parallel with the edge of the table.

6. Fasten the boxes securely to the table, by tightening the clamps, and then, with surface gage and square, again test all points as previously described. If the boxes are not properly set, again loosen the bolts and adjust the liners, and continue to make adjustments until the boxes are set properly. Fix a brace S against one box, as shown, to take thrust of cut.

SHOP OPERATION SHEET NO. 72.

Arthur J. Humphrey. MACHINERY, August, 1908.



To Re-plane the Shoe and Wedge Faces

NOTE—It is assumed that the points J, M, K and L, to which the faces of the boxes are to be planed, have been located, and that the boxes have been set up as previously described.

1. Clamp a roughing tool in the tool-post of the planer, and take a roughing cut over the flanges of both boxes at a, removing enough metal to true them. Take a roughing cut over the shoe, or wedge bearing surface T, setting the point of the tool 1/32 inch above the prick-punch marks K and L. When taking the roughing cut, be sure to leave enough stock in the corners b for the fillets.

2. Replace the roughing tool with a broad finishing tool, rounded at both corners to the radius of the fillet desired at corners b. Set the cutting edge of the finishing tool the same height as the prick-punch marks K and L, and take a finishing cut over the shoe, or wedge bearing surface T, using a coarse feed. With the rounded corners of the tool finish the fillets at b. With the same tool take finishing cuts over the flanges.

3. Remove the clamps and turn the boxes over, setting them as described in the preceding operation sheet by the points J and M, and plane the faces on the opposite sides until they coincide with these marks.

NOTE—When taking the finishing cuts, the cutting edge of the tool may be set with the points K, L, or J, M, by setting the pointer of the surface gage with the prick-punch marks, and then raising or lowering the tool to correspond with the height of the pointer, or, after the cut is taken over the flanges, the depth of the cut may be determined by the use of a depth gage set to these points. After the finishing cuts are taken, the work may be proved by means of the box gage used in connection with Shop Operation Sheet No. 70.

without experiment. For each of the three feeds, there is a hole drilled in the side of the knee, below which is stamped the feed that will be engaged if the plunger shown on the side of the knee, in Fig. 1, below and somewhat to the right of the hand-wheel, is engaged in either of the three holes. The lever on which this plunger is mounted is connected in such a manner with the remainder of the mechanism that either of the two feeds for which the plunger is not set, becomes inoperative, until the plunger is changed to another hole. Adjustable trip blocks are provided to trip the feed at any desired point, and fixed trips are provided at the end of the stroke of all the feeds.

General Features of Design.

Ball bearing thrust collars are provided for all feed-screws. A second ball bearing on the cross feed screw, inside of the knee, takes the thrust in the opposite direction. The handles shown on the side of the saddle, in Fig. 1, pointing downward,

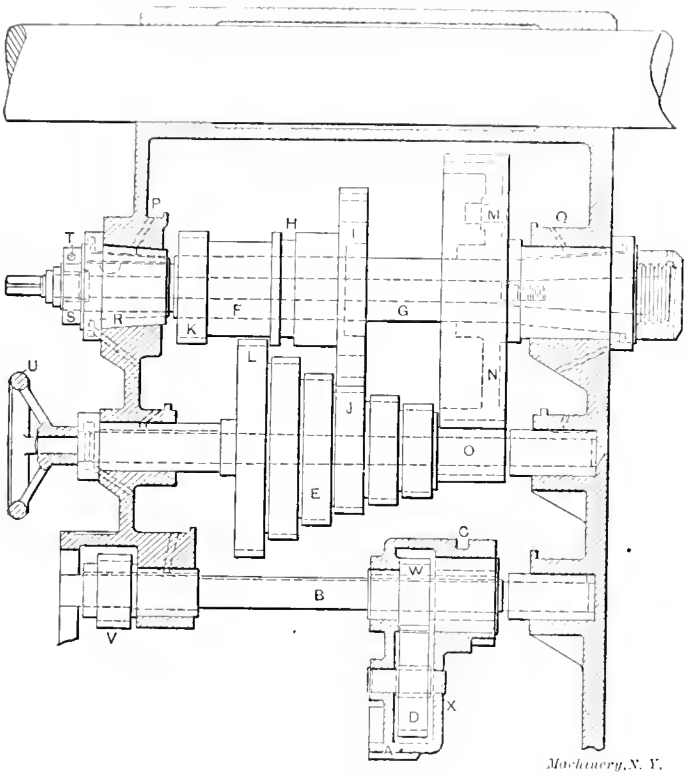

Fig. 4. Section through Speed Gear Box.

are used for clamping the saddle to the knee. To prevent the knee from becoming distorted, on account of this clamping, or from distortion produced by strains from the action of the cutters on the work, it is cast without a hole through the top, this construction being a continuation of the Kearney & Trecker Company's practice, having been inaugurated in the first cone pulley machine built by the company, and regarded as a very important feature in this type of machine. It not only renders the machine more rigid, and less liable to distortion under strain, but also permits greater cross range and

Fig. 5. Speed Change Lever Mechanism.

wider tables on universal machines. This machine has a table 14 inches wide, with a cross range of 12 inches, and is capable of being swiveled to an angle of 52 degrees, utilizing the full table travel. It can also be swiveled through an angle of 360 degrees, the table feed remaining operative at any angle.

The arm braces are so constructed that they can be removed from the machine without taking off any nuts. They are very simple in construction, and their efficiency is much enhanced by the bolt at the top which ties the two braces together.

Dividing Head.

The universal dividing head claims some attention. This is shown in Fig. 7. It will be seen from this engraving that the worm-wheel is on the front end of the spindle, which

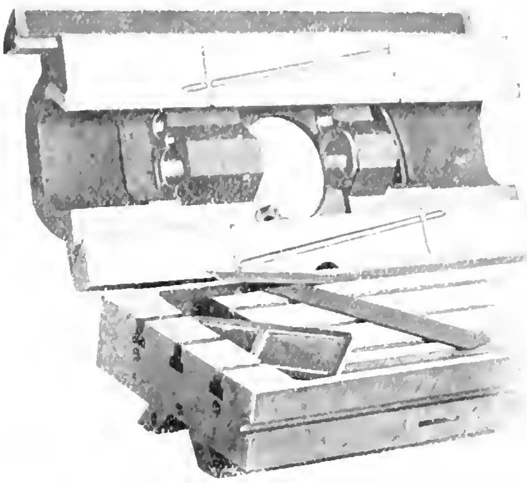

Fig. 6. Oil Return Arrangement in Table and Swivel Carriage.

makes it possible to make it very much larger in diameter than if it were placed in the interior of the head, where it could be no larger than the opening through which the spindle is introduced, or at most, no larger than the distance between the housings. A large diameter worm-wheel is clearly conducive to accuracy, other things being equal, and the placing of the index plate with the index lever directly on the worm shaft eliminates the inaccuracy that may arise on account of indexing through gearing, which is necessary when the index plate is placed on a secondary shaft. In order to prevent the spindle from becoming exceedingly high when turned to a vertical position, the center line of the spindle is considerably above the axis of the center block, so that the end of the spindle, when it swings in an arc around this axis, reaches the highest position before it stands in a vertical direction, and commences to move downward before reaching the vertical position. On account of the worm-wheel being large in diameter, larger work may be carried out on this machine than could otherwise be considered, and for this reason the driving mechanism and the change gears connecting the worm shaft with the table feed-screw must of necessity be strong enough for heavy work, and the method of carrying the change gears must be sufficiently rigid to withstand heavy duty. The swinging bracket in connection with the semi-circular bracket clamped to the end of the table, as shown in Fig. 7, fills these requirements. In order to facilitate the setting of the universal head to any angle, in relation to the spindle of the machine, and make it fully universal, it is arranged to interchange with the circular base on the milling machine vise.

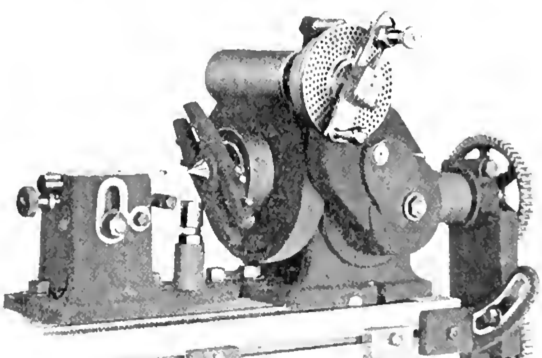

Fig. 7. Dividing Head.

The longitudinal table feed of the machine is 36 inches, the cross feed, as already mentioned, is 12 inches, and the vertical feed 19 inches. The driving pulley is 16 inches in diameter for a 5-inch belt, and runs at 350 R. P. M.

NEWTON CYLINDER AND VALVE CHAMBER BORING MACHINE.

The accompanying half-tone illustration, Fig. 1, shows a new machine brought out by the Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine is especially designed for the boring of the cylinder and piston valve chamber of simple and compound engines, at one setting. The machine shown in the illustration was built specially for a locomotive building company, where one machine was used for the valve chamber and another for the cylinders, and in this the vertical bearing is keyed to the spindle and revolves with it. Both of these sleeves are lapped in the hole for the spindle, so as to insure proper bearing, and are ground on the outside and fitted in brass bushings, a cap bearing being provided for compensation for wear.

To each of the sleeves is fitted a facing arm, as plainly shown in the illustration, Fig. 1. This arm can be engaged or disengaged without stopping the spindle motion. The arm is provided with a tool slide, having adjustment out and in for setting the proper depth of cut, while, at the same time, it has a feed in either direction on the arm by means of a small star wheel and screw. The spindle is fed forward by a carriage or trolley operated by a screw and nut, and has a continuous motion of 11 feet 8 inches, so that it can be entirely withdrawn, when removing the cylinders from the table of the machine, at one single traverse motion. The foot-

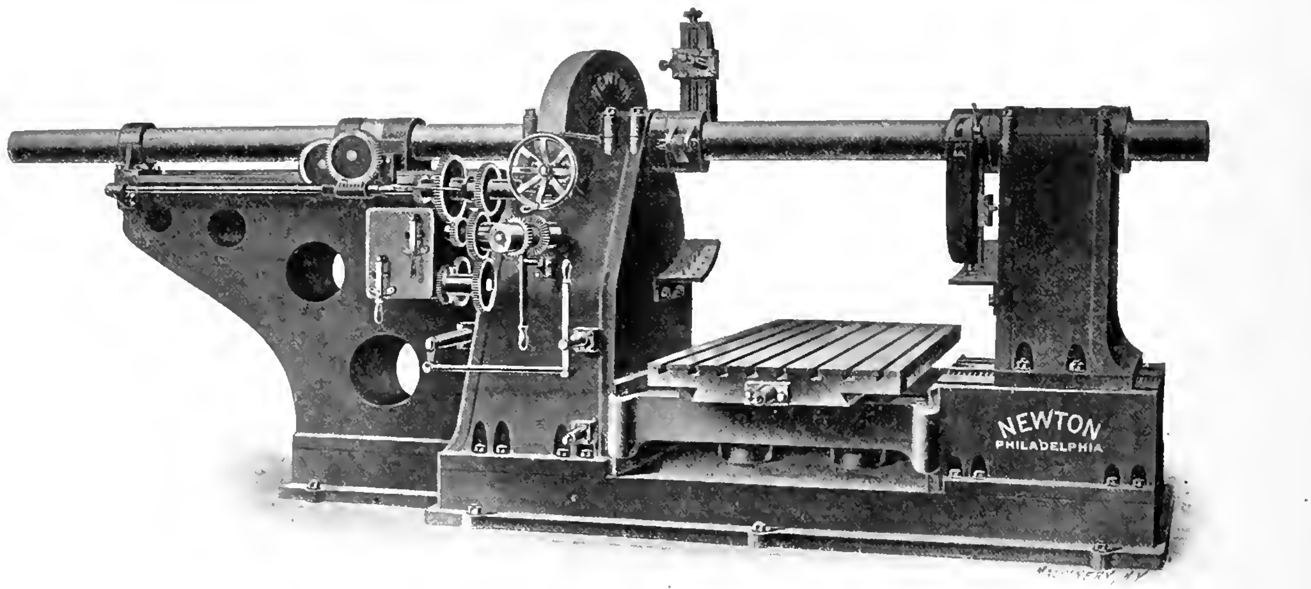

Fig. 1. Newton Cylinder and Valve Chamber Boring Machine.

travel of the table is only 8 inches. The regular type of machine, however, is provided with longer ways for the knee which carries the work table, so that in this case the work table has a vertical movement of 36 inches, the maximum distance between the spindle and the table being 51 inches, and the minimum 15 inches. When this machine is used, work such as shown in the line engraving, Fig. 2, can be carried out to advantage. The adjustment on the machine being vertical, longitudinal, and transverse, a cylinder, after it has been planed, can be placed on parallel strips on the table, and the high pressure and low pressure cylinders and the valve chambers bored without resetting, which insures perfect alignment of the cylinders, the proper centers being maintained by the use of gages.

Six changes of feed in either direction are supplied to the spindle through the gear box, the feeds amounting to 0.062, 0.100, 0.166, 0.333, 0.667 and 1 inch per revolution of spindle. The feed is engaged by the lever above the feed box, which when moved to the left engages the feed, and when moved to the right engages the quick traverse, both of these movements being reversed by the lever directly under the hand-wheel in the front of the machine. The quick power motion in either direction is at the rate of 10 feet per minute.

The spindle has a speed range of from 4 to 15 R.P.M., and is operated either by a four-step cone or by a 20 H.P. 3 to 1 variable speed motor, the drive being connected with the spindle through a clutch, so that the spindle can be started and stopped without stopping the motor or counter-shaft. A fly-wheel is attached to the motor to overcome the shock of the engaging and disengaging of the clutch. The spindle is 7 inches in diameter, and provided with two splines for driving, and is ground and fitted into two sleeves, one in each bearing. The sleeve in the head bearing is used for driving the spindle through a worm and worm-gear connection. The worm-wheel is made of bronze, and the worm of steel, the mechanism being encased and running in oil. The sleeve at the foot-stock bearing is adjustable by means of a rack and pinion, giving a minimum distance between the facing arms of 45 inches, and a maximum distance of 60 inches. The cross adjusting table is fitted with steel plates on the top, which give a steel web to the T-slots, and prevent the edges from breaking out, and at the same time the alignment of the top of the table is maintained. The table has both hand and power adjustment, and is adjustable longitudinally on the

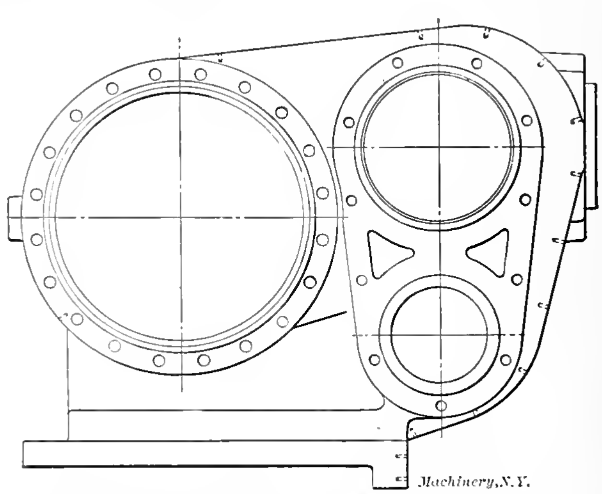

Fig. 2. Example of Work Bored in Machine at One Setting.

knee in order to permit bringing different lengths of cylinders centrally between the facing arms. The knee is raised and lowered by power, the vertical adjustment, however, having a fine hand adjustment as well. The hand adjustment for the table, vertically, is accomplished by a ratchet through a shaft visible in the illustration, Fig. 1, directly to the left of the knee. The knee is accurately fitted between ways on the front and back part of the bed, and is supported by four

screws, 6 inches in diameter, which are also used for the vertical adjustment.

It is possible on this machine to bore a simple cylinder and valve chamber in five hours, and an auxiliary table can be furnished for boring inclined cylinders. This table can be swiveled to an angle of 20 degrees so that inclined cylinders may be bored without requiring additional setting.

SINGLE PULLEY GEARED-DRIVE ROCKFORD SHAPER.

The accompanying half-tones, Figs. 1 and 2, and the line engraving, Fig. 3, illustrates a shaper equipped with a new positive speed changing device, which has been placed on the market by the Rockford Machine Tool Co., Rockford, Ill. In

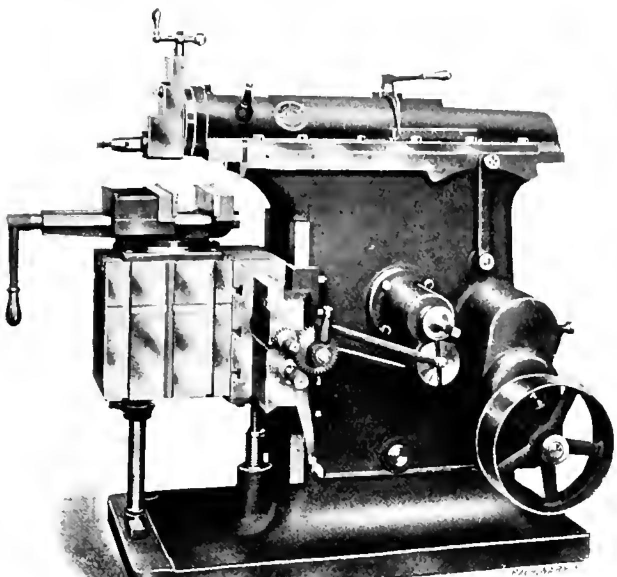

Fig. 1. Belt-driven Geared-drive Rockford Shaper.

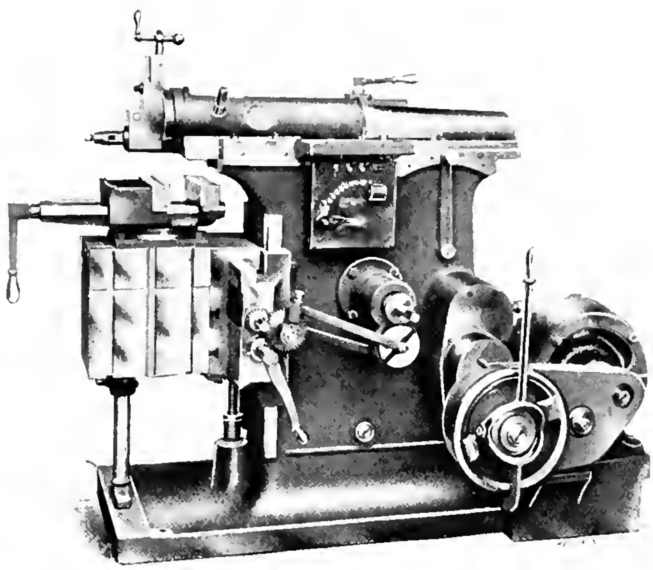

Fig. 2. Motor-driven Geared-drive Rockford Shaper.

Fig. 1 is shown a machine equipped with a single pulley, belt-driven from the counter-shaft. In Fig. 2 is shown a motor-driven machine, direct-connected by gearing to a Northern constant speed motor. This design is provided with a friction clutch for stopping and starting the machine without stopping or starting the motor, a long lever on the side of the machine at the outside end of the gear box operating this friction clutch. In the line engraving, Fig. 3, is shown an arrangement where the machine is belt-driven, but equipped with a friction clutch of the same type as that on the motor-driven machine, so that the driving pulley may be driven by belt directly from the line shaft, no counter-shaft being necessary. The line engraving, Fig. 3, also showing a section through the driving mechanism and an end view of same, gives a comprehensive idea of the design of the gear box and shifting mechanism, the simplicity and carefully thought out design of which is plainly in evidence.

The machine has eight speed changes for the ram, arranged in geometrical progression from 12 to 90 cutting strokes per minute. Referring to Fig. 3, the lower shaft *F* carries the friction pulley and clutch and two driving gears, either one of which may be locked to the shaft by means of a spring key. The gear not locked by the key will run loose on the shaft, driven by its mate on the second shaft *G*. The position of the spring key is changed by operating the lever *H* on the back side of the gear box frame. This lever is connected to a fork *E*, which, in turn, engages sleeve *J* on shaft *F*, by means of which the spring key is moved, so as to engage with either of the two driving gears. A sleeve carrying four gears, any one of which may be engaged with its corresponding gear on the upper shaft *K*, is keyed to the second shaft *G*. The shifting of this sleeve is effected by the shifting lever *D* on the side of the shaper, which connects with the sleeve through the forged levers and links *A*, *B*, and *C*. The lever or arm *A* immediately effects the motion of the sleeve and gears on the shaft *G*. The arm is carried in a bearing at its lower end, as shown in Fig. 3, and is provided with a steel pin at the upper end, which operates between two flanges on the sleeve.

It will be noticed that this arrangement is very simple, and places the two shifting levers within easy reach of the operator. An important feature of the design is that it is impossible to get any two combinations of gears in mesh at the same time. A speed plate is provided, showing the proper location of the two levers for the correct speed required. It will be noted, in particular, that the gear-driving device is very compact, and that the parts are easily accessible. The machine itself is of the regular Rockford design.

Conforming to their usual practice of not placing any new device on the market before it has been thoroughly tested in their own shops, the builders have been constantly using a 16-inch shaper equipped with this gear-driving device for a period of eighteen months, and is operation has been very satisfactory. The floor space required is less than that of a cone-driven machine.

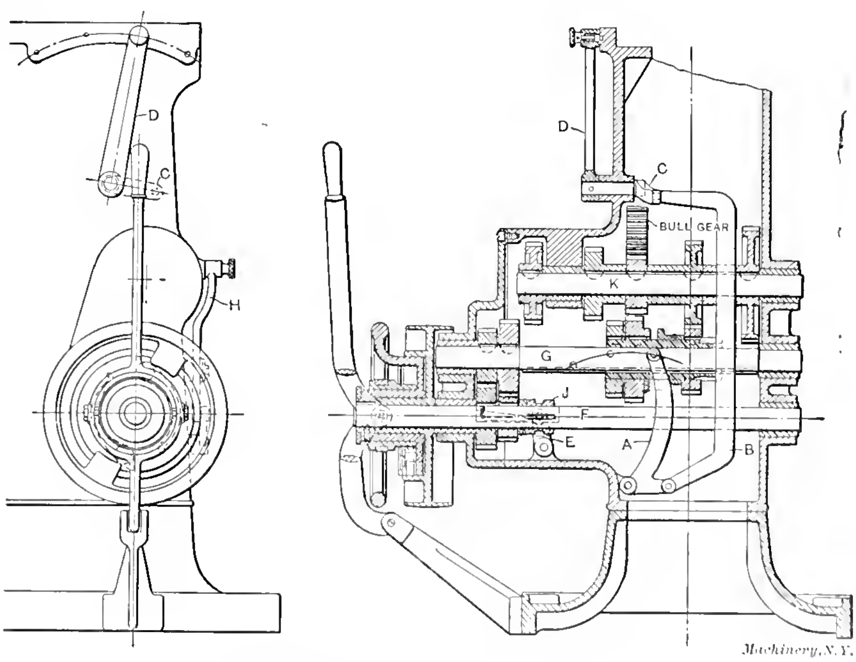

Fig. 3. Section through End View of Gear Box.

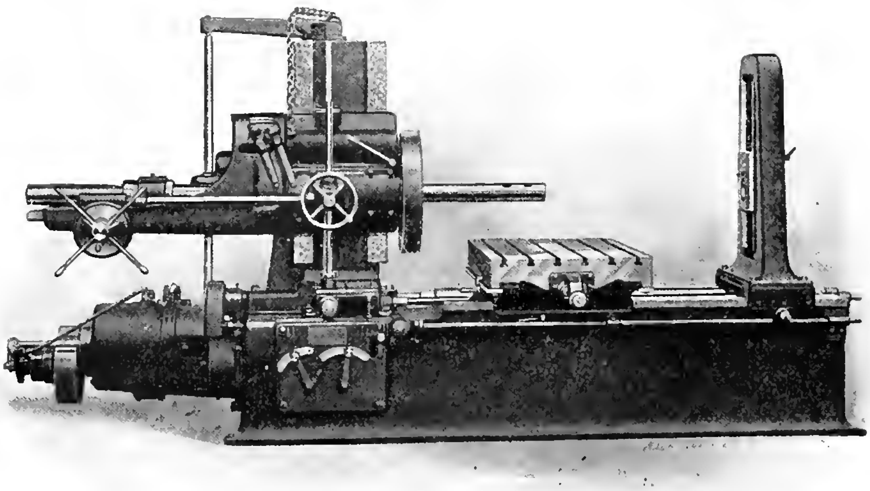
LUCAS HORIZONTAL BORING, DRILLING AND MILLING MACHINE.

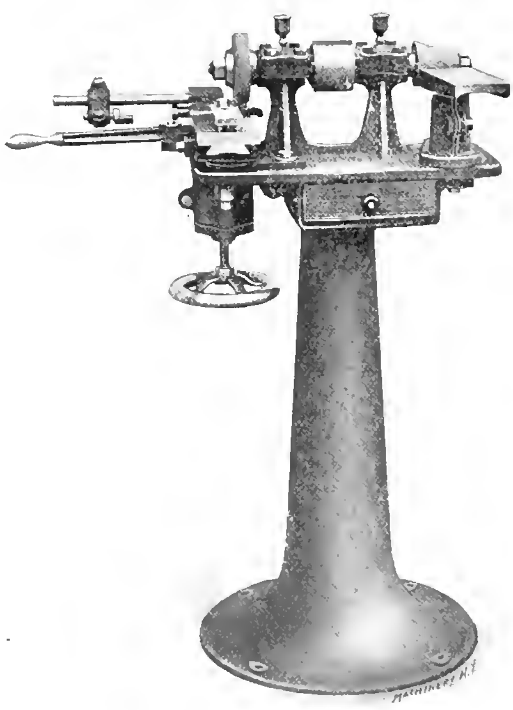
In the July issue of MACHINERY a description and illustration appeared of a No. 3 precision horizontal boring, drilling and milling machine, built by the Lucas Machine Tool Co., Cleveland, Ohio. The machine shown in the illustration was a cone-driven machine, whereas the description referred particularly to the same type of single pulley gear-driven machine. The latter type of machine which should have been shown instead of the cone-driven one, is reproduced herewith. The description of the mechanism of this machine will be found by referring to the July issue.



Lucas No. 3 Gear-driven, Precision, Horizontal Boring, Drilling, and Milling Machine.

BIGNALL & KEELER DIE-CHASER GRINDING MACHINE.

In order that a die may cut a clean and perfect thread, it is of great importance that the die chasers are provided with proper rake and clearance; if not, the threads cut are liable to be torn or stripped. It is equally important that a die chaser be kept sharp, as it is, for instance, that a lathe tool or a milling cutter be kept properly sharpened. As a rule, however, in most shops but little attention is given to the proper grinding of die chasers, and ordinarily no two chasers in the same die are ground alike. This mainly depends upon the fact that in the average shop there is no machine specially intended for doing this class of work.



Bignall & Keeler Die-chaser Grinding Machine.

Recognizing that there is a demand for a machine which will properly carry out the work mentioned, the Bignall & Keeler Mfg. Co., Edwardsville, Ill., has placed on the market the die-chaser grinding machine illustrated in the accompanying half-tone. It has been the aim of the makers to produce a simple and convenient tool which could be easily and rapidly operated, and which would require no particular skill of the operator of the machine. As seen from the illustration, the machine is provided with a special formed wheel on one end of the spindle. The die-chaser is clamped on the slide beneath the wheel, and is moved back and forth with a lever, the slide at the same time being gradually raised up closer towards the wheel by means of the hand-wheel shown. A gage on the slide, against which the die-chaser is placed, is adjustable at any angle with the wheel, in order to make it possible to grind straight thread die-chasers, as well as chasers for regular taper pipe dies. The shape of the wheel gives the die the correct angle of rake. A templet is furnished with the machine which will assist in dressing the wheel to the correct shape; a wheel dresser is also furnished. The cone-shaped wheel shown at the other end of the spindle is intended for grinding the lead or chamfer of the die-chasers. The specially shaped wheel at the left-hand end can easily be removed, and a straight face wheel used in its place, when it is required to grind tools other than die-chasers. The machine requires a floor space of 20 x 30 inches and weighs 425 pounds.

TRIPLEX BUFFING WHEEL.

A remarkable improvement in buffing and polishing wheels has been made by an invention of Mr. William A. Painter, of Pittsburg, Pa. This buffing wheel, known as the "triplex buff," is shown in the half-tone, Fig. 1, the construction also being indicated in the line engraving, Fig. 2. The buffing wheel is manufactured by the Zucker & Levett & Loeb Co., of 516-524 W. 25th St., New York City. The buffing wheel is made of the same grade of muslin as ordinarily employed for buffing wheels; but shows remarkable wearing qualities, the secret of the improved wearing qualities being in the manner in which the disks of muslin are folded and attached together. Instead of simply placing a number of disks side by side as in the ordinary buffing wheel, the Painter "triplex buff" is made in the following manner: A disk, as shown at *A* in Fig. 2 is folded along the dotted line, so as to appear as at *B*. It is then again folded along the dotted line, appearing as at *C*. A number of these folded sectors, the material of which is then four-ply, are arranged in a wheel as shown at *D*, each sector entering in between the folds in the next previous sector, for about 45 degrees of its full 90-degree angle. The prime object of this manner of making the wheel is to prevent the threads of the material at the edge of the wheel from pulling out, and fraying on the working edge. It is evident that in wheels consisting of plain circular disks, when fraying is started, it will continue all around the wheel, whereas in a wheel built up as described, there is no possibility for a continuous fraying all around the circumference of the wheel, on account of the fact that no one edge of the material continues for more than a quarter turn around the wheel.

There is another very important feature in connection with this method of making buffing wheels. When the wheel is worn down to, say, about half its original size, so that it can no longer be used to advantage, the stubs may be re-made into a wheel of the standard size, using two old wheels to make one new wheel. This is accomplished by fitting the

portions of the old wheel together in a manner as indicated at *E* in Fig. 2. In assembling a wheel of this form, two circular pieces of the diameter of the completed wheel are employed on the outside. One of these is spread out flat, and scrap pieces already folded in quarter sectors are arranged

Fig. 1. The Triplex Buffing Wheel.

radially as shown, and interwoven with one another in the same manner as described for the wheel at *D*. When a sufficient number are placed on one another to give the desired thickness, the second outside disk is placed over the folded disks and the folded disks are secured to the two outside ones by staples, the positions for which are indicated at *F*. The re-made buffing wheel is fully equal to the original buffing wheel in its wearing qualities.

The triplex buffing wheel wears at least twice as long as the ordinary wheel, and in some cases it is stated that the wear has been four times that of the regular buffing wheel.

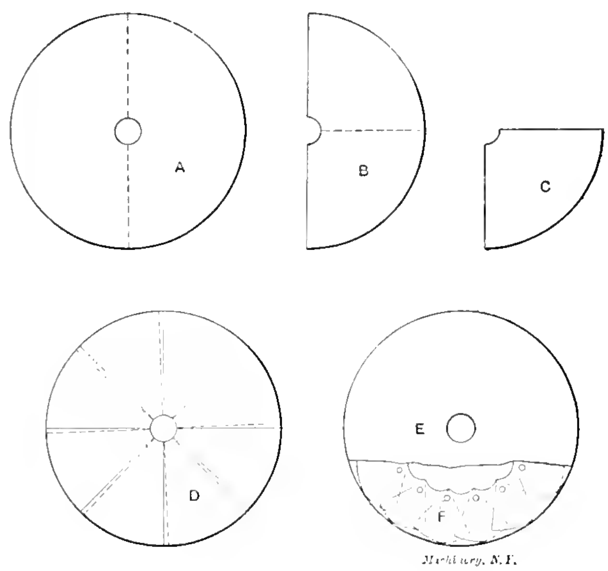


Fig. 2. Illustrations showing the Construction of the Triplex Buffing Wheel.

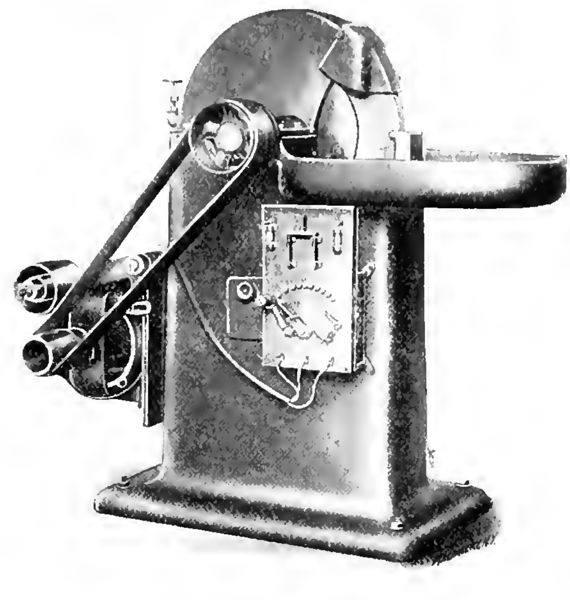
Another advantage of the wheel is that it saves rouge or other polishing composition to a considerable extent, the construction of the wheel tending to hold the composition in a better manner than does a regular circular disk. Wheels of this description have been in actual use for over a year, and thus do not constitute a mere experiment, but have actually proved their value.

RANSOM MOTOR-DRIVEN TOOL GRINDER.

The illustration herewith shows a motor-driven tool grinder brought out by the Ransom Mfg. Co., Oshkosh, Wis. One of the principal features of this machine is the application of the Ransom patent speed controller, which may be adapted to these machines when used with direct current. This device automatically speeds up the motor as the grinding wheel wears down, thus maintaining the same peripheral speed of the wheel. In general, this device consists of a field rheostat, the arm on which is connected by a link to the so-called water trap, or the piece of the guard at the front of the hood shown in the illustration, which is shoved down as the wheel wears. The connection is made in such a way that the proper amount of resistance is put into the field coils to give the proper speed for the various diameters of the wheel. Attaching the motor, as shown in the illustration, permits any size and type of motor, using any current, to be placed in position.

The water is contained in a large tank holding a month's supply. The tank can be taken out-of-doors for cleaning purposes. The pump is, in reality, a vertical blower in which there are no packed joints, so that the grit in the water does not affect it. A rubber hose is used to feed the water, as it is more easily cleaned than a gas pipe with its elbows and connections. The tool rest is perforated on the inside so that the water shoots through it on the wheel instead of spattering



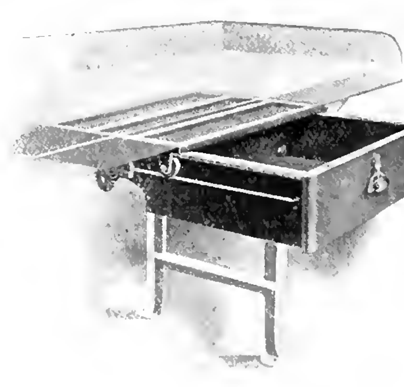
Ransom Motor-driven Tool Grinder.

all over from a nozzle above the tool, as is the case with most tool grinders. On account of this, there is no water on the upper part of the wheel except when running.

On this grinder the wheel is 20 inches in diameter by $1\frac{1}{2}$ inch wide. The floor space required by the base is 20 x 33 inches. The pulley is 6 inches in diameter by $4\frac{1}{4}$ inches wide, and the weight of the machine is 950 pounds.

NEW BRITAIN BENCH DRAWER.

A bench drawer for machine shop use has been placed on the market by the New Britain Machine Co., of New Britain, Conn. The accompanying illustration shows the appearance of the drawer, the principal features of which are the locking arrangement and the fact that the drawer is sold as a unit, and



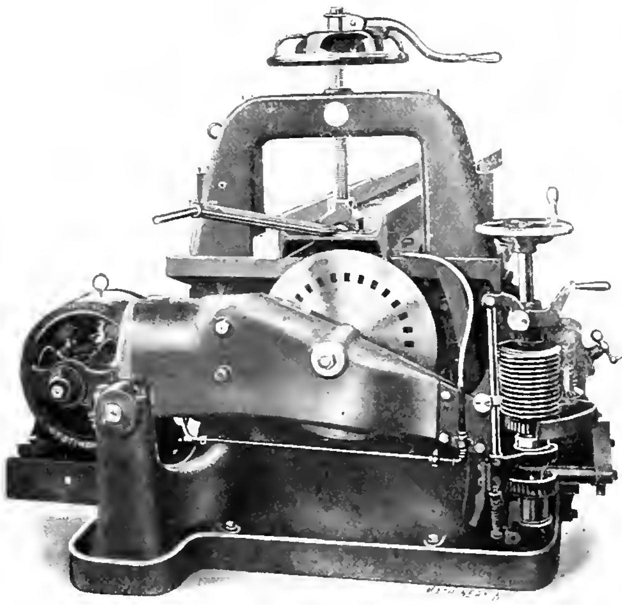
"New Britain" Work Bench Drawer.

can be applied by anybody who can insert a few screws, without any cutting of the work bench. There is no assembling to be done, and there is no damage or loss if it is ever desired to move the drawer. The locking arrangement, as mentioned, is a special feature; when locked, the drawer cannot

be entered or removed without breaking the lock. A smooth plate over the top of the drawer prevents any tampering with it from the rear. The dimensions are such that the drawer is long enough to hold, laid straight, the longest hammer or file a machinist is liable to use, and broad enough to contain the required variety of tools, without piling them on top of one another. Wood is used for the back, top and front, so that fine edge or precision tools may be laid in the drawer without damage. The drawer runs on anti-friction rollers on finished surfaces, giving a smooth movement, and at the same time clamping or wedging of the drawer is entirely prevented by a parallel motion, consisting of a cross shaft and pinions on racks. The inside dimensions are 22½ inches long, 15 inches front to back, and 5 inches deep. The weight, ready for shipment, is 75 pounds.

LEA MOTOR-DRIVEN COLD METAL SAW.

The cold-metal saw illustrated in the accompanying half-tone has been placed on the market by the Lea Equipment Co., 136 Liberty St., New York City, and has been specially de-



Lea Equipment Co.'s Motor-driven Cold Metal Saw.

signed for motor drive. This adaptation will make it particularly valuable for installation in such parts of the shop where it is difficult to locate a saw driven from a counter-shaft. There are, for instance, in the average machine shop, one or more saws required in the stock room or at some other equally inconvenient place for a belt-driven machine. In such a case, the use of a self-contained motor-driven machine will be particularly appreciated. The machine is fitted with a Westinghouse variable speed motor, having a speed range of from 1 1/3 to 1, with a speed controlling rheostat. It is only necessary to move the handle of the controller to obtain any desired speed. The size of machine shown in the illustration requires a 3½ H. P. motor, and is capable of cutting off round stock up to 8 inches in diameter. The motor is connected with the driving shaft of the saw by a Morse silent chain, direct-connected gearing having been eliminated because experiments have shown that a chain drive is more satisfactory. The variable speed of the motor permits adjustment of the cutting speed for different materials, in order to obtain the maximum efficiency of the saw. The most advantageous peripheral speed of the saw is 52 feet per minute with a very coarse feed for structural iron, machine steel, and similar materials. For annealed steel a lower speed of but 37 feet a minute gives greatest efficiency. The same speed is also used on chrome-nickel steel. The cutting-off machine itself is heavily and rigidly designed and embodies all the features required of an up-to-date tool of this description.

CONKLING REVERSING DEVICE.

The accompanying half-tones illustrate the application and construction of a new mechanical reversing device which has been designed by the Conkling Company, Chicago, Ill. The particular features of this device are that it is applicable to any

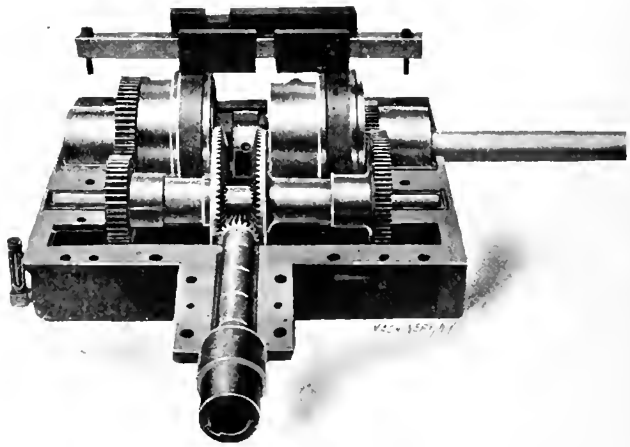


Fig. 1. Construction of Reversing Device—Upper Half of Cover removed.

machine requiring reversing, that it will reverse without shock, is self-adjusting, and automatically takes up the wear. The device is running in oil so that the wear, therefore, is reduced to a minimum.

In Fig. 2 the device is shown applied as a reversing mechanism to a planer. In this capacity the mechanism has been in operation in the Conklin Company's shop on a planer, used in connection with an individual motor drive. When applied as shown, the platen of planers ranging in size from 24 to 40 inches can be run on the return stroke at a speed of 200 feet per minute. Ordinarily the platens of these sizes of planers are not run on the return stroke at a higher speed than 75 feet, or at most 100 feet per minute.

Referring to Fig. 1, this illustration shows the construction of the reversing mechanism. The shaft extending at the right is coupled to the pinion shaft on the planer, while the other shaft extending toward the front of the device is connected to the driving motor. On this shaft is placed a bevel pinion

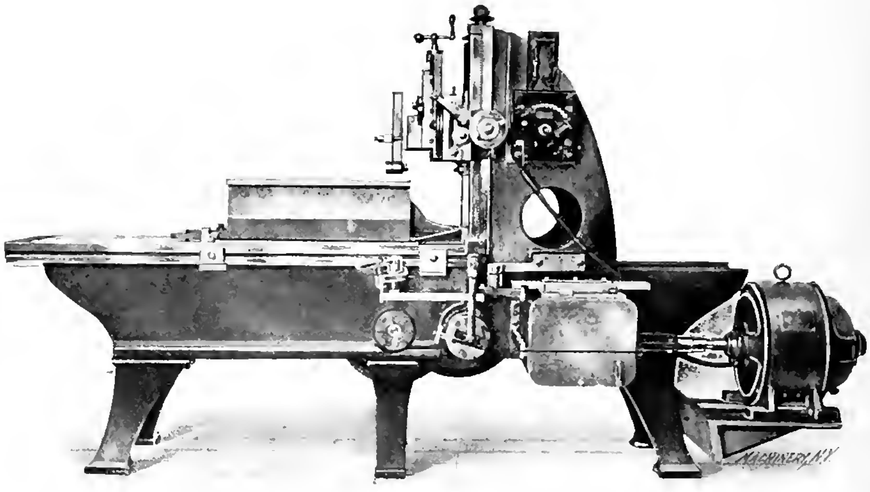

Fig. 2. Planer equipped with Conkling Reversing Device.

driving one bevel gear on each side, these gears, of course, running in opposite directions. The gear at the right runs the platen on the return stroke at high velocity, and the gear to the left drives the planer on the forward stroke. The manner in which the speed reduction is obtained is easily visible from this illustration, a large spur gear being placed to the right,

meshing with a smaller one on the planer driving shaft, while to the left a small spur gear on the same shaft as the bevel gears drives a large gear on the planer driving shaft. On this latter shaft are placed the clutches by means of which either of the spur gears on this shaft are connected with the shaft itself, the controlling yokes being shown in place in the illustration, together with the bar by means of which they are operated. To the extreme left in Fig. 1 is shown an oil gage glass which shows the depth of oil that should be kept in the gear case.

This device can be applied to any planer, whether new or in use, and in connection with individual motor drive it adds a valuable feature to the machine.

DUST EXHAUSTER FOR WALKER SURFACE GRINDER.

The accompanying half-tone and line engravings illustrate the arrangement and construction of a dust exhauster for surface grinding machines, recently brought out by the Walker Grinder Co., Worcester, Mass. The device consists principally of an ordinary exhaust fan, mounted over an iron receptacle partially filled with water, and exhausting downward into the tank. The hood over the grinding wheel is provided with a large mouthpiece on the rear side near the bottom, so arranged that it is in close proximity to the work and so that the natural course of the sparks from the grinding will be toward the suction pipe. The detailed construction is

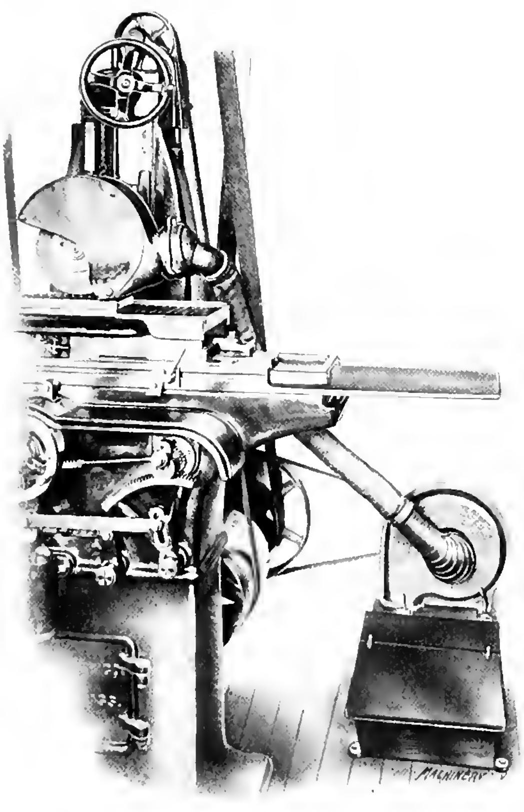

Fig 1. Arrangement of Walker Exhauster for Surface Grinder.

very plainly shown in Figs. 2 and 3. In Fig. 2, *A* is the grinder hood provided with a detachable side *B*, for the purpose of being able to easily remove and replace the grinding wheel when required. The mouthpiece of the hood is lined with a leather cone *E*, forming a seat for the ball joint exhaust connection *C*, which is held in place by the ring *D*, which is concaved on the inside opening so that it may be set to any desired angle, and clamped by means of screws *F*. The hood *A* is fastened to the grinder head and swivels around the axis of stud *G*, being clamped in position by a screw passing through the oblong slot *H*. This adjustment is introduced for the purpose of setting knife *K* of the device, so that it will just clear the top of the work, and also to provide for different diameters of wheels. The wheel shown in the half-tone Fig. 1 is about half worn out.

The fan, mounted on the water tank, as shown in Fig. 3, is driven from a 14-inch pulley on the drum counter-shaft, belonging to the surface grinder itself. If preferred, the fan can be belted to a counter-shaft in the ceiling, but as there is

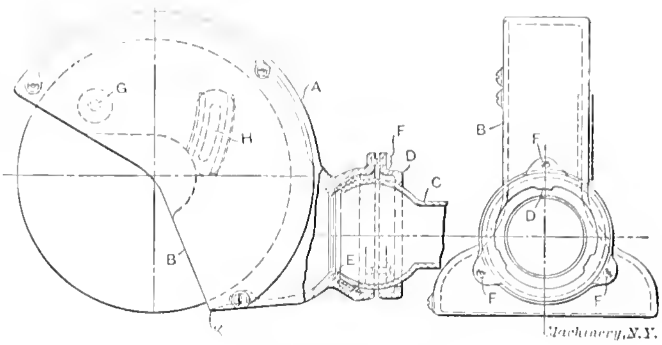

Fig. 2. Dust Exhauster Hood.

no objection to the arrangement shown, it is recommended on account of being very compact, and also because it has the merit of being self-contained. The tank is provided with a cover *M*, which can easily be raised at the front for the purpose of cleaning, and renewal of the water.

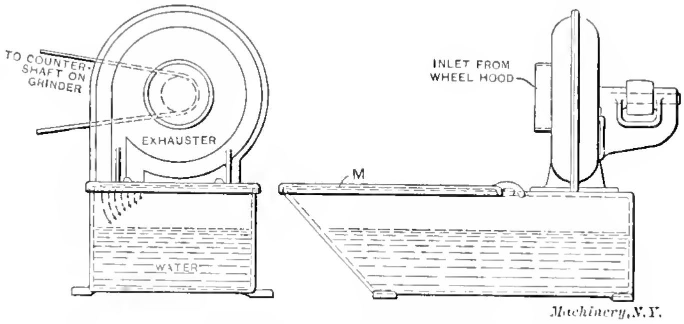

Fig. 3. Water Tank and Fan Exhauster.

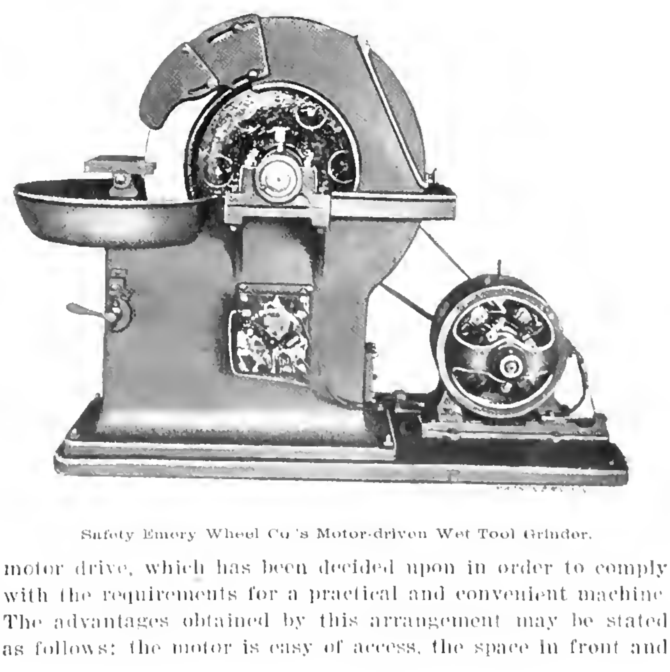
The Walker Grinder Co. has had one of these devices in operation in its own shops for several months, and has found it highly desirable for a machine used for dry grinding. While it is not claimed that the device takes care, entirely, of the metal dust from the grinding, it does exhaust all the fine dust, so that the air is not contaminated, and the slight amount of metal dust remaining is of no consequence.

MOTOR-DRIVEN TOOL GRINDER.

The wet tool grinder illustrated herewith, arranged, as shown, for motor drive, has recently been placed on the market by the Safety Emery Wheel Co., of Springfield, Ohio. The main feature of the new machine is the arrangement of the



Safety Emery Wheel Co.'s Motor-driven Wet Tool Grinder.

motor drive, which has been decided upon in order to comply with the requirements for a practical and convenient machine. The advantages obtained by this arrangement may be stated as follows: the motor is easy of access, the space in front and

on the sides of the grinder is unobstructed; there is no difficulty in renewing the wheel; and the belt connection between the motor and the wheel prevents undue wheel shock from being transmitted to the motor, and, at the same time, the belt tension is easily adjusted by moving the motor slightly back and forth on its base-plate pads. Incidentally, the advantage of being able to use any standard motor is gained, the pulleys being proportioned accordingly. The machine and the motor, although independent of each other, as shown in the illustration, are both mounted on the same sub-base plate, so that the motor forms an integral part of the complete machine. The controller is placed very conveniently on the side of the machine, as shown. As regards the grinder itself, it possesses some valuable features not commonly found. Long tools, bars, etc., can be ground by opening a hinged door or cover in the back of the gear guard. The motor is properly covered to prevent any disastrous effects from the water which may spray over it from this grinding operation. Topheaviness is avoided by ample distribution of metal near the base.

SPUR GEAR HOBBING MACHINE.

A machine for hobbing spur gears, remarkable for its simplicity of design, has been brought out by the Moline Tool Co., Moline, Ill., and is illustrated in the half-tones, Figs. 1 and 2, Fig. 1 showing a general view of the machine, and Fig. 2 a view of the machine from above.

The machine is a marked departure from any previous designs of spur gear hobbing machines. A feature that at once demands the attention of the observer is that the hob spindle is set at a permanent angle to the travel of the gear blank and is not adjustable, which, as far as we know, is a feature wherein the tool differs from all other machines for hobbing gears. Thus the spiral angles of all the hobs are set the same, and the hobs are made of different diameters in order to allow for the different pitches. For the finer

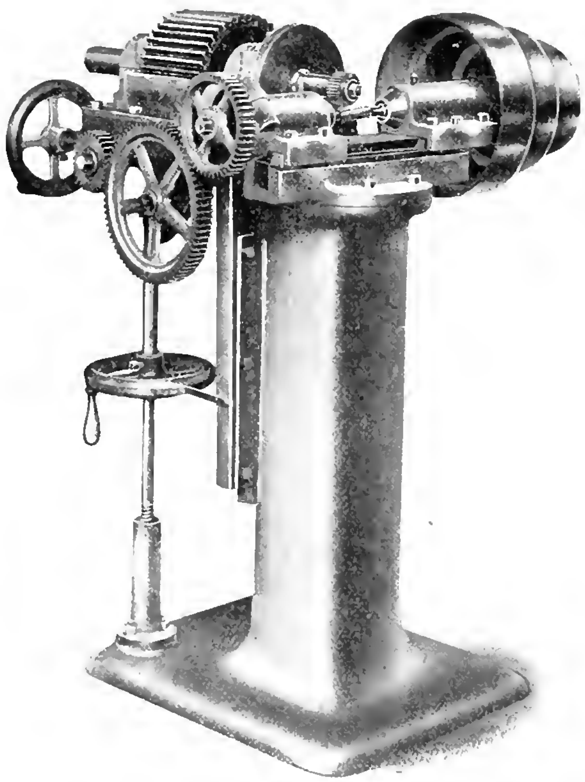


Fig. 1. Moline Tool Co.'s Automatic Spur Gear Hobbing Machine.

pitches, where the hob would become too small to be advantageously used, it is made with double thread. As is very plainly shown in Fig. 1, the hob spindle on which the driving pulley is mounted is connected by gearing to a shaft *A*, Fig. 2, at the rear of the machine, from which the rotary motion to the gear blank is transmitted. This motion, however, is not transmitted to a worm-wheel from the worm on shaft *A*, but instead of a worm-wheel a master spur wheel is used, which has sufficient width of face to traverse past the worm on the shaft *A*, Fig. 2, when the blank is fed forward. The worm shaft runs in an adjustable bearing, so that the worm can always be kept in proper mesh with the master wheel. The worm is cut at the same angle as are the hobs, so that the worm shaft and hob spindle are set parallel with each other, and are permanently in line. It is evident that this greatly adds to the simplicity of the design.

The master wheel *B*, Fig. 2, is mounted directly on the work-carrying spindle, and is mounted in bearings on a carriage or slide, which is fed automatically forth and back, so that when the master wheel traverses past the master worm, the blank to be cut is traversed past the cutting hob. On account of the parallelism between the hob and the worm-driving master gear *B*, the matter of gearing is very much simplified, and, in fact, is no more complicated than that of the gearing in an ordinary screw-cutting lathe.

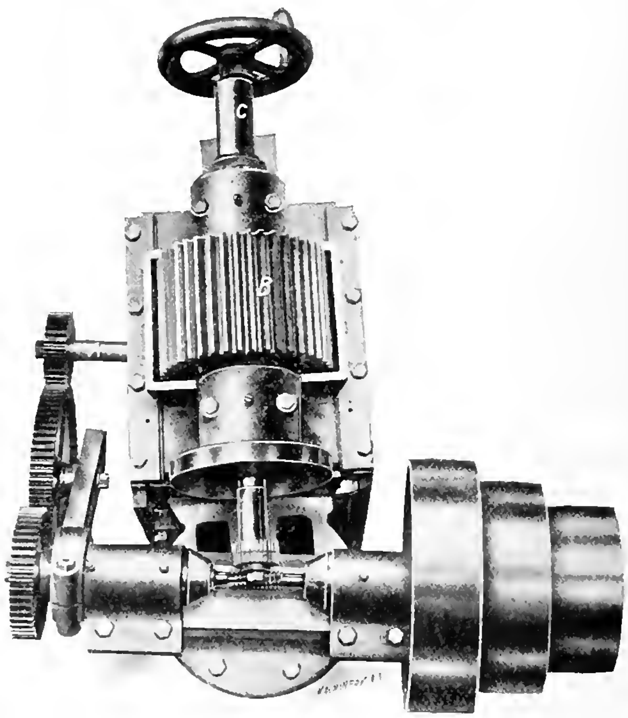

Fig. 2. Top View of the Spur Gear Hobbing Machine.

The feed of the carriage is directly from gears mounted on the rear end of the work spindle at *C*, Fig. 2, to gears on the feed-screw directly below. The end of the feed-screw is provided with a hand-wheel for feeding by hand. In the half-tones, the feed gear on the end of the work-carrying spindle and the feed-screw gear, are removed and are not visible. There is also a cover over the master gear *B*, which is removed in order to show this part.

The hob end of the column, under the hob and work, is open, so that all the chips fall directly into the opening, and are removed through a door at the bottom of the column on the back side of the machine, thereby avoiding scattering the chips around the floor. This machine is made in one size only, and has a capacity of cutting spur gears up to 12 inches in diameter, 5 diametral pitch, and 6-inch face.

GARDNER COMBINATION DISK GRINDER.

In the July, 1908, issue of MACHINERY a double disk grinder, built by the Gardner Machine Co., Beloit, Wis., was described and illustrated. The company has also brought out a combination disk grinder, consisting of the grinder as previously shown in MACHINERY, and fitted with a third wheel on the right-hand end, and with a rocker shaft fastened in the base of the machine on which any style of work table may be mounted. A style of table particularly convenient for manufacturing purposes, where rapid handling of duplicate pieces is required, termed the universal lever feed table, is particularly recommended. This table has a vertical and angular adjustment and is counter-balanced. The top surface of the table is provided with T-slots for bolting fixtures or holders

for the work. The table is operated by a hand lever, and is adjusted by a micrometer stop screw, graduated to 0.001 inch. When the right-hand end of the machine is used alone, the head carrying the double disks is uncoupled from the rest of the machine. When the machine is not used for double-face grinding at all, the movable head can be entirely removed, and a special table substituted for single-face grinding. The weight of this machine, which is termed No. 12 Combination Gardner's improved disk grinder, with all its accessories, crated for domestic shipment, is 2,200 pounds.

NORTON MOTOR-DRIVEN GRINDING MACHINE.

The accompanying two half-tones show a front and back view of a new grinding machine which has been brought out by the Norton Grinding Co., Worcester, Mass. This machine is known as a 20 and 32x168-inch self-contained electric drive grinding machine, the name being derived from the fact that the machine swings 20 inches, except in the gap plainly indicated in Fig. 1, where it will swing 32 inches. One of the principal features of the machine is this gap arrangement. In the grinder shown in the half-tones the gap is in the center of the table and is 44 inches long. The gap can, however, be made of any length and placed at any position on the table to suit the work for which the machine is especially intended.

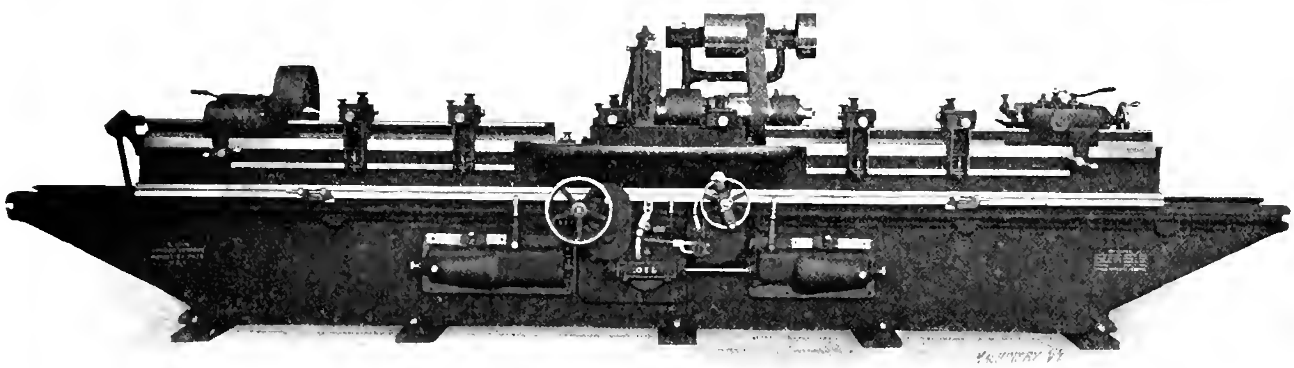

Fig. 1. Front View of Norton Self-contained Motor-driven Grinding Machine.

The rear view of the machine, Fig. 2, shows the manner of application of the electric motor. It will be seen that no extra floor space is required for the motor, as it stands within the rectangular outlines defined by the extremities of the base of the grinding machine itself. The motor should be of 20 horsepower for large and heavy work, but if the machine is regularly used for small work, a smaller motor could be applied, the makers stating that from 5 to 20 horse-power should be reckoned upon, according to the character of the work and the ambition of the operator in turning out the product. The details of the construction are practically the same as those of the regular sizes of the Norton grinding machines, and the same methods of construction as employed in the building of the regular types have been adhered to. The foot-stock is arranged for sensitive adjustment in order to secure straight work, and both the head and foot-stock are made extra heavy to insure durability as well as accuracy when heavy work is supported. The grinding wheel used with this machine is 24 inches in diameter by 4 inches face.

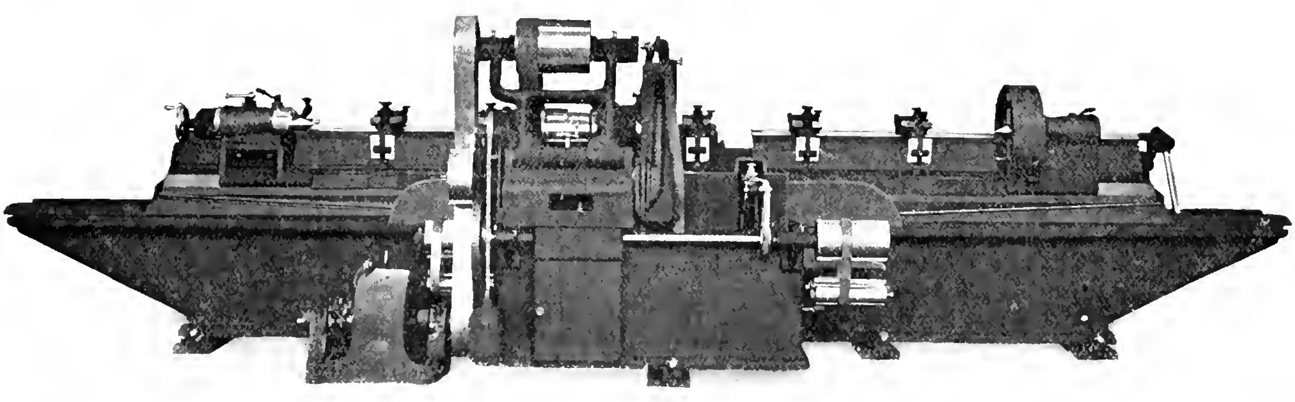

Fig. 2. Rear View of Grinding Machine, showing Arrangement of Motor and Drive.

The plates shown under the grinder bed in both Figs. 1 and 2 are intended to be carefully imbedded to straight-edge and level in the foundation of the machine. Wedges are used under the machine, resting on these plates; these wedges are adjusted with two nuts, one on either side of the projecting end of the wedge, the nuts being operated on threaded studs fixed in the base of the machine. Both the plates and the wedges are machined to insure broad permanent contact.

The machine shown in the half-tones was made especially for a German railway works, for grinding crank-pins, valve stems, truck axles and piston rods, the pistons having extension rods. Steady rests are shown mounted on a base, which is arranged to be moved along the front edge of the gap, to accommodate different thicknesses and different positions of pistons. These rests with their base can be removed to give a clear space over the entire gap. The total length of the machine is 22 feet and the total weight is 25,000 pounds.

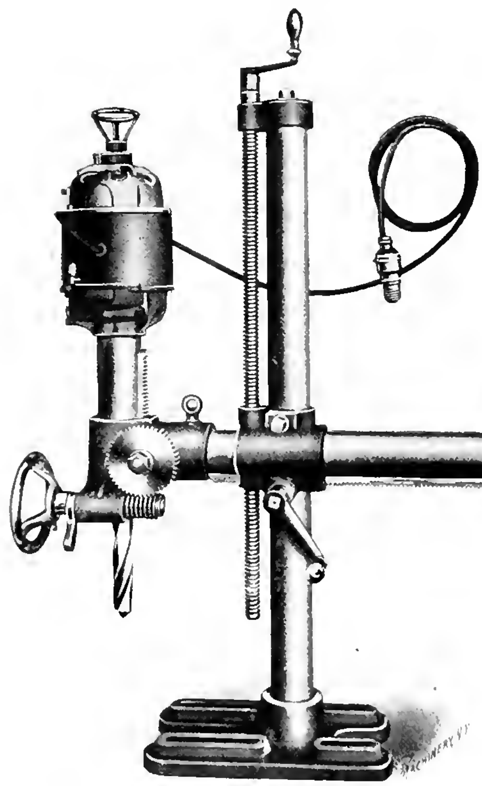
PORTABLE ELECTRIC RADIAL DRILL.

The accompanying half-tone illustrates a portable electric radial drill placed on the market by the United States Electrical Tool Co., Cincinnati, O. The general features of this machine are plainly indicated in the illustration. The drill is fitted with a rack and pinion for feeding the radial arm outward, and it can drill at a radius of 32 inches at any place in the horizontal plane and at any angle. The radial arm is provided with an index line and a corresponding line is made in its sleeve, so that the drill can be set in a perfectly vertical position in a very few seconds.

The drill can be fed downward 5 inches by means of the hand-wheel shown to the left in the illustration, which, through a worm and worm-wheel, connects with the usual rack and pinion feed arrangement. On the back side of the machine, not shown in the illustration, a crank is provided for quick return by hand. The vertical column and the horizontal arm are made of a hollow steel tubing, the column being fitted with a screw to raise and lower the arm. The drill spindle is fitted with thrust ball bearings. The motor is of the air-cooled type, and the current is taken directly from an ordinary incandes-

cent lamp socket, the motor being supplied either for direct or alternating current. The hand-wheel shown on the top of the electric drill motor, is used for knocking out the twist drills.

It will be noticed that the horizontal arm is fitted with an eye-bolt so placed that the device counterbalances at this point. This eye-bolt is used for carrying the drill about the shop



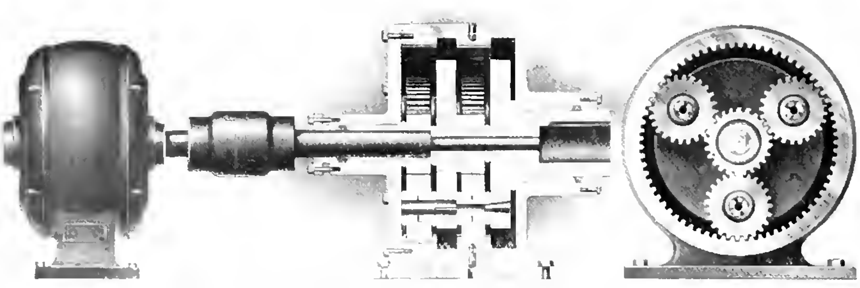
United States Electrical Tool Co.'s Portable Electric Radial Drill.

with a crane or hoist, or by placing a bar through the eye-bolt for two men to carry the drill, the weight of which is 160 pounds.

These drills are made in two sizes, one intended for drilling holes up to ⅞-inch in steel, and the other for drilling 1¼-inch holes in the same material, the drill spindle being fitted with a No. 2 Morse taper socket for the smaller size, and with a No. 3 socket for the larger size drill.

SPEED REDUCING GEAR.

The accompanying illustration shows a speed reducing gear intended particularly for reducing the speed from the motor driving shaft to any required speed of the driven shaft on the machine to which the motor is connected. As plainly shown in the illustration, the design is based on the principle of using planetary gears, two sets of which are used in order to bring down the speed reduction to the required ratio. The mechanism is entirely encased and oil-tight. The special advantage of this reducing gear is that the power is taken from



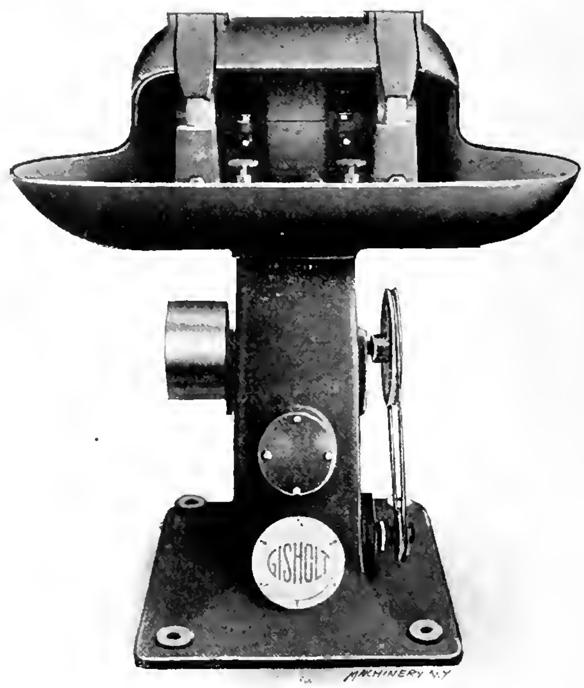
D. O. James Mfg. Co.'s Speed Reducing Gear.

three points, and all the moving parts run in the same direction, so that it gives a balanced drive that has a greater margin of safety than a drive with one or two planetary gears would have, and it requires practically no attention. The annular or internal gears are made of semi-steel, the idlers being made of steel, and bushed with hardened steel bushings. The bearings are bushed with phosphor-bronze. The device is made in a variety of sizes and speed reductions, for ⅛ to 50 H.P., and can be arranged either vertically or horizontally. A universal coupling is also made by the makers for connecting the motor to the reduction gear shaft, which obviates the necessity for perfect alignment between the motor and the device.

Several applications of the use of this speed-reducing gear could be mentioned. In one case, for instance, a 5 H.P. vertical motor driving a vertical shaft is provided with a speed-reducing gear having a reduction ratio of 73 to 1. In another case a 7½ H.P. motor with a reduction gearing of 4 to 1, is direct connected to a worm-gear elevator, this drive eliminating the objectionable belt drive. In another case, a 2 H.P. reduction gear is placed between the motor and an automatic gear-cutting machine, reducing the speed from 1,800 to 245 R.P.M. As a last example we may mention a 5 H.P. motor with reduction gear, direct connected to a line shaft, reducing the speed from 1,000 to 150 R.P.M. This device is manufactured by the D. O. James Mfg. Co., 351-353 W. Monroe St., Chicago, Ill.

GISHOLT DOUBLE EMERY GRINDER.

The double emery grinder illustrated herewith, represents one of the latest machines brought out by the Gisholt Machine



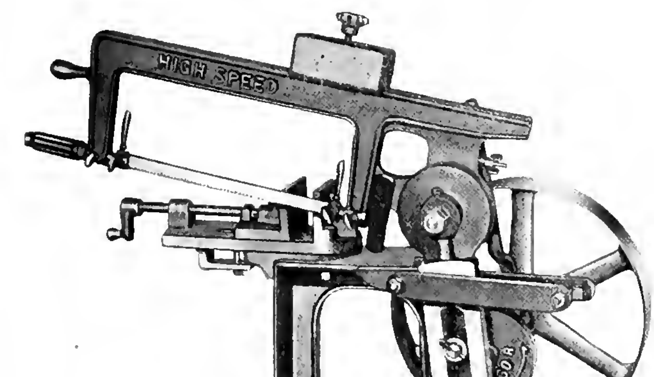
Gisholt Double Emery Grinder.

Co., Madison, Wis. This machine is supplied with two emery wheels, 1½-inch face and 14 inches diameter, mounted on a spindle running in adjustable self-oiling boxes. Any end play in the spindle may be easily taken up by adjusting two screws in the face of the spindle driving pulley. The machine is supplied either belt-driven or provided with motor drive. Several improvements have been embodied in the design of this grinder. The wheels and driving parts are enclosed as much as is possible by suitable guards. The method of water supply largely eliminates the splashing of the water, and materially assists in keeping the floor by the machine dry. A fan water pump and a large water reservoir are provided in order to insure an abundant supply of water. The water nozzle, instead of being at the usual position on the upper side of the work rest, is placed in the back or wheel side of the work rest; the water, therefore, instead of coming from the nozzle directly over the wheel and rest, follows the wheel nearly a

full revolution, and comes around in a fine spray, meeting the work at the point of contact with the emery wheel. The work is thus always in plain view. The machine has a large water pan of such dimensions that a piece of work up to 14 inches in length will come entirely within the pan when grinding, and therefore any drip from it will go directly into the pan, from which it drains into the tank, instead of splashing on the floor. It will be noticed from the engraving that the spindle pulley is well protected, so that the belt is kept entirely free from water and emery, thus materially increasing the life of the belt. The machine is very heavy for its size, and was originally designed by the Gisholt Machine Co. for its own use.

CHALLENGE HIGH-SPEED POWER HACK-SAW.

The power hack-saw illustrated in the accompanying halftone engraving is manufactured by the firm of C. J. Weinman & Co., Dayton, Ohio. It embodies several interesting features, and differs in some respects to a great extent from the ordinary type of power hack-saw. One of the special features of the machine is that a friction device is provided for raising the saw blade from the work on the return stroke, the same device forcing the blade into the metal during the cutting stroke. This on the one hand saves the saw teeth, and on the other, makes the saw cut faster. Another feature of interest is embodied in the design of the connecting arm; by having this slotted in the center, a quick return stroke is accomplished, while the forward stroke is slow. This arrangement adds about thirty per cent to the speed of the machine as compared with a machine of the old type, where the forward and return strokes are at the same velocity. Having done away with the regular type of connecting-rod, the builders have been able to present a machine that is much more compact than the ordinary power hack-saw, making it more rigid and at the same time taking up less space. The machine is provided with a swivel vise for cutting off stock at an angle, and with an adjustable stop for the length of the

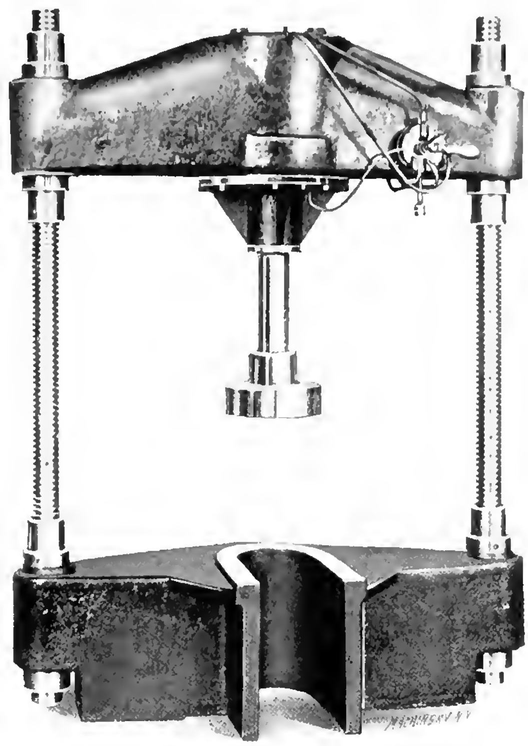


C. J. Weinman & Co.'s High-speed Power Hack-saw

stock to be cut off. The machine has adjustments to insure straightness of cut, and proper adjustment for wear. The most important dimensions are as follows: The capacity of the machine is $4\frac{1}{2}$ x 5-inch stock. The floor space occupied is 15 x 31 inches. The diameter of the driving pulley is 15 inches, the width $2\frac{1}{2}$ inches, and its speed 60 revolutions per minute. The length of saws used is 12 inches. The weight of the machine is 160 pounds.

SPRINGFIELD PNEUMATIC PRESS.

The accompanying illustration shows a pneumatic press designed and built by the Springfield Machine Tool Co., 631 Southern Ave., Springfield, O., for use in the company's own factory for making press fits, as an arbor press, etc. The tool, however, has proved to be so useful that it has been decided to place the device on the market. Besides its vari-



Pneumatic Press built by the Springfield Machine Tool Co.

ous uses in ordinary machine shops, this tool ought to find application in railroad shops, where a large number of bronze boxes are forced into locomotive parallel rods and for forcing crown brasses into locomotive driving boxes, and for many other purposes. The special feature of the press is that it is operated by compressed air. The device consists of two main frame castings and two heavy upright screws. The base casting is of massive proportions, in order to give adequate strength, and is wide enough to permit work 40 inches in diameter to be laid upon it. The opening in the base casting at its center, clearly shown in the illustration, extends back beyond the center of the device, and is for the purpose of permitting a portion of the work, such as a shaft, axle or arbor, to extend below the device a considerable distance.

The upper frame casting contains in its center the air cylinder, 12 inches in diameter, the piston having an 8-inch stroke. If required for special cases, the stroke can be made longer. The piston is fitted with three rings, which prevents air leakage. The lower end of the piston rod carries a heavy circular shoe, as shown in the engraving, the central portion of which is filled with babbitt, so that the work will not be bruised when the pressure is applied. The object of threading the two uprights is to permit adjusting the upper casting to whatever height is required by the work. By the use of the adjusting screws the press can be made to accommodate almost all classes of work.

The operation of the air for the piston is through a valve at the right-hand side of the upper frame casting, this valve controlling the air both above and below the piston. The valve is very simple in its operation. As it is moved from the left-hand position the piston is raised, while a further movement will shut off all the air; then by moving the handle still further in the same direction, the piston is lowered, which permits the full air pressure to be applied to the work. If the pressure thus obtained does not prove to be sufficient to give the desired results, a further movement of the controlling handle in the same direction throws into operation a small, quick-acting air pump, which is placed on

the top of the upper frame, but not shown in the accompanying engraving. This pump is capable of raising the pressure to 250 pounds, when the main line is supplied with air having 80 pounds pressure to the square inch. The air supplied through the valve is so regulated that the piston cannot move too rapidly in either direction. The press as shown, without the auxiliary pump, when supplied with air of 80 pounds pressure per square inch, is capable of exerting a total pressure of 8,800 pounds at the end of the piston rod, but when the pump is brought into action, it will exert a total pressure of 27,000 pounds.

TOLEDO DOUBLE-PITMAN GANG PRESS.

The demand for machines for performing punching operations rapidly and economically, as well as the activity of the manufacturers of this class of machines, is exemplified by the fact that hardly a month passes without our recording some progress in press design. In the half-tone, Fig. 1, and the line engraving, Fig. 2, a general view and the design of a double-pitman gang press, brought out by the Toledo Machine & Tool Co., Toledo, Ohio, is shown. This press is designed for operating a gang of six sets of dies for cutting out the tops or bottoms of tin cans, but the press can, of course, be used for various other classes of work of a similar nature. It is set in an inclined position in order to permit the sheet metal to feed through by gravity. The press has a capacity for producing 200,000 pieces of this character in ten hours, and its construction embodies several interesting features, which we shall refer to in detail.

When first placing the sheet in the press, the hand lever just visible on the left-hand side of the press in Fig. 1 is operated, after which the press is started in the regular manner by the foot treadle and runs continuously for the required number of

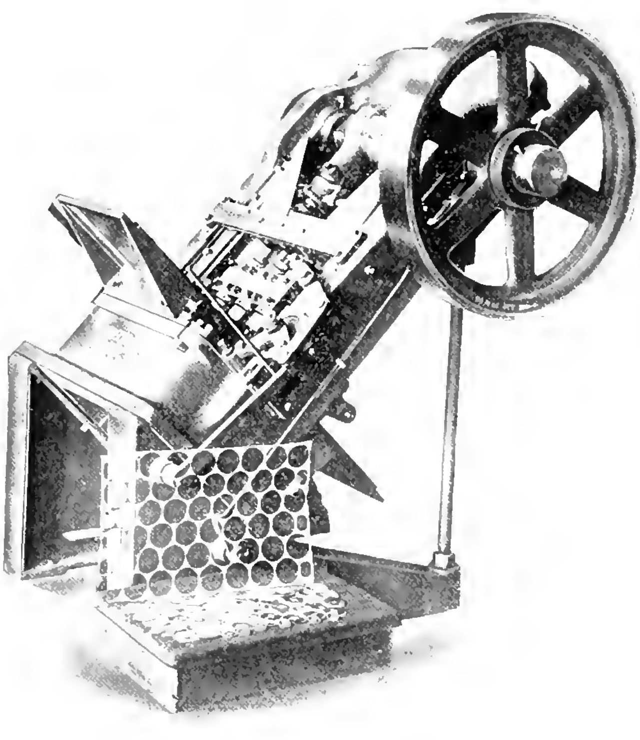


Fig. 1. Toledo Double Pitman Gang Press.

strokes to finish the sheet. At this point the press is automatically stopped by a cam movement of the disk at the right-hand side of the housing, which disengages the locking device for the foot treadle, and in this manner releases the driving clutch. The hand lever shown in Fig. 1 on the right-hand side of the press, enables the operator to instantly release the clutch mechanism, before the completion of the entire sheet, at any stroke required.

The relative position of the dies is shown in the line engraving, Fig. 2, which also shows in the sectional view the construction of the dies, and the independent means for control and adjustment of each die. The six dies are set in two rows in an alternate or staggered position in order to be able to use up the amount of stock to its fullest extent. How well this latter object is obtained is shown by the scrap left from the punching operation, which is shown in front of the base of the machine in Fig. 1. This illustration also shows how in a separate punching operation in another press the small amount of scrap left in three places at each end of the sheet is used up for rectangular can bottoms. This procedure, and the arrangement of the dies reduces the scrap to the smallest amount possible, yet leaving a web of the sheet between the holes to prevent clogging up or buckling of the sheet in the dies. This web, however, is a trifle less than 1/16 inch at its smallest width.

Referring to Fig. 1, it will be seen that the slide proper or main ram is very long, having bearings practically twice the

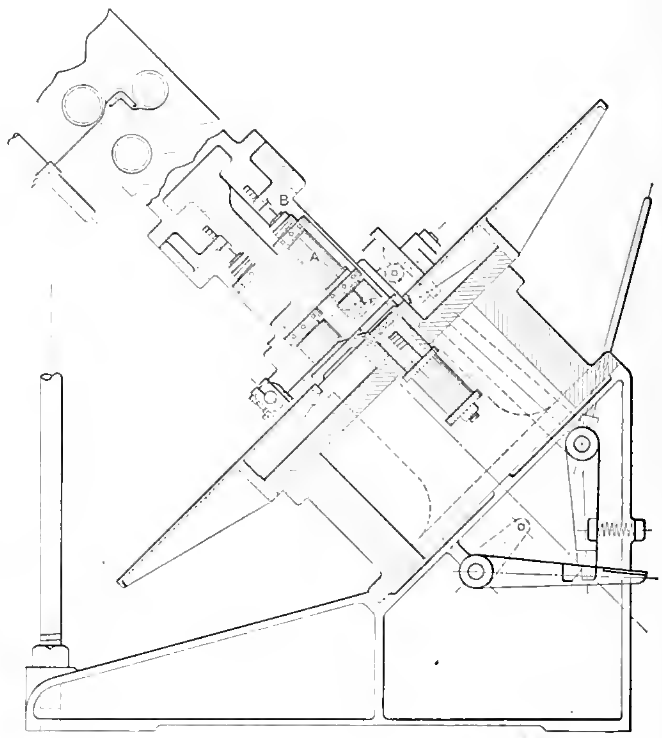

Fig. 2. Section through Press, showing Construction.

length of similar bearings in ordinary presses. Each of the upper dies fits in a recess or socket, the dies being securely clamped in position by means of a cap and four studs, as indicated. These punch holders or upper dies are provided with an adjustment obtained by a threaded shank *A*, Fig. 2, on which collars are fitted above and below the socket or cap, providing in this manner an easily accessible adjustment, in addition to the regular twin gear adjustment provided for the slide or ram proper. The cutting punches or upper dies are screwed to the ends of the shanks referred to, and can be removed for repairs or renewal without difficulty. The lower dies are each mounted separately in independent holders, which are in turn set in recesses in the main bolster or bed plate. In this manner positive and correct alignment of the upper and lower dies is obtained at all times.

An automatic positive knock-out to the upper dies is provided by means of a stem or bar *B*, running down through the threaded plunger or sleeve *A*, shown in Fig. 2, and connecting to the inner pad of the upper die. Directly above this rod or bar, and attached to the cross bar, running from right to left of the press, both in the front and rear of the machine, is the knock-out arm. This arm is fitted with a screw and jam nut, providing an independent adjustment for the knock-out to each set of dies.

The heavy bolster or bed plate is held in position by means of four large bolts. This plate has massive lugs or ears on the right- and left-hand side in front of each housing of the press, and the plate is securely held obviating the tendency to slide downward because of the inclined position.

It is not required to square the sheets to prepare them for this press, and one operation taking considerable time is thereby avoided. As already intimated, each die or set of dies in the group of six may be removed, replaced and adjusted independently of each other in the same manner as when

using similar dies in a single die press. This is one of the principal features of the machine, whereby it overcomes one of the greatest sources of inconvenience heretofore experienced in the use of gang presses.

American Steam Gage and Valve Mfg. Co., Boston, Mass. Vest pocket speed counter, registering accurately the number of revolutions in plain figures. The device is very small and convenient to carry.

Birdsboro Steel Foundry and Machine Co., Birdsboro, Pa. Motor-driven cold saw, especially designed for small work. The table on which the work is clamped has vertical and horizontal adjustment, and the saw-carrying head can be swiveled around to any angle desired. Speed variation is effected by using a variable speed motor.

H. C. H. Walsh Co., 2448 W. Kinzie St., Chicago, Ill. Turret bench press carrying four sizes of punches or other tools for punching, bending, shearing, wire cutting, riveting, embossing, etc. The capacity of the machine for punching is a 5/16-inch hole through 1/4-inch stock. It will punch holes 1 1/4 inch from the edge of the stock. The device is built to be worked by hand, but may also be fitted so that it can be worked by power.

Hamilton Machine Tool Co., Hamilton, Ohio. Double back geared lathe, intended for unusually heavy work or for high speed. The machine is known as style A lathe, and this type is made in all regular sizes up to and including 28 inches swing. Larger lathes are furnished with double gears for doing extra heavy work. The double back-gears can be instantly connected or disconnected by a spring-locking device, and either set of back-gears can be thrown in and out very rapidly.

Williams Tool Co., Erie, Pa. Improvement in the company's No. 2 pipe threading and cutting-off machine, principally in the method of the drive. The speed changes are obtained mechanically from a single speed driving shaft which may be either belt or motor driven, the size of motor required being 2 H.P. The drive for the spindle is through gears under the head-stock in the bed of the machine, the changes in gear combinations being made by sliding gears. Six speed changes in all are obtainable.

Fay Machine Tool Co., Second and Glenwood Aves., Philadelphia, Pa. Cam-cutting machine designed especially for cutting cams for textile machinery. The cams usually cut are grooved face cams up to 20 inches in diameter. Cams of other descriptions can, of course, also be cut. The machine has a duplex head, the former or master cam being bolted to one face-plate, while the cam to be cut is held to the other and operated upon by the milling cutter, which latter is driven by a belt independent of the drive for the two face-plates of the machine.

Pratt & Whitney Co., Hartford, Conn. Double spindle spline milling machine intended for slotting work of any description clear through, or grooving work to any depth required. It is particularly adapted for milling the oblong openings in drill sockets, tool-posts, boring-bars, etc. The machine is provided with two cam-controlled spindles mounted one on each end of the machine, the table for feeding the work being between the cutters in the center. Each head may be operated independently when a single keyway or a shallow groove is to be cut

Ingersoll Milling Machine Co., Rockford, Ill. Special horizontal spindle milling machine of the planer type provided with a head carrying a vertical spindle and a spindle in an angular direction adapted especially for milling gas engine beds. The machine is of large dimensions, with a distance of 42 inches between the housings, the table being 10 feet long and the weight of the machine 30,000 pounds. While especially intended for gas engine beds, the design of the machine adapts it to any other milling which could conveniently be done on a machine of this size.

Eberhardt Brothers Machine Co., 66 Union St., Newark, N. J. Automatic worm-wheel hobbing machine designed for automatically hobbing large quantities of worm-wheels for manufacturing purposes. A cam feed is used, having been decided upon on account of the large quantities of each size gear to be cut, the cam being driven through change gears from the work spindle. The wheels are hobbed without being previously gashed. The machine feeds the head downward to the proper depth of cut, automatically, and proceeds with the hobbing process until finished. When the head returns to its original position, the machine stops.

MACHINERY SWINDLER ON PACIFIC COAST.

J. J. McCabe, 30 Church St., New York, manufacturer of the McCabe double-spindle lathe, has been informed that a man representing himself as Eddie Ward, and professing to be McCabe's western traveling agent, is at present making a tour of the Pacific Coast, ostensibly selling McCabe's double-spindle lathe. He introduces himself with cards printed in large letters "McCabe" and underneath in small letters "as sure as the hand of fate—New York office, 916 Brent St.; Chicago office, 8 So. Canal St." A few weeks ago Ward called on Mr. James Roake, Oregon City, Ore., and inquired if he was in the market for a double-spindle lathe. Mr. Roake was more interested in a shaper, and gave Ward an order for one which Ward claimed McCabe had taken in connection with other tools from a defunct shop at Suisan, Cal. The shaper was represented as an 18-inch machine in first-class condition, having been used but eighteen months, and fully equipped. It was claimed that the cost of the tool was $425.00 less 6 per cent. Ward "sold" the tool to Mr. Roake for $252.50 and Mr. Roake gave Ward a check for $39.60 to prepay the freight to Oregon City. Neither Ward nor the shaper has been heard from since.

Mr. McCabe informs us that he has no Mr. Eddie Ward in his employ and that the individual representing himself as his representative is an imposter. His Pacific Coast interests are cared for by Harron, Rickard & McCone, of San Francisco and Los Angeles, and by the Hahlidie Machinery Co., of Seattle and Spokane.

* * *

About three years ago B. J. Lambert, professor of structural engineering, State University of Iowa, designed a rather novel blue-print frame, a description of which was printed in the 1908 issue of the *Transit* as follows: The frame proper is of wood with a slightly curved top, over which is stretched a thin sheet of celluloid, fastened firmly at one end of the frame. By means of a cam action and adjusting screws at the other end, the celluloid sheet can be quickly tightened, or released and rolled back to insert tracings, films, and paper. The paper can be examined readily, without removal, by partly unrolling the celluloid cover. In this way the printing can be timed as desired. Rolled tracings, films, and papers are much more readily handled than in an ordinary glass frame. The frame is also very light in weight, gives perfect contact over all the surface, prints as readily as with glass, and is, in all respects, perfectly satisfactory.

The firm of Hans Renold, Ltd., Manchester, chain manufacturer, has issued an interesting pamphlet, giving accounts of a number of tests made at the works of the firm to ascertain the relative efficiencies of belts and chains for power transmission. The results show a decided advantage in favor of the chain when used for machine tools, both in respect to output and in regard to the finish of the work, the cutting action in machines with chain drive producing a smooth finish, as compared with the results obtained by belt drive. The difference in action is attributed to two causes, the irregular slipping of the belt on the smooth surface of the cone, and a vibrating movement arising out of this slipping, owing to the elongation and the contraction of the belt under the tension of the power transmitted. The tests have been extremely thorough, having extended over two years, and the records of tests taken over this period show, as is stated in the pamphlet, an increase of 23 1/2 per cent in favor of the chain-driven machine over a similar belt-driven one.

AN AMERICAN MECHANIC IN EUROPE—5.

A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

ASKLANDA, SWEDEN, July 3, 1908.

Since writing the letter published in the July issue, dated at Paris, France, I have been through England and visited a number of the well-known machine tool builders, and other large manufacturing concerns. It can be said that, generally speaking, the commercial situation in England does not differ to any extent worth mentioning from the conditions in Germany. The replies from dealers and manufacturers are in agreement that the trade at the present time is dull, but many of the largest and best informed dealers in London and elsewhere see signs of improvement in trade all along the line. In the machine tool works which the writer has visited, the situation differs materially, even to so great an extent that one concern in Halifax reported itself as still being forced to work overtime to fill the orders, while another concern stated that it was almost entirely out of orders. This concern is working short time, and with part of its normal working force, and even then is occupied principally with stock. These two cases represent the extremes between which the true state of affairs is to be found.

The general situation in the works which are principally building large heavy machine tools, is that they are still working full time and with full force, but having only a few recent orders on hand, and not being able to secure many new orders, they fear a reduction of time or force will be necessary in the near future. On the other hand, the works making the middle-sized or smaller machine tools, as a rule have reduced their output to below the average. Mr. Cooper, with Messrs. Buck & Hickman, London, stated that their sales of machine tools amounted to about ten per cent of that of a year ago, but, inasmuch as the small tool business kept up well, the total amount of business done was about sixty per cent of that for a year ago.

The New Patent Law.

The new English patent law, of which mention has been made in MACHINERY, is now in force. A few prominent people have kindly stated their opinions to me in regard to the consequence of this legislation. Judging from their statements, there is general satisfaction with the law and its probable effect on manufacturing industry. The opinion expressed is that the various branches of Great Britain's manufacturing will be benefited by the new law, that work will be obtained for a larger number of people because of the new lines of manufacturing established to conform to its requirements, and that the buyers or consumers will reap the benefit of a keener and more highly developed competition. At first glance, it appears that the new law would cause some damage to foreign patent holders or industries that export to England, but so far as the American machine tool industry is concerned, it is not believed that the law will cause material harm. The American manufacturer of a patented American machine tool has gained advantage over the English manufacturer of the same class of machines, as regards workmanship, methods of manufacturing, etc. With the same effort and enterprise in the future as in the past, he surely will be able to keep ahead of the game, and American-made machines should continue to be bought in preference to English makes.

The Franco-British Exhibition.

The machinery section of the Franco-British exhibition, which is now in progress at Shepherd's Bush, London, is not so large or so well represented as many other sections of the exposition. On the French side, the attention is mainly drawn to the line of wood-working machinery. Very few metal-working machines are to be seen, and these are of no great interest. On the English side the showing is comparatively large, and a number of interesting machine tools are to be seen, although nothing radically new is exhibited. Outside of the machine tool exhibit, the gas engine section consisting of two- and four-cycle engines, and the textile machinery sections are the principal sections of interest to the engineer and mechanic.

Wages in England.

In my previous letters a few figures have been given on the wages paid mechanics in the countries visited, and for the sake of comparison the figures of England may have some interest. Messrs. Alfred Herbert, Ltd., Coventry, states that the average pay in its works is 5 shillings ($1.50) a day for skilled labor, and this wage appears to be a fair average for other concerns. One Halifax concern reported that its pay for skilled labor varies from 32 to 42 shillings a week, which makes practically the same average.

Shop Notes from Machine Tool Building Works.

In my notes from Germany, it was remarked that the German machine tools, generally speaking, have the characteristics of being heavier and more solidly built than American machine tools. This is noticeable in a still greater degree in English machine tools, these being more heavily designed and more liberally dimensioned, even than German tools. The average Britisher likes a machine tool that looks very strong and rigid. This fact probably should be credited for the not unusual occurrence of finding machine tools in English works of great age, sometimes up to forty or fifty years, which are still doing work sufficient to warrant continuing them in service in this age of high-speed heavy duty machines. One feature that is sometimes found in English heavy duty lathes, which lends rigidity, is that of having the head-stock cast in one piece with the bed. This practice, however, is not followed to a large extent now, because of the greater manufacturing cost as compared with the separate head-stock construction.

One of the best known of all the English machine tool works is that of Messrs. Alfred Herbert, Ltd., Coventry. The growth of this establishment has been rapid and continuous. When it started twenty-one years ago it employed but twelve men, and now it employs not less than 1,500 throughout the works. The original plant is located in Coventry. Extensions required to accommodate the rapidly growing business, long ago covered the available space, and the company was forced to build an additional plant on a plot removed about two and one-half miles from the old works. The new plant is located at Edgwick where the foundry and pattern stores are already built. In laying out and equipping the new works, the company utilized its experience gathered throughout the years spent at the old plant, and in view of the past rapid growth, it has deemed it advisable to provide for large extensions in the future. The machine shop, in fact, has been designed so that it can be multiplied by four should trade conditions warrant such extensions. Provisions have also been made to extend the various auxiliary departments to a corresponding extent. (See MACHINERY, March, 1907.)

The chief machines manufactured in the new works are milling machines of both vertical and horizontal types, sensitive drills, cutter grinding machines and milling attachments. The old works are principally devoted to the manufacturing of turret lathes, automatic screw machines, and gear-cutting machines. The line of turret lathes comprises principally the hexagonal turret lathe for bar work, the combination turret lathe for chuck work, and the capstan lathe. The turret lathes are equipped with new roller back rests which have the advantage over the common back rest usually provided with turret lathes, of making heavier cuts and higher work speeds possible. With the heavy type of Herbert hexagon turret lathe a bar can be reduced from two inches diameter to one inch diameter at the rate of six inches per minute. It was interesting to note in these works to what large extent special jigs and fixtures are employed in order to reduce manufacturing cost. A feature of the manufacturing practice, of technical interest as well as indicative of the care that is taken to obtain good workmanship, is that all heavy castings such as lathe beds, milling machine columns, heavy slides and tool rests are stored for about six months after having been planed or milled. Then they are sent to the erecting department for assembling. The claim is made that the storing of the castings is necessary because they change shape slightly during the seasoning period. This change of shape is very slight, however, and does not necessitate re-machining when the parts are taken from the store-

room to the assembling department. Scraping is sufficient to correct the change of shape.

Generally speaking, the English machine tool builders do not specialize on one or a few machines, but build a multiplicity of types and sizes. Some concerns go so far in this direction as to build a complete line of machine tools from the smallest up to the largest sizes, but, of course, this complete line does not include any but the types that are most commonly found in average machine shops. Even in small and middle-sized shops where specialization is of, perhaps, greater importance than in the larger works, this condition holds true. A large establishment can afford to carry a larger number of sizes and types than the smaller works, and still employ the labor-saving devices and methods that are employed in specialized manufacture. There is safety in building several types of machines as compared with specialization on one, because at one time some one machine tool is in demand in the market, and at another time another machine tool will have a call, and so on. When a concern has only one type, it feels the fluctuations of the market more, while in the other case the fluctuations of the market for one type will, to a certain extent, be balanced by the fluctuations of the other types. This is probably the chief reason why English manufacturers do not specialize.

The small and middle-sized concerns seldom make any machines for stock, but as a rule build only to order. It seems to be a very common practice to build machines in batches of two, four, or six at a time, and only occasionally in such large batches as twelve. To fill out a batch, sometimes one or two machines are made extra for stock in case the order is not large enough.

An interesting middle-sized concern which the writer visited is H. W. Ward & Co., Birmingham. Some time ago this concern set out to supply a full line of machine tools, but it has dropped the manufacturing of a few types and sizes which it intended to build. The firm still makes a large variety of machines, engine lathes, turret lathes, milling machines, etc. A short time ago the concern took up the manufacture of a few types of grinding machines, and it has now placed on the market an internal grinding machine with a special feature. The machine is designed especially for the grinding of bushings and similar parts, and is equipped with two grinding wheels. The principal wheel for internal grinding is mounted according to the common practice, while the second one for grinding the ends of the part is mounted on a slide behind the internal grinding wheel spindle. The object, of course, is to be able to face the end of the bushing at the same setting at which the internal grinding is done.

One of the largest centers of machine tool manufacture in England is Halifax, and besides size, it offers many features of interest to the American visitor, one being that it is typically English. In explanation of this statement, we might say that the larger machine tool works on the Continent and in England cannot be said to be typically representative of the countries in which they are situated. The lay-out of the works and the methods employed are generally in accordance with the best internationally recognized practice. The practice that is typical of a country's work is to be found in the middle-sized and smaller shops. Generally speaking, this is so, but, of course, it does not always hold true. The machine tools made in Halifax are of the heavy English design to which reference already has been made. Regarding the quality and workmanship, the product varies from the good average machines which will satisfy all requirements of the ordinary up-to-date machine shops, down to the cheap grades of machines which are only good enough for the small repair shops, and whose principal recommendation is low price.

The manufacturers of the low class of machinery and tools are, one can say, without exception, small concerns with work laid out without system, equipped with old-type cheap-class tools, and evidently lacking all modern methods and devices. It seems impossible that these small old-fashioned works, in this age of highly developed labor-saving machines and methods, could still continue to do business enough to keep alive and pay interest on capital invested. About the only reason that the writer has been able to assign is that there is not enough competition in the cheap class of machinery. There is quite a large demand for cheap tools from small repair shops and small jobbing shops having a limited amount of capital, but this demand is neglected by the ordinary manufacturers. A concern employing modern methods and machinery goes in for the manufacture of high-class machinery and it does not care about the demand for the cheap machines. The consequence is the existing condition under which the buyer of cheap machinery has to pay a much higher price than should be the case were modern methods employed for manufacturing this class of tools.

J. Butler & Co., Halifax, is one of the middle-sized concerns making a good heavy class of machinery. This concern is engaged in the manufacture of nearly all kinds of machine tools from the small size up to the largest size, but is principally pushing its line of planers, shapers and slotting machines. Another concern in the same class, but somewhat smaller, is John Stirk & Sons, Ltd., Halifax. One of the few concerns that have started out to specialize to a large extent is Messrs. William Asquith, Ltd., Halifax. About eight years ago this concern devoted itself to building drills and boring mills. Its line of radial drills is very large, and contains types ranging from the smallest size for use of tool-makers, up to the largest size used by large ship-building concerns. The company usually builds the machines in lots of three throughout all departments, only occasionally making a larger number at a time.

Probably the oldest and at the same time the largest of the concerns in England, is that of W. G. Armstrong, Whitworth & Co. This concern owns several large plants for ordnance work, ship-building, engine building, machine tool manufacturing, etc. The chief work executed at its plant at Openshaw, Manchester, consists of ordnance work, armor-plates machine tools and small tools. The line of machine tools is large and the concern claims to build as complete a line as it is possible for any concern to build. Of special interest is its line of heavy machine tools for ordnance work, especially for planing and cutting off armor plates. Its heavy armor plate planer has not less than eight tools cutting at a time. To save the time ordinarily lost on the return stroke, the planer is built to cut both ways. The principle of the reversible tool-holder which is used on smaller planers here, could not be employed on this large planer on account of the great strength and rigidity required. Instead, the tool-holders are made to carry two tools, each of which is arranged so that one tool cuts in one direction while the other cuts with the table traversing in the opposite direction. The work remains stationary because of its heavy nature, while the two housings and cross-rails are traversed back and forth by heavy screws. (See MACHINERY, June, 1908, for photographs of pit planers used on armor-plate, etc.) The principle of using double tool-holders with two tools, one cutting one way and the other the other way, is applied to nearly all of the Armstrong armor-plate working machines and is a feature of much time saving.

It was of much interest to the writer to see planers fifty years old still in use in these works. These planers are of small size, built along common lines for small planers, that is, with reciprocating work table and fixed housings. A feature of interest is the reversible tool-holders which enable the planer tool to cut both ways. There is no quick return of work. A mechanism operated at each reverse of the table, reverses the tool-holder and the tool. The design is necessarily somewhat weak and it cannot be used successfully on heavy duty planers.

Another old established concern is Messrs. Smith & Coventry, Salford, near Manchester. This concern now employs about 500 men, and is principally pushing its lines of milling machines and drills, although also engaged in making boring and turning mills, ordinary engine lathes, gear-cutting machines, etc. In building sensitive drilling machines, careful attention is paid to the reducing of friction by means of ball bearings and anti-friction devices. Much attention is also paid to the rigidity of construction and with their heavy-duty drills a rate of drilling speed of 12 inches a minute has been obtained when drilling 1-inch holes.

Regarding the system of manufacture, all standard parts such as screws, studs and small parts that can be used for

several sizes of machines, are made in quantities sufficient to last six months or more. When the store for a certain size of stud is exhausted, an order for new studs is placed, sufficient to last another six months, and so on. As a rule large machine parts are not made for the store, but only to order.

Regarding the use of automatic labor-saving machinery in the machine tool works, it can be said that not so much automatic machinery is used in England as in America. Many English manufacturers claim that they can do better with less automatic machinery. For example, take the case of a machine tool manufacturer making his own supply of studs. The Englishman's view of the situation is that a cheap man, or even a boy can easily be put on this work on a hand-operated turret lathe, and will soon acquire skill in the particular operations involved, and consequently will soon reach high efficiency. There is no expensive machinery and no large capital invested. On the other hand, with automatic machinery, a high-priced man has to be employed for running it, and, in addition, there is a higher rate of interest on the capital invested. In a middle-sized machine tool shop which does not specialize, there is not sufficient work to be done on automatic machinery to keep the highest number of automatics that one man can manage efficiently, running all the time. When there is not sufficient number of automatics employed, and not sufficient work obtainable to keep the machines running but a small part of the time, the cost of labor becomes higher than with hand-operated machinery.

In the works of Messrs. Mather & Platt, Ltd., Salford, near Manchester, where gas engines, steam turbines, pumping machinery, textile machinery, electric motors, etc., are built, an interesting kink for cutting long screws was noted. An ordinary lathe is used for the purpose, the carriage being operated by a feed-screw as in ordinary thread-cutting practice. In addition to the common mechanism of all thread-cutting lathes, there is a device on the carriage which automatically reverses the traverse of the carriage, and at the same time operates the tool slide at the end of the screw, moving the threading tool backward to clear on the return, and advancing it into the work at the beginning of the cut. The depth of the cut can be regulated by hand when desired. The feed is automatic and at the back of the lathe a reversing bar is provided carrying two adjustable stops by which the reversing mechanism and tool slide are operated. Provisions are made for quick return of carriage. There is no automatic stop to stop the tool slide when it has reached the correct depth, the workman having to watch the work and stop the machine by hand when a screw is finished. With the exception of this omission, the machine works automatically. One man can operate three machines when cutting screws. [These lathes are evidently adapted to cut screws automatically in about the same manner as performed by the automatic threading lathe built by the Automatic Machine Co., Bridgeport, Conn.] —Editor.

Messrs. Hulse & Co., Ltd., Salford, near Manchester, a middle-sized concern, is putting its efforts into building large heavy machine tools for ordnance work, turbine shops, shipbuilding shops, etc., its works being equipped for just this kind of machine tool building. At the present time it is, to a large extent, engaged in machinery for the ordnance trade.

Another concern engaged in the same line of machine tool building is Messrs. Craven Bros., Manchester, but this concern is also building a few smaller sizes of machine tools. At the present time it is principally engaged on a large number of heavy machine tools for ordnance work, thus to some extent indicating the activity of Great Britain in her defensive and offensive preparations for war.

* * *

MISCELLANEOUS FOREIGN NOTES.

German Locomotive Exports.—Last year Germany exported 552 railway locomotives, and 395 smaller locomotives for industrial purposes, up to 10 tons each, together with 3,605 tons of locomotive parts. Italy was the principal customer for German locomotives, but large shipments were also made to France, Chili, Argentina, and Brazil.

German Ship Building Profits.—While the English ship building yards have experienced considerable difficulty during the last part of the last year and during the first part of the present year, one of the chief German ship building yards, the Vulcan, of Stettin, does not seem to be financially embarrassed by the present depression, a dividend of 14 per cent having been declared for the last year. The company has reduced the working hours from 10 to 9½ hours a day.

Russian Steel Trust.—Rumors have long been circulated about the plans for the formation of a Russian steel trust. This trust or union has now become an established fact. The syndicate comprises the works in Southern Russia, and will control about 65 per cent of the aggregate steel production of the country; it will also be the owner of important ore deposits and coal mines. The working capital comprises about $75,000,000, and the trust is financed by Belgian and French financiers.

Electrical Industries in Germany.—Messrs. Felten and Guilleaume-Lahmeyer, of Mülheim-on-Rhine, Germany, one of the most important of the German electrical companies, state in their annual report, that the past year was one of exceptional activity. During the year the company obtained orders for dynamos amounting to total capacity of 500,000 horsepower. The capital of the company is nearly $14,000,000, and the dividend declared was 10 per cent. It is mentioned that the new patent law in England is likely to influence the German electrical trade.

British Trade Conditions.—The British machine tool trade is likely to be seriously affected for some time to come by the conflict in the ship-building trades between employers and employes, on account of which some works have closed. The difficulty is caused by the resistance of the employes to a reduction in wages. Unless an early settlement of the differences can be arranged, between 50,000 and 60,000 men will be affected directly in the ship-building trades, and a great many more indirectly by the stagnation in other trades which will necessarily follow.

Shipbuilding in Great Britain.—The conditions in the British shipbuilding trades are rather discouraging. The tonnage of vessels launched in Scotland during the month of May was exceedingly small. On the Clyde 25 vessels of only 11,072 tons were launched, as compared with 30 vessels of 43,670 tons in April this year, and 40 vessels of 62,246 tons in May last year. The comparatively large number of vessels launched is accounted for by the number of barges, tugs, and other small craft included. For the first five months of the year the total tonnage launched was 114,826 tons, as compared with 242,392 tons for the same months last year, a decrease of considerably more than 50 per cent.

The German Iron Industry.—At a recent meeting of the Union of German Iron Masters it was stated that while there had been a falling off in the business since last December, the depression was less pronounced in Germany than in other countries. Rather than to dismiss a large number of men, the iron industry had disregarded the trade requirements of the moment, and had continued its production to a certain extent, and kept the surplus material in stock. The advantage of the quiet time now prevailing after the past period of high tension was appreciated, inasmuch as it gave many works an opportunity of completing and repairing their plants. The basis for future development is considered sound.

Trade Conditions in Sweden.—According to a report read at the last quarterly meeting of the Union of Swedish Iron Masters, the general business depression has made itself felt in the Swedish iron market, and the exports of bar iron show a decline of 25 per cent during the first three months of this year, as compared with the same period last year. Many of the works, however, have orders since last year which have not yet been filled, and these will keep them busy for several months. The number of blast furnaces going was 114 as against 120 for the same period last year. The machine tool and general machine building industries seem not to have been affected very much by the general depression. Several important firms are extending their works, and as soon as the present uncertainty in business becomes settled the demand for machine tools is likely to be considerable, as many extensions to shops now being built will then have to be equipped.

WORK OF THE U. S. GEOLOGICAL SURVEY IN CONSERVING NATURAL RESOURCES.

The United States Geological Survey has been an important factor in the movement for the conservation of our natural resources, for many years, and while its work has been to a certain extent altruistic in that the immense benefits will come to the generations of the future, it has already saved millions of dollars' worth of resources for the people of to-day. The Survey's geologic and topographic work have resulted in an inventory of the natural resources, a stock-taking such as a prudent manufacturer takes once a year. This has disclosed the waste that has been going on, and led directly to the conference of the governors of the States in Washington in May. The study and classification of the coal deposits of the United States and especially those on the public domain, have established the value of these coals and have prevented the thoughtless disposal of the 50,000,000 acres of government coal lands. The values of the mineral deposits on government land have been approximated to such an extent that it will now be impossible to dispose of them without getting a fair return.

While there have been many immediate benefits from the topographic work and a study of the water resources of the country, their value to the people will be many fold greater in the near future. Without an accurate topographic survey of the land and water, the contemplated improvement of the waterways, the drainage of swamps and the great irrigation projects would be impossible. The work already done along these lines will push these big improvements forward several years and result in the saving of much money.

In its endeavors to check the great waste of the natural resources, the Survey a few years ago extended its field by taking up the subject of the utilization of the fuels of the country and so fruitful have been these investigations that there is every promise of a saving of millions of dollars within a short period. These investigations appeal directly to the manufacturer, the business man and the consumer, for they show him how to realize immediate economies he never dreamed of before.

Authorized to test the fuels owned by or for the use of the government itself, the Survey has made a number of discoveries of the greatest importance to the entire people. At the government's fuel-testing plant, it has been shown that the gas engine is capable of generating from two-and-one-half to three times as much power, using a given amount of coal, as can be obtained from a steam engine. This means, it is declared, that a 600 horse-power gas engine will save $5,000 a year in its coal bill over the same power steam engine, and that the saving on a 6,000 horse-power gas engine ought to amount to $72,000 a year.

The gas engine has also opened the way for the use of millions of tons of low-grade fuel, much of which has heretofore been thrown away as useless. The tests have shown that coals, practically valueless under steam boilers because of their high percentages of impurities, have in a gas producer generated sufficient power for the gas engine to render them of high commercial value. Coals as high in ash as 45 per cent have been used successfully in the gas engine.

In the West, where the supply of high-grade coal is inadequate, the low-grade lignites (the poorest form of coal) of North Dakota developed as much power when converted into producer-gas as did the best West Virginia bituminous coals when used under the boiler of a steam engine.

To the West, this discovery of the government scientists is of the utmost importance. It makes possible the introduction of cheap power and therefore the establishment of an industrial empire of immense proportions. There are many million acres of lignites in the West, an almost inexhaustible supply for fuel that, so far, has been practically useless, the people being compelled to send a great distance for their coal and pay big freight charges on what they used.

In the average steam engine to-day but 5 per cent of the coal energy is transformed into work. In the gas engine, this percentage of efficiency is 12½ per cent. The coal used in generating power in the United States last year amounted to about 300,000,000 tons. With the universal use of the gas engine, it is estimated that at least 100,000,000 tons of this coal could be saved.

In testing the efficiency of coals under the boiler of a steam engine, the Survey engineers suggest still another way to save the fuel. Recent experiments indicate that boilers ought to perform two or three times the work they do now. In New York City, a certain large corporation has almost doubled the capacity of its power plant by placing furnaces in the rear of its boilers as well as the front. This was done at a saving of several hundred thousand dollars, as it would have been necessary to purchase additional land held at a high figure to carry on the work. The tests of different coals under the steam boiler at the government plant have also showed the possibility of increasing the general efficiency of hand-fired boilers 10 to 15 per cent over ordinary commercial results.

The Survey is also engaged in a general analysis of the coals of the country. These analyses have resulted in the government purchasing coal on definite specifications based upon its heating value. Under this system a better grade of coal and coal better adapted to the types of furnaces in the government buildings has been obtained without any increase in cost, which in itself is a saving to the government. These investigations, by suggesting changes in equipment and methods, are also indicating the practicability of the government's purcnasing cheaper fuels such as bituminous coal and the smaller sizes of anthracite, instead of the more expensive sizes. With new boilers in the heating plant of the State, War and Navy Building in Washington, $15,000 is now being saved each year in the coal bill for this building alone. Many power plants are now buying fuel on specifications and have obtained increased efficiency as a result of the government's investigations. These tests of the coal will aid manufacturers, wherever situated, to save money in the purchase of coal, for they will enable them to learn where they can buy coal that is best suited to their purpose.

The government has found still another way of conserving the fuel resources in the briquetting of coal. The investigations show that in the near future the great quantities of waste coal seen about every mine and the low grade coal that is now being left in the mines, will be utilized in the generating of power and for locomotive power and domestic heating. Successful tests of briquets were recently made on two railroads. The briquets, which were made from the slack of high-grade bituminous coal, showed an economy of 20 per cent over the same lump coal, not taking into consideraton the cost of making the briquets.

At the government fuel-testing plant at Denver, Colo., investigations into the washing and coking of coal have been carried on for a year with much success. In the washery plant, it has been shown that coals were greatly improved by washing, at the nominal cost of from three to ten cents a ton. In recent experiments, the experts have succeeded in making coke out of several coals that have been regarded as non-coking. Of thirty-seven samples tested from the Rocky Mountain region, all but three produced good coke, though a number of these were considered non-coking coals. When the metallurgical interests of the West are noted, the importance of these investigations will be realized.

* * *

PERSONAL.

J. B. Doan, vice-president and general manager of the American Tool Works, Cincinnati, O., returned July 17 from a business trip in Europe.

S. E. Balcom has been appointed chief engineer of the power, light and heat service of the Worcester Polytechnic Institute, following the resignation of Noah Ashwood.

C. A. Parsons, the inventor of the Parsons steam turbine, received, on June 11, the honorary degree of doctor of engineering, at the Liverpool University.

Dyer Smith, formerly an associate editor of MACHINERY, and later an examiner in the Patent Office, Washington, D. C., has graduated in a course of patent law, and is now employed as a patent attorney by Mr. Thomas A. Edison, Orange, N. J.

Carleton A. Reed, recently professor of mechanical engineering at the New Hampshire State College, has been appointed to fill the position vacated by Prof. George I. Rockwood, as professor of steam engineering, at the Worcester Polytechnic Institute.

George I. Rockwood, who for the past two years has occupied the chair of professor of steam engineering, at the Worcester Polytechnic Institute, has resigned. It is Professor Rockwood's intention to take up his entire time with the Worcester Fire Extinguisher Co.'s business, with which he has been connected for some time.

J. W. Lutz, since 1880 assistant superintendent and general foreman of the O. S. Kelly Co., Springfield, Ohio, has resigned to become superintendent of the Duplex Mill and Mfg. Co., Springfield, Ohio. This concern has bought the grinding business of the O. S. Kelly Co. and will extend its business to include other products. Mr. Lutz is a stockholder in the new company.

Walter M. Nones is here from London, England, to get in touch with manufacturers of specialties in machinery, tools and allied lines, who care for European trade, either for the purpose of securing agencies or licenses of patents. Mr. Nones informs us that he has placed some important lines abroad and would like to hear from manufacturers who are interested.

L. Moulthrop, who has been connected for the past thirty years with the New Haven Mfg. Co., New Haven, Conn., manufacturer of machine tools, recently resigned as secretary and treasurer, still remaining as director. William H. Brown, who has been with the company a long time, succeeds Mr. Moulthrop as secretary and treasurer, and J. Judd continues as superintendent.

* * *

OBITUARY.

Charles H. Dale, of New York, died at his summer home in Larchmont, N. Y., July 18, from heart disease, after a brief illness. Mr. Dale was born in 1852. He was prominent in the rubber manufacturing business, being president and director of the Peerless Rubber Manufacturing Company, the Mechanical Rubber Company, the Morgan & Wright Company of Detroit, the New York Belting & Packing Company, the Rubber Goods Manufacturing Company, the American Commerce Company, and director in other rubber companies.

George H. Daniels, for many years general passenger agent of the New York Central R. R., died at Lake Placid, New York, July 1. He was born in Hampshire, Ill., 1842, and was in railroad service one way or another since he was a young lad. He entered the service of the New York Central in 1886, and in 1889 became general passenger agent. He doubtless was the best-known passenger agent in the world. His advertising methods were unique, and the literature issued was the most interesting issued by any railway. Mr. Daniels retired from active service of the New York Central May 1, 1907.

NEW BOOKS AND PAMPHLETS.

THE HEWITT CORRESPONDENCE SYSTEM. By W. C. Holman. 38 pages $4\frac{1}{2}$ x 6 inches. Published by W. C. Holman, Chicago, Ill.

This booklet describes a system of correspondence, devised by Mr. Frank L. Hewitt, of the National Cash Register Co. It outlines a method of formulating letters and numbering paragraphs by which the correspondent can indicate to a stenographer the letter to write for any given condition likely to recur in correspondence, thus saving much valuable time and securing the maximum beneficial results that can accrue from a well-conducted business correspondence system.

CURVES FOR CALCULATING BEAMS, CHANNELS AND REACTIONS. By Sidney Diamant. 38 pages, 7 x 10 inches. Published by the McGraw Publishing Co., New York. Price, $2.00.

As indicated by the title this book was prepared to save time in structural designing by using the graphical process. The graphic method greatly facilitates the economic design of steel floor beams for various intensities of loading, and twenty-five plates for loadings of 80 pounds per square foot, up to and including 500 pounds per square foot for various lengths of span, and widths, center to center of arches, are included, these being the principal part of the work.

DESIGNING METHODS; REINFORCED CONCRETE CONSTRUCTION. 76 pages $4\frac{1}{2}$ x $8\frac{1}{2}$ inches. Published by the Expanded Metal and Corrugated Bar Co., St. Louis, Mo.

This pamphlet is No. 2 of Volume 1 of a series designed to educate engineers and others on the qualities of reinforced concrete construction. This issue is devoted to detailed design of a typical building made of reinforced concrete, in which the reinforcement is rectangular and with T-shaped beams. The pamphlet is highly technical, and will be found a valuable contribution to engineering literature on reinforced concrete construction.

DRAWING INSTRUMENTS; THEIR USE AND ABUSE. By Walter G. Stephan. 108 pages, $4\frac{3}{4}$ x $7\frac{1}{4}$ inches. 74 illustrations. Published by the McGraw Publishing Co., New York. Price, $1.00.

This book is intended as a guide for students and young draftsmen in the purchasing of drawing instruments, drawing boards, paper, T-squares, triangles, protractors, etc. It lists a complete drafting equipment and describes the various instruments—triangles, scales, boards, T-squares, etc.—giving many valuable hints on the care and selection. It also touches on the slide rule, section liner, elliptograph, blue printing, drafting machine, planimeter, etc.

ORGANIZATION, EQUIPMENT AND OPERATION OF THE STRUCTURAL MATERIALS TESTING LABORATORIES AT ST. LOUIS, MO. By Richard L. Humphrey and Jos. A. Holmes. 84 pages, 6x9 inches. Illustrated. Published by the Department of the Interior, U. S. Geological Survey, Washington, D. C.

This account of the organization, equipment and operation of the structural materials testing laboratories, at St. Louis, Mo., is bulletin No. 329, and is intended to give a comprehensive account to the public of the various activities of this important part of the government's experimental work for the improvement of industrial conditions.

SOME THINGS MANUFACTURERS SHOULD KNOW ABOUT COAL. By E. G. Bailey. 10 pages, 6 x 9 inches. Published by Arthur D. Little, 93 Broad St., Boston, Mass.

This paper is No. 3 of a series of contributions to engineering chemistry made by the members of the staff of Arthur D. Little's laboratory, and was presented at the annual meeting of the National Association of Cotton Manufacturers, Boston, Mass., April 16-17, 1908. The object of the paper is to educate coal users in regard to the qualities of coal, what coal is most economical to burn, and how the highest percentage of the heat energy may be converted into useful work. No charge is made for individual copies for these pamphlets.

ADDRESSES DELIVERED AT THE INSTALLATION OF W. F. M. GOSS. 59 pages, 6 x 9 inches. Published by the University of Illinois, Urbana, Ill.

This pamphlet is a program of the installation of W. F. M. Goss, Dean of Engineering, at the University of Illinois, February 5, 1908, and includes addresses on "Significant Events in the History of the College of Engineering," by Ira O. Baker; "Standing of the Technical Graduate in the Engineering Profession," by Wm. L. Abbott; "The Value of Engineering Research," by Robert W. Hunt; "The Need of Graduate Courses in Engineering," by Willard E. Smith, and "The State College of Engineering," by W. F. M. Goss.

PRACTICAL PERSPECTIVE. By Frank Richards and Fred H. Colvin. 56 pages, $5\frac{1}{2}$x8 inches. Published by Norman W. Henley & Son Publishing Co., 132 Nassau St., New York. Price 50 cents.

This little work on drawing, explaining the principles of isometric perspective and the use of isometric paper, has just been issued in the third edition. It illustrates how to make all kinds of mechanical drawings in perspective, so that any mechanic unfamiliar with reading ordinary drawings can understand the shape and purpose of the parts illustrated. It will be found useful to mechanical draftsmen otherwise, as it frequently is advantageous to make "pictures" of parts which will show in one view what ordinarily requires three or more views to show and then in a way intelligible only to those who have learned to read drawings.

SLOW BURNING OR MILL CONSTRUCTION. 28 pages, $9\frac{1}{4}$ x 11 inches, and 8 folding plates. Published under the direction of the Boston Manufacturers Mutual Fire Insurance Co., 31 Milk St., Boston, Mass. Price, 25 cents.

This pamphlet is report No. 5 and is of the third edition, having been revised in accordance with the accepted practice of to-day. The pamphlet will be found of great value to all contemplating the construction of new shops and factories, or the reconstruction of old buildings with a view to improving their fire-resisting qualities. The great loss annually sustained because of mill and factory fires makes the problem of reducing fire losses of the greatest importance to all, and this pamphlet is recommended to students of economics, as well as to manufacturers.

AIR BRAKE CATECHISM. By Robert H. Blackall. 380 pages, 5 x $7\frac{1}{4}$ inches. Illustrated. Published by Norman W. Henley, & Son, 132 Nassau St., New York. Price $2.00.

This work is recognized as a standard treatise on the air brake, and its large circulation is indicated by the fact that the book in review is of the twenty-third edition. It treats of the equipment manufactured by the Westinghouse Air Brake Co., including the No. 5 and No. 6 E. T. locomotive brake equipments, the K quick-service triple valve for freight service, the cross-compound air pump and the operation of all parts of the apparatus in detail. The subject is handled in the well-known catechism style; over 2,000 questions and answers are required for presentation. The illustrations include a number of large folding plates, which show clearly the details of the apparatus, and their relations to one another. The work is recommended to all interested in air brake theory and practice.

BOOK OF THE ECONOMIZER. 159 pages, 6 x 9 inches. Published by the Green Economizer Co., Matteawan, N. Y.

This book treats of the history and merits of the fuel economizer, taking up such topics as the absorption of heat by different parts of the boiler surfaces, the relative economy of boiler surface and economizer surface under various conditions, effects of oil fuel, high steam pressures and superheat on boiler economy, etc. One chapter is devoted to a novel explanation of the often observed fact that the economy from pre-heating boiler feed water is greater than would be found by calculating the ratio which the heat contributed by the feed water heater or economizer bears to the whole amount of heat required for evaporation. While primarily issued to advertise a proprietary apparatus, the subject is treated in a broad and comprehensive way, making a pamphlet of much interest and value to all interested in the economical production of power.

COMPARATIVE TESTS OF CARBON METALIZED AND TANTALUM AND FILAMENT LAMPS. By T. H. Amrie. 44 pages, 6x9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

This bulletin, which is No. 19 of the series issued by the Experiment Station, records the results of tests made upon metalized carbon, tantalum and filament lamps in the laboratory of the electrical engineering department, with a view of bringing out the good points of each lamp, together with their faults, and offers help in the selection of the proper type for any particular purpose. The conclusion is that the tantalum and filament lamps cover adequately all the phases of incandescent lighting now covered by the three types. For a low power cost and rough usage the carbon lamp is best. For high power cost upon poorly regulated circuits the tantalum lamp is best, provided it is carefully handled.

IRON AND STEEL WORKS DIRECTORY OF 1908. 500 pages, 6 x $8\frac{1}{2}$ inches Published by the American Iron and Steel Association, Philadelphia, Pa. Price, $12.00.

This directory gives a full list of the blast furnaces rolling mills steel works, bloomaries and tin and terne plate works in the United States; also classified lists of wire rope mills, rail mills, plate steel mills, bessemer, open hearth, crucible and steel casting works. The present edition is the seventeenth and is corrected to March 1, 1908 The general plan of compilation adopted in the preparation of recent editions of the directory has been followed in the present edition.

Whenever possible the history of each plant has been preserved, giving the date of its erection, with all subsequent additions to the plant, changes in ownership, if any, etc. In view of the tremendous changes in ownership caused by the consolidation of plants under the ownership of the United States Steel Corporation, the importance of preserving an individual history of the various plants is apparent. The directory is one that can be heartily recommended to all interested in the information contained therein.

VOIDS, SETTLEMENT AND WEIGHT OF CRUSHED STONE. By Ira O Baker. 29 pages, 6 x 9 inches. Published by the University of Illinois, Urbana, Ill.

This bulletin, which is No. 23 of the series issued by the Engineering Experiment Station of the University of Illinois, records the results of experiments made to determine the proportion of voids in crushed stone, loaded by various methods in cars and in wagons; to find the amount of settlement during transportation; and to obtain the relation between the weight and the unit of volume of solid stone and of the same volume of crushed stone immediately after being loaded in various ways. All the results are summarized in a table which gives, for different sizes of crushed stone the coefficients by which to multiply either the weight of a cubic foot of solid stone or its specific gravity to get the weight of a cubic yard of crushed stone at the crusher and at the destination. This elaborate table is summarized in the following statement: The mean coefficient by which to multiply the weight of a cubic foot of solid lime stone to obtain the weight of a cubic yard of crushed lime stone, is as follows: For ½-inch screenings, 15.5; for ½-inch to 2-inch stone, 14.6; and for 2-inch to 3-inch stone, 15.2. For trap rock corresponding methods are as follows: For ½-inch screenings, 14.6; for ½-inch to 1½-inch stone, 13.5; and for ½-inch to 3-inch stone, 13.9.

CATALOGUES AND CIRCULARS.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4590, describing self-starting device for alternating current motors.

H. G. OSBORNE, 74 Cortlandt St., New York. Catalogue of Osborne's extension drills for drilling holes in brick walls.

PRATT & WHITNEY CO., Hartford, Conn. Catalogue illustrating and describing a spline milling machine, a machine for slot milling, cutting splines, key-ways, grooves, etc.

HARDINGE BROS., 1034 to 1040 Lincoln Ave., Chicago, Ill. Leaflet illustrating the Cataract precision bench lathe outfit No. 3, and catalogue illustrating the Beyer single record watchman's portable clock.

ESTEP & DOLAN, Sandwich, Ill. Catalogue of hand bending tools, for forming eyes, hooks, rings, hinges, staples, chain links and other parts made by the blacksmith.

BURKE MACHINERY CO., 1837 Thirty-fifth St., Cleveland, O. Leaflet illustrating and describing the Burke cold saw, and the Burke No. 3 and No. 4 bench milling machine.

CROCKER-WHEELER CO., Ampere, N. J. Bulletin No. 105, superseding Bulletin No. 88, illustrating and describing polyphase induction motors, made in sizes from 15 to 250 H.P.

SKINNER CHUCK CO., 94 N. Stanley St., New Britain, Conn. 1908 price-list of independent universal and combination lathe chucks; also drill chucks, planer chucks, face-plate jaws, drill press vises and reamer stands.

EXPANDED METAL & CORRUGATED BAR CO., of St. Louis, Mo. Catalogue illustrating use of corrugated bar for reinforced concrete construction in factories, machine shops and other buildings.

BALDWIN LOCOMOTIVE WORKS, Philadelphia, Pa. Record No. 65 of Mallet compound locomotive, being a paper read before the Engineers' Club of Philadelphia, March 12, 1908, by Mr. Grafton Greenough.

BROWN HOISTING MACHINERY CO., Cleveland, O. Catalogue of hoisting machinery adapted to the use of artificial gas, coke and electric light companies, for the rapid and economical handling of coal, coke and other materials.

BAUSH MACHINE TOOL CO., 200 Wason Ave., Springfield, Mass. Leaflet descriptive of the Bocorselski turret tool-holder for lathes. This tool-holder is made in three sizes, and two styles, and may be used with the turret in either a vertical or horizontal position.

LUCAS MACHINE TOOL CO., Cleveland, O. A set of four cards, distributed at the recent Atlantic City convention of the Master Car Builders' and Master Mechanics' Associations, descriptive of the Lucas power forcing presses.

WHITING FOUNDRY EQUIPMENT CO., Harvey, Ill. Catalogue of cupolas, charging machines, bottom door hoists, electric travelers, jib cranes, air hoists, foundry ladles, tumblers and other equipment for the foundry.

GISHOLT MACHINE CO., Madison, Wis. Small catalogue of Gisholt turret lathes, vertical boring mills, universal tool grinders, horizontal drilling machines, double emery grinders, worm hobbing machines, gear testing machines and chucks.

HESS-BRIGHT MFG. CO., 2111 Fairmount Ave., Philadelphia, Pa. Catalogue descriptive of the Hess-Bright radial and thrust ball bearings. The catalogue illustrates applications to line shafting, automobiles, motors and dynamos, and machinery in general.

BLACK DIAMOND BORING MACHINE CO., Monongahela, Pa. Catalogue descriptive of special boring machine for boring locomotive rod brasses and rolling and compressing the babbitt lining. The machine can also be used for other purposes, such as drilling, tapping, reaming, etc.

ROBBINS & MYERS CO., Springfield, O. Bulletin No. 67, descriptive of the "Standard" motor. The bulletin illustrates the various styles of motors built and applications to sewing machines, grinders, buffing and polishing wheels, speed lathes, drill presses, pumps, blowers, fans, punch presses, linotype machines, printing presses, etc.

JOSEPH DIXON CRUCIBLE CO., Jersey City, N. J., has issued a little booklet of twelve pages on brushes for generator and motor commutators. The booklet gives valuable hints on the care of commutators, and some conclusions drawn from the results of tests made by Professor Albert F. Ganz, at Stevens Institute, Hoboken.

BANTAM ANTI-FRICTION CO., Bantam, Conn. Issue No. 2 of the *Bantam Anti-Friction Booster*, containing items of local interest, "hot shots," humorous paragraphs, and advertising the line of ball and roller bearings made by the company. This issue is published on pink paper, and is a unique specimen of advertising.

UNITED STATES ELECTRICAL TOOL CO., Cincinnati, O. Catalogue illustrating a complete line of electric hand drills, breast drills, electric-driven radial drills, electric-driven center grinders, bench grinders and surface grinders. The catalogue also demonstrates a few of the many uses of portable electric tools.

GENERAL ELECTRIC CO., Schenectady, N. Y., has just issued a small circular, No. 3664, descriptive of its new locking socket. This socket prevents the removal of an incandescent lamp by an unauthorized person. The peculiarity of this socket lies in the fact that the lamp is safe when the socket is unlocked. The socket and key are clearly illustrated in the circular.

WALKER GRINDER CO., Worcester, Mass. Circular descriptive of the Walker No. 3 plain surface grinder of the column and adjustable wheel head type. This machine has been specially designed to adapt it for finishing cast iron parts that are usually filed and polished, and in combination with the Walker magnetic chuck made by the same concern, it is exceptionally well suited for all kinds of surface grinding.

MARK FLATHER PLANER CO., Nashua, N. H. Bulletin No. 8, illustrating and describing 14, 16, 18, 20 and 24-inch Flather shapers, belt- and motor-driven. The bulletin also reproduces the analysis of the Flather shaper motion published in the March, 1907, issue of MACHINERY, in connection with the description of the shaper motion model built for the University of Michigan.

R. D. WOOD & CO., Philadelphia, Pa. Catalogue of hydraulic tools and machinery for steel works, boiler shops, bridge works and other plants requiring heavy bar shears, splitting shears, angle shears, punches, riveters, flanging presses, die presses, upsetting presses and other machinery required in the construction of boilers, bridges, cranes, etc.

AMERICAN BLOWER CO., Detroit, Mich. Illustrated sectional catalogue, No. 232, of "A B C" self-oiling steam engines, types A and E. This catalogue supersedes Bulletins 171, 181, 193, 194 and 206. It illustrates in detail the construction of the engine, showing the self-oiling features by which lubrication is assured to all working parts without the attention of the engineer, other than renewing the lubricant about once in three months, and filling the sight-feed cylinder lubricator.

LANDIS MACHINE CO., Waynesboro, Pa. Catalogue of pipe threading and nut tapping machinery and special threading machines. The Landis all-steel die-head, using a special form of chasers made from flat pieces of steel with threads milled their entire length on the flat side and adapted to cut either right or left-hand threads, is illustrated and described in detail. High speed steel dies are supplied for these die-heads to order. The high speed dies have the advantage of never needing to be re-hobbed or re-tempered.

GENERAL ELECTRIC CO., Schenectady, N. Y., has just issued a new bulletin on Thomson astatic instruments for continuous current switch-boards. These instruments are extensively used, and have a reputation for reliability and accuracy regardless of external influence. They have no controlling springs, and their accuracy is not affected by changes in magnet strength. The damping effect in these instruments is produced by an aluminum disk moving in a magnet field, and the indications are dead beat. The bulletin describes voltmeters and ammeters of the feeder board and illuminated dial types, and gives complete dimension diagrams.

CUTLER-HAMMER MFG. CO., Milwaukee, Wis. Catalogue of push-button switch mechanism and push-button specialties. This electric push-button switch is of particular interest, on account of the simplicity and ingenuity of the design. Disregarding the casing, the switch mechanism consists practically of only three parts; first, a push bar extending clear through the switch, having its largest diameter in the center and having a conical shape from the center for some distance towards each end; second, a coil spring, which encircles the bar previously mentioned in such a manner that the axis of the spring forms a circle around the bar; third, a moving contact piece encasing the spring. The action of the device is simply this: when the bar is pushed, the coil spring rides up on the conical surface until it reaches the center, all the time preventing the contact piece from releasing until the spring has reached the central and highest part of the bar; then it suddenly contracts and moves swiftly along the conical shape on the other side of the highest point of the bar, carrying with it the moving contact piece. It is not possible to move the contact piece part way and let it slip back again, thereby drawing an arc which burns the contacts and eventually destroys them. The contact piece is either positively in contact or out of contact.

MANUFACTURERS NOTES.

WILLIAM HAHN, Chicago, Ill., maker of flexible shafts, etc., has changed his location from 220 Washington St., to his own building at 621-623 North Campbell Ave.

HOLBROOK-ARMSTRONG IRON CO., Racine, Wis., recently equipped its factory with three brass furnaces and an aluminum furnace at an outlay of $10,000. Crude oil is used for fuel.

GLOBE MACHINE & STAMPING CO., 974 Hamilton Ave., Cleveland, Ohio, has secured the shop rights from the United States Sherardizing Co., New Castle, Pa., for the dry galvanizing process, discovered by Sherard Cowper-Coles, London, England. Samples of articles to be sherardized may be sent to the company for an estimate as to the cost of the treatment.

CROCKER-WHEELER CO., Ampere, N. J. At a meeting of the directors, July 10, the following officers were elected: S. S. Wheeler, president; Gano Dunn, vice-president; A. L. Doremus, second vice-president; Gano Dunn, chief engineer; Rodman Gilder, secretary; W. L. Brownell, treasurer; J. B. Milliken, assistant secretary; G. W. Bower, assistant treasurer.

CUTLER-HAMMER MFG. CO., Milwaukee, Wis., manufacturers of electric controlling devices, will be represented on the Pacific Coast by Otis & Squires, 111 New Montgomery St., San Francisco, Cal. Mr. A. W. Vinson, who for several years has been connected with the engineering department of the Cutler-Hammer Mfg. Co., has been transferred to the office of Otis & Squires, where his services will be available to those having problems in electric control to be solved.

HAYES FILE CO., Detroit, Mich., has just purchased the entire plant of the Peacock File Co., located at Buffalo, N. Y., which was formerly the Maisholf Bros. factory, and has removed the machinery to Detroit. The company has been unable for some time to accept orders from new trade as it has been running its plant to full capacity to supply old customers, but after installing the Buffalo machinery it will increase the output about one-third.

L. S. STARRETT CO., Athol, Mass., has opened a warehouse at 36-37 Upper Thames St., London, England, where a line of fine mechanical tools, hack saws, steel tapes, etc., will be kept in stock. The London store will be a great convenience to British and Continental customers. It will save three to four weeks in getting goods and all goods will be shipped from London. Bills will be rendered in pounds, shillings and pence, and payments will be made in London. The London branch will be in charge of Mr. E. P. Barrus.

BROWN & SHARPE MFG. CO., Providence, R. I., will close its works from August 1 to August 30, inclusive, for annual vacation and repairs. On account of the unusual length of the vacation, special provision will be made to fill the reasonable wants of customers for special cutters and gears that may be wanted quickly. During the vacation the office will be open as usual, and orders for machine tools, machinists' tools, and cutters will receive the same attention as at other periods of the year.

ELECTRIC CONTROLLER & SUPPLY CO., Cleveland, Ohio, has changed its name to Electric Controller & Mfg. Co. The latter name more truly indicates the nature and scope of its business as evidenced by the following list of apparatus manufactured by the company: Controllers both manual and magnetic switch types for all purposes, lifting magnets, electric brakes, magnetic switches, solenoids, limit stops, arc welders, crane fittings, knife switches, flexible couplings, and the electric fault finder.

BECKER MILLING MACHINE CO., Hyde Park, Mass., has taken over the business of the Becker-Brainard Milling Machine Co. and will continue under the management of Mr. John Becker, whose practical experience in the design and development of the Becker Milling Machine has placed him among the foremost mechanics of the day. Many changes and improvements have been made in the plant, carrying out Mr. Becker's ideas and making it virtually the successor of the business which he started in Boston fifteen years ago and afterwards successfully built up in Fitchburg.

CONTENTS FOR AUGUST.

Electric Welding Products Co., Cleveland, Ohio, recently installed a grinding and finishing department equipped with Brown & Sharpe plain and universal grinders, special imported machines for spline milling or slot cutting and centering machines. This department will enable the company to turn out completely finished gas engine valves and valve stems and other similar work. It will finish gas engine valves made with nickel steel heads and carbon steel stems ground on both seat and stem and with slot, groove or thread cut or a hole drilled and the end hardened, thus making a product that is ready to be slipped into the engine in the assembling room.

Wilmarth & Morman Co., Grand Rapids, Mich., reports that the sales of "New Yankee" drill grinders for June, 1908, exceeded the volume of sales not only for June, 1907, but for every other month in the year 1907 with one exception. While the company appreciates this testimonial of recognition of the value of its machines, it is specially gratified by the fact that manufacturers are recognizing the need for mechanical appliances for grinding twist drills. It has taken many years of hard work to prove to mechanics the need of special machines for grinding drills and to demonstrate to them that machine-ground drills are far superior in efficiency to hand-ground drills, as usually done by the average workman.

COMING EVENTS.

August 18.—International Master Blacksmiths' Association Convention, at Cincinnati, Ohio. A. L. Woodworth, Lima, Ohio, secretary.

October 5-10.—First International Congress of Refrigerating Industries, Paris, France. J. F. Nickerson, 315 Dearborn St., Chicago, Ill., Secretary American Committee, will send circular and further information upon request.

MISCELLANEOUS.

Advertisements in this column, 25 cents a line, ten words to a line. The money should be sent with the order. Answers addressed to our care will be forwarded. Original letters of recommendation should not be enclosed to unknown correspondents.

APPLICATIONS ARE DESIRED from shop men who believe that they would have ability as real estate salesmen, selling new farm lands. This is an exceptional opportunity to earn good money in your spare time and to work into a better paying line of business. Address Box 403, Madison, Wis.

DO YOU KNOW WHAT THE MACHINERY LEAGUE IS? Do you know what a friend in need is? The League was instituted by Machinery for the benefit of its active friends in the shops, and membership is limited to them. There are no dues. Write for information, giving the address of your works as well, to the Secretary, The Machinery League, 49-55 Lafayette St., New York City.

DRAFTSMEN AND MACHINISTS.—American and foreign patents secured promptly; reliable researches made on patentability or validity; twenty years' practice; registered; responsible references. EDWIN GUTHRIE, Corcoran Building, Washington, D. C.

DRAFTSMEN cannot know too much about shop practice—many of them know too little and are handicapped thereby. Machinery's Shop Operation Sheets can help greatly. They are direct, definite and practical. The set now comprises 72 distinct operations. Write for pamphlet. Machinery, 49-55 Lafayette St., New York City.

FOREMAN.—For erecting heavy machine tools; must be experienced on accurate machine tool work, with ability to increase production and efficiency. State age, experience and salary expected. Box 182, care Machinery, 49 Lafayette St., New York.

FOR SALE.—Local hardening and tempering of tool steel by flexible cover or shield process. Patented in United States, Great Britain and Canada, patent pending in Germany. Shop rates or licenses for sale in United States, under patent No. 882,162, at reasonable rates, graded according to amount of benefit derived. The smallest die or machine shop can afford to use it. British and Canadian patents for sale outright. For further particulars and information address the patentee, WILLIAM A. PAINTER, 1515 Franklin St., N. S., Pittsburg, Pa.

H. VOGEL, Room 823, 112 S. Clark St., Chicago, 'phone Main 3777. Designer of any kind of machinery.

MECHANICAL ENGINEER of vast experience, as designer of special machinery, automatic and otherwise, also as superintendent of factory and toolroom, wants similar position. Address, Room 823, 112 So. Clark St., Chicago, Ill.

NEW PATENTS ACT.—A firm of engineers and merchants having warehouses and offices in London, Birmingham, Glasgow and Manchester, are prepared to take up selling agencies for machines and small tools. Apply to "Y. Z.," care Machinery, 49 Lafayette St., New York.

PATENTS.—H. W. T. Jenner, patent attorney and mechanical expert, 608 F Street, Washington, D. C. Established 1883. I make an examination free of charge, and report if a patent can be had and exactly how much it will cost. Send for circular. Member of Patent Law Association.

PATENTS.—Write now. Inventors, for "Patent Particulars." STERLING P. BUCK (Registered Attorney), 3118 Dillon St., Baltimore, Md.

SEND 30 CENTS for copy of Rocking Valves and Gears. Covers the subject fully. THE INDUSTRIAL MAGAZINE, Cleveland.

SUPERINTENDENT FOR OUR GAS ENGINE WORKS, able to organize a perfect shop system, get work out economically and accurately. An ordinary shop foreman or theorist will not do. Salary \$1,800 upwards; chance for something else. Witte Iron Works Co., Kansas City, Mo.

TAPS.—Wanted, automatic machinery of modern design for manufacturing taps. Would buy patents of a perfect machine already running. Write to HEINRICH DREYER, Importer of American Machinery, Berlin, C. Kaiser Wilhelmstrasse 1.

THE RIGHT DATA SHEET, just when you want it, might be worth ten dollars, or even a hundred dollars, to you. There are now 360 6 x 9 pages of Machinery's Data Sheets, and they are all right. You can get the complete set immediately under offer No. 4—Machinery, engineering edition, one year, and the complete set of Data Sheets, \$3.00. Address Machinery, 49-55 Lafayette St., New York City.

USE OF FORMULAS and of Tables of Sines and Tangents, without a knowledge of Algebra or Trigonometry, is made easy to you by SHOP ARITHMETIC FOR THE MACHINIST, which is No. 18 in Machinery's Reference Series fully described in a pamphlet sent free on request.

WANTED.—Agents, machinists, toolmakers, draftsmen, attention! New and revised edition Saunders' "Handy Book of Practical Mechanics" now ready. Machinists say "Can't get along without it." Best in the land. Shop kinks, secrets from note books, rules, formulas, most complete reference tables, tough problems figured by simple arithmetic. Valuable information condensed in pocket size. Price postpaid \$1.00 cloth; \$1.25 leather with flap. Agents make big profits. Send for list of books. E. H. SAUNDERS, 216 Purchase St., Boston, Mass.

WANTED.—Agents in every shop to sell Calipers. Liberal pay. Address E. G. SMITH CO., Columbia, Pa.

WANTED.—Salesmen visiting hardware, sheet metal workers' and boiler makers' trade to carry as a side line our highly recommended modern portable hand metal punch. Endorsed and used by five largest U. S. navy yards and arsenals. Sells itself on merit. Send references. Only business getters answer. W. A. WHITNEY MFG. CO., Rockford, Ill.

WANTED.—Partner on patent of a tool for mechanics' use. Will give one-third interest for expense of patent, or will sell idea outright. Apply E. H. THORNE, Hagan, Ga.

WANTED.—A first-class man to take a position as factory superintendent with a concern which has been in the agricultural implement business for fifty years. Lawn mower experience preferred. Must be able to reduce costs, handle men, and a man with drafting experience preferred. A good position for the right party. Address "G," care Machinery, 49 Lafayette St., New York.

WANTED.—Copy of Machinery, Engineering Edition, for September, 1907. Address with price, FOREIGN DEPT., Machinery, 49 Lafayette St., New York.

WANTED.—A skilled and experienced machine designer about 28 to 32 years of age for a teaching position in a technical school in the East. Pleasing and forceful personality and enthusiasm required. Entering salary about \$1,500.00. Apply, stating age, education, practical experience and any other qualifications in detail to "X," care Machinery, 49 Lafayette St., New York.

WANTED.—General Manager of your firm to learn that I can reduce the cost of production of any article of manufacture by special machinery. Send me a sample or drawing of the piece to be made and its present cost to produce, and I will answer, stating for what price I can produce it and the first cost. Will call if work justifies. JOSEPH J. HOSLER, 30-31 Eagle Block, Canton, Ohio.

YOUNG MAN, 22 years of age, of good character and best of references, desires position with an electrical firm. Has had experience, and possesses technical knowledge. Address W. W., Box 423, Newark, N. J.

How Else Could You Do This Work?

THE VERTICAL MILLER

is the most adaptable tool to be found in the modern machine shop; it will do a larger variety of work, do it better and do it quicker than any other single machine. The new horizontal attachment adds to the **Becker-Brainard Vertical Miller** the essential features of the horizontal type, including the cutting of spirals. The permanency of alignment of the vertical spindle, the staunch design, the great depth of throat, the convenience of operation, all combine to make it an indispensable tool.

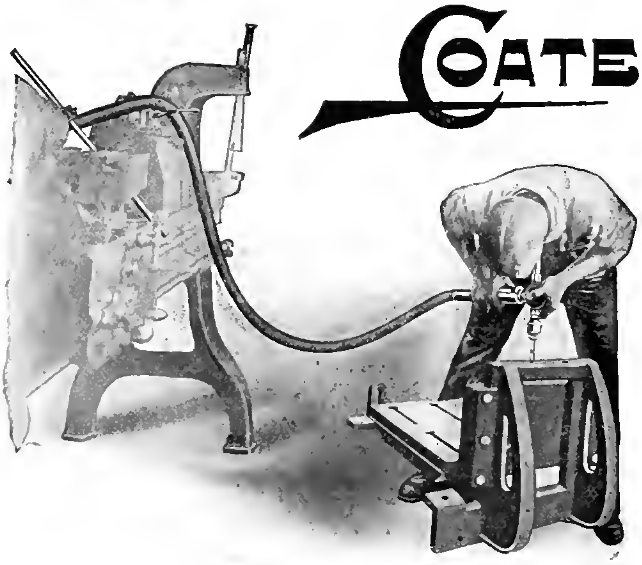
COATES UNIT LINK FLEXIBLE SHAFT

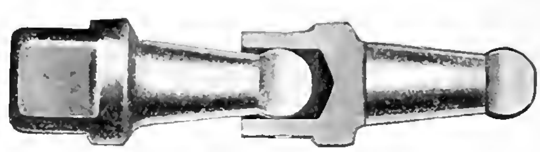


Coates Flexible Shaft used in connection with breast drill.

For Drilling, Grinding, Polishing—for a hundred and one purposes of every day work—there is no device that equals the Coates Flexible Shaft. It will save an immense amount of time and labor; can be used anywhere and at any angle; the drive is steady throughout the entire length, running either backward or forward. It is perfectly flexible—bend it as much as you like; each link is a unit made of hardened steel and driven by by a square spheroid — the strongest drive possible. If a link breaks it is only a matter of a few minutes time and a few cents expense to replace it.

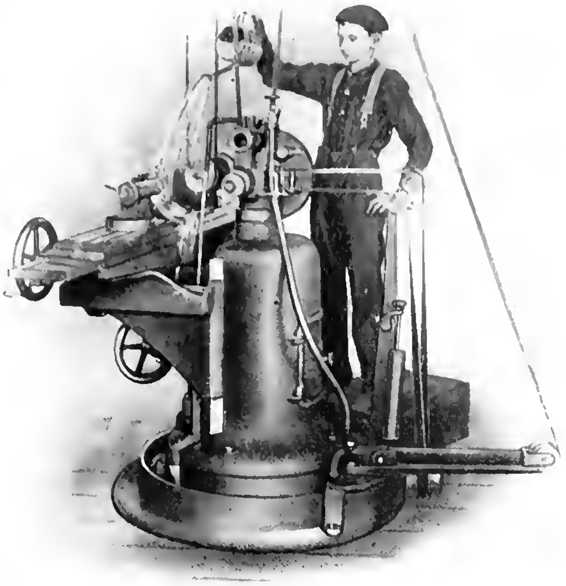
Convenient, durable and efficient—a Coates outfit should be in every shop.

Ask for Bulletin No. 21—the latest.



Section of the Unit Link Shaft.

COATES CLIPPER MFG. CO., Worcester, Mass.



This picture is shown for the purpose of emphasizing the fact that the

Thompson Universal Grinding Machine

is built with a perfect **water attachment.** Long open tank on base, easy to keep clean. Top of knee cast solid in the form of a basin, into which all water drains from above, and from which it is conducted through pipes to the tank.

This grinding machine is **convertable** into a **plain** grinder ; a **surface** grinder ; a **knife** grinder ; a **die** grinder ; a **cutter** grinder, or an **internal** grinder, and in each form it works to perfection.

Circulars and prices upon request.

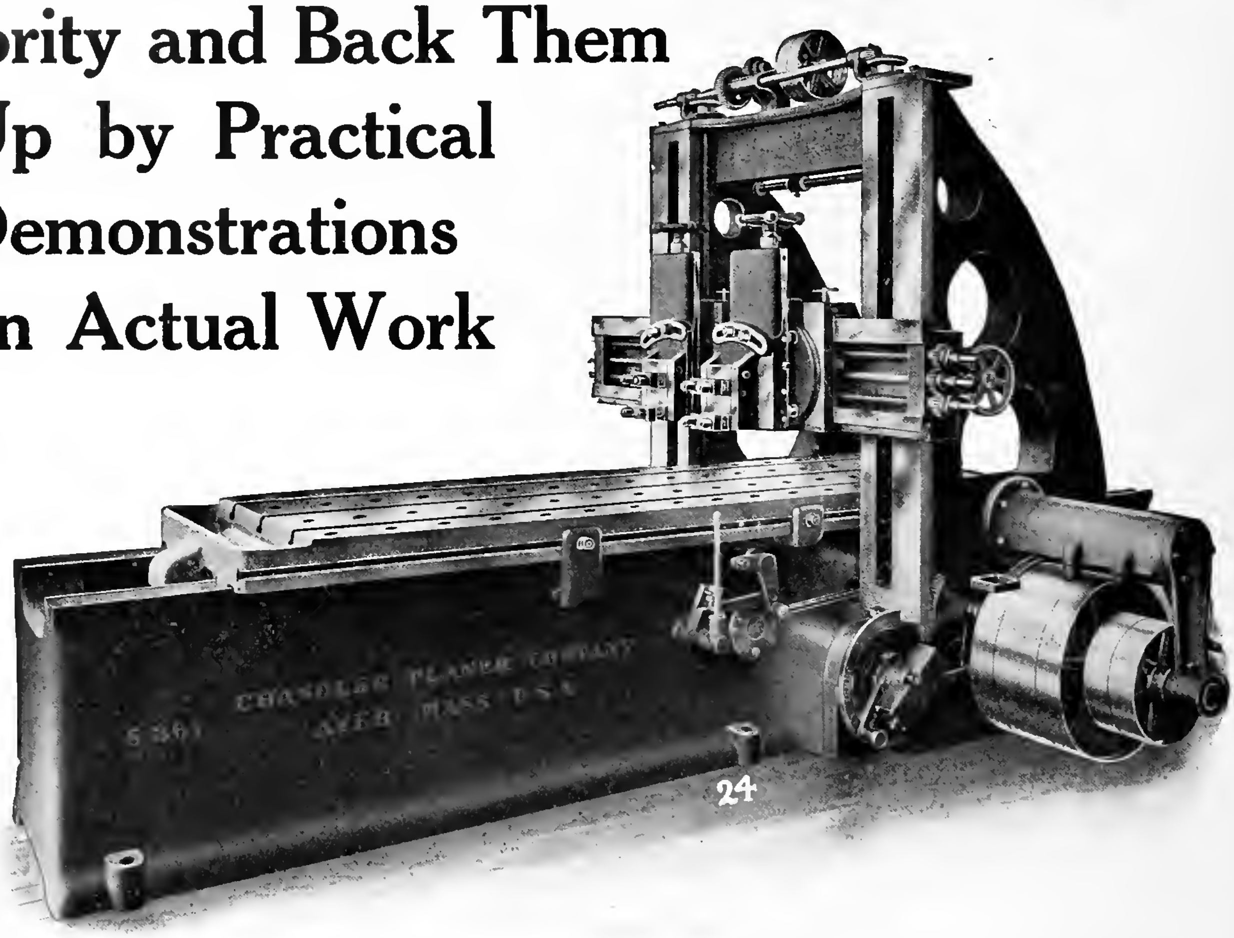
We Make Unqualified Claims of Superiority and Back Them Up by Practical Demonstrations on Actual Work



Why and Wherein Chandler Planers Surpass:

1. They cut more linear feet per minute by running faster in each direction and reversing more promptly at each end.
2. They remove more metal per each foot of run.
3. They secure an accurate surface in less chips.
4. They do the same amount of work in fewer strokes, thus economizing power. Reversing and returning represent wasted energy.
5. They deliver at the tool point a larger per cent. of the belt power.
6. By massive construction and accurate gear train, chattering is reduced to a minimum and an increased efficiency is secured with high speed steel.
7. Every adjustment is instantly made without the necessity of stopping the planer. This not only saves time but insures the best operating conditions on all classes of work.
8. They can be operated more hours per year. No planer requires so few repairs and has so few breakdowns.

TRADEMARK NORTON REGISTERED

Norton Grinding Wheels are made of Alundum.

Grinding Information reprinted from booklet entitled "Helps-Don'ts"

To increase the speed of a grinding wheel gives the effect of a harder wheel; decreasing the speed gives the effect of a softer wheel.

For surface grinding, it is customary to run wheels at a somewhat slower rate of speed than for general grinding. A speed of 4,000 to 5,000 surface feet is usually employed.

Wheels are run in actual practice from 4,000 to 6,000 feet per minute.

Speed up the spindle as the diameter of the wheel is decreased. Approximately the same periphery rate should be maintained as the wheel wears down.

Transferring a wheel after worn down to a small diameter, from a large machine to a small one, is a good plan.

—*From Booklet: "Helps-Don'ts."*

"Helps-Don'ts" is a booklet full of valuable points on Grinding; information on the selection of the right grinding wheels for the work, mounting and truing wheels, operating speed, care of wheel, etc.

Grinding Points Ground Down for the benefit of all who grind—for foremen, for superintendents. It contains information based on many years of "Norton Experience" in the manufacture and use of grinding wheels and grinding machinery.

It will be sent without charge to anybody. Send a postal now.

Perfectly Accurate Threads

can never be obtained with hand-ground chasers, because it is impossible to give each one the same angle. For good results it is necessary that all the chasers in a set be ground exactly alike, and the

Wallace Chaser Grinder

accomplishes this to perfection. Being accurately ground, each chaser does its proper share of work, does it well and wears five times as long as if ground by hand. The grinder is simple in construction, easy to operate and a time and money saver. For full details write

New Machine Tools

TAKE a look over your machine tools. You will soon have to make some replacements—some additions. You *need* new tools.

How about your engine lathes? Have you been using them for a class of work you should have done on Gisholt Lathes? One Gisholt, you know, will do as much chucked work as two to four engine lathes. There's twenty years of successful experience in "making good" behind that statement.

Why not ask what we can do for you?

Ask about Gisholt Lathes, Boring Mills and Tool Grinders. A new booklet we have issued recently will interest you. Write for it.

The Peerless Hoist

The latest type of spur geared hoist embodying special features that make it the most efficient device of its class.

Safety, Durability Speed and Power

are prominent characteristics of the "Peerless"—all qualities that go to make up the perfect hoist. The single load chain tends to light weight and compact form; all working parts are protected by dust proof cases; the hoisting mechanism—a train of compound balanced steel gears—insures smooth action and reduces wear to the minimum; and all danger of the load slipping is eliminated by a chain guide and stripper.

We shall be glad to furnish full particulars on request.

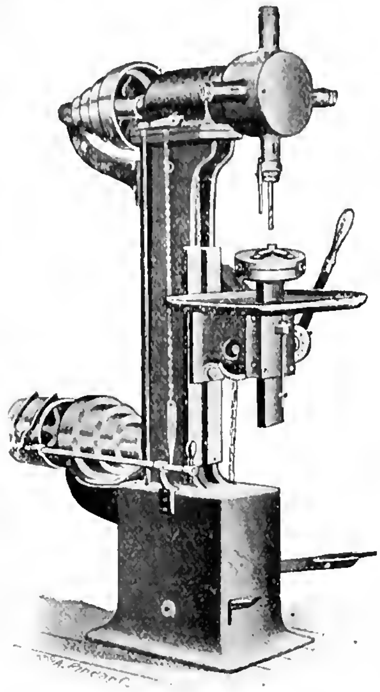
The Fosdick Machine Tool Co.
Cincinnati, O. U.S.A.

Quint's Vertical Turret Chucking Machine



A tool designed for light work and differing from all other chucking machines in the fact that the **cutting tool rotates**—not the work—thus obviating waste of time in stopping the machine to change the work. The chuck is balanced so when the feed is released the work drops with a quick return; a hole through the chuck and stand allows all chips to fall out of the way, leaving the work clear. Built with four or more spindles, positively driven with steel gears.

Write for details and price.

A. E. QUINT, Hartford, Conn.

Twelve to One in Favor of Novo Steel

NORTHERN MALLEABLE IRON COMPANY

RAILROAD AND AGRICULTURAL CASTINGS, CAR COUPLERS, CLEVISES, ETC.

ST. PAUL, MINN.

ALL AGREEMENTS CONTINGENT UPON STRIKES, ACCIDENTS, OR OTHER CAUSES BEYOND OUR CONTROL

April 10th, 1908.

Hermann Boker & Co., Chicago, Ill.

Dear Sirs:—We are pleased to report that Novo steel has gone beyond our expectation, in our factory. We have been able, by the use of Novo Steel, to reduce price of bolt cutting, 20%. We also feel that we have saved at least 50% of the first cost of Dies, because the Novo lasts so much longer.

Before using Novo, we found it necessary to re-cut the ordinary carbon steel die for about every 5000 threads, material cut being hard, and we now find it possible to cut as high as 50,000, or 60,000 with one re-cutting of the Novo Dies

We are now trying the 17/32 machine tap and as soon as we obtain some accurate figures, we will forward same to you.

Hoping you will call on us, whenever you are in the city, we are,

Yours truly,

NORTHERN MALLEABLE IRON CO.

S. Horsley

Asst. Superintendent.

BENNETT HANDY OILERS

Twenty to Thirty Letters can be Engraved with the Gorton Engraving Machine at a Cost of One Cent.

This is a fact which should interest you and we would like an opportunity to prove that the machine will not only do better work than can be done by hand, but do it in a fraction of the time usually required. Engraving either in relief or sunken, on metal plates, seals, dies, patterns, etc.

Send samples of your requirements, we will then duplicate the same, stating the time required, quoting price with photo on suitable equipment.

GEORGE GORTON MACHINE CO., Racine, Wisconsin

Turret Tool Block

The advantages of this Carriage Turret will be readily appreciated in all modern, well equipped machine shops.

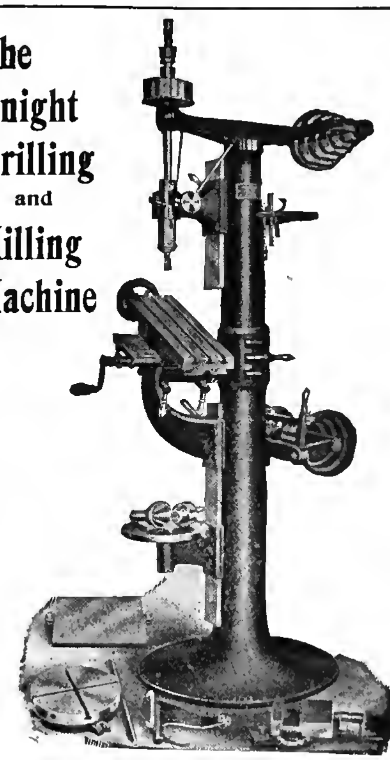
Attached to an ordinary engine lathe you secure a combination of Engine and Turret Lathe; the only difference being this Turret does not work automatically.

Of course the usual **FAY & SCOTT** excellence enters into the making of it.

Our booklet will tell you all you want to know.

Fay & Scott Dexter, Maine

The Knight Drilling and Milling Machine



Economy, Convenience and Efficency are the strong points of this machine. Handles a wide range of work and in many operations will save from 20 to 50 per cent. over other methods.

Write for circular showing samples of work.

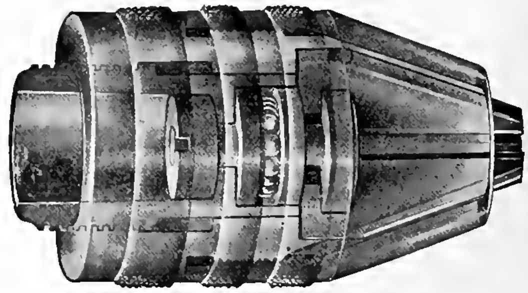
Little Giant Auxiliary Screw Drill Chuck.

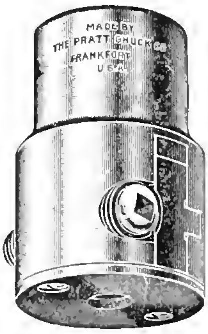
The Russell Anti-Friction Drill Chuck

Has the grip of a bull-dog—no slip, no wavering, no give up; is easily adjusted—operated entirely by hand, no key or spanner needed; saves time and drills.



The antifriction bearing is the special feature, overcomes all frictional resistance in tightening. Do you see the advantage? We'll tell you more about it if you will write us. Five sizes.

RUSSELL ANTI-FRICTION DRILL CHUCK CO., Elmira, New York, U. S. A.



A Securely Held Drill

is half the battle. You can't do good work or do it quickly unless the drill, reamer—or whatever tool you are using —is held firmly.

The Pratt Chuck

is the ideal drill holder, because its construction makes slipping impossible. It not only holds the tool securely but it holds it without damage to the shank. The flattened end of the shank is passed through a little dog floating at the top of the chuck jaws, and which must turn as the chuck turns; the jaws are tightened just enough to keep the drill from falling out—and the shank is kept in good condition.

The simplest, most practical and most reliable Drill Chuck on the market.

Write for the book.

Frankfort, N. Y.

European Agents—Selig, Sonnenthal & Co., 85 Queen Victoria Street, London, Eng.

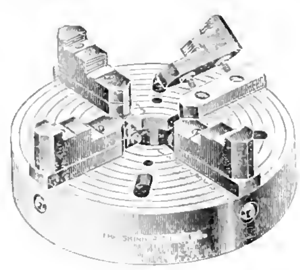
? ? ? CHUCK QUESTIONS ? ? ?

Are they accurate?

Are the Jaws and Adjusting Screws of such grade of steel, properly tempered, to withstand the wear and tear?

Are they so constructed that the operator has to go through only a few convenient motions, in adjusting them?

All **Skinner Chucks** are guaranteed for accuracy, the chuck jaws being ground true in the chuck body after hardening.



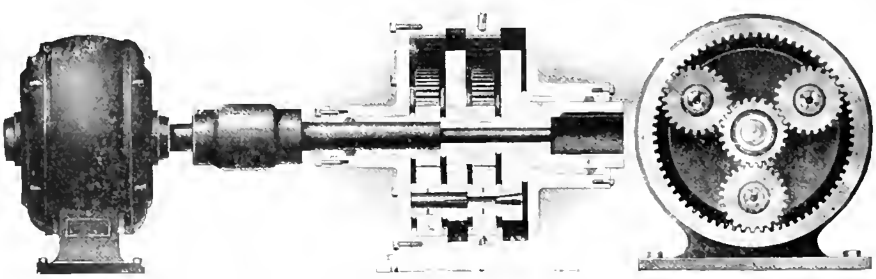
Convenience of operation was an important factor is designing each different style.

Write us in regard to your requirements for **Lathe, Drill** or **Planer Chucks,** and we will be pleased to recommend sizes and styles. You want our 1908 Price List at least.

THE SKINNER CHUCK CO.

94 N Stanley St., New Britain, Conn , U. S A.

94 Reade St., New York City.



O'Kelly Patent, June 27, 1905.

We use a Universal Coupling to Connect the Motor to the Reduction Gear Shaft, which Obviates the Necessity of Perfect Alignment.

The engraving illustrates a Speed Reducing Transmission for reducing the speed from a motor or driving shaft to any required speed of machine or driven shaft. It will be found efficient, strong and durable, being entirely incased and oil tight. It is absolutely safe and requires practically no attention. All the moving parts run in the same direction and you will note by taking power from three points of the pinions it gives a balanced drive with great emergency strength. The annular or internal gears are made of semi-steel; the idlers are made of steel, bushed with hard steel bushings. The idler pins are steel, case-hardened and keyed to the discs with a hard taper pin which can be quickly removed as shown in the cut. The bearings are bushed with Phosphor bronze. We make this device in a variety of sizes and speed reductions from ½ to 50 horse-power, either vertical or horizontal

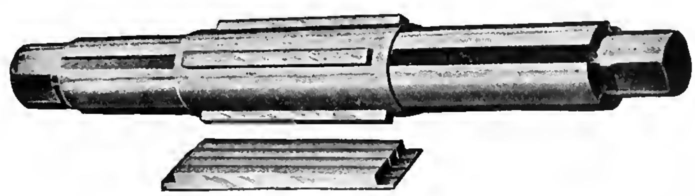
Still Sorting over those Solid Mandrels?

Better throw the whole lot into the scrap heap and get a set of NICHOLSON EXPANDING MANDRELS, they are what you want.



A set of nine of these will fit you out for work anywhere from one to seven inches in size, and you'll have the job done in the time it takes to look for an ordinary mandrel that's just the size required. Workmanship and material the best. Catalogue gives full description.

CUT OUT AND FILE the three **Shop Operation Sheets** in this number. Your set **may be** worth a hundred dollars to you some day.

"TRIMO" PIPE WRENCH

TRADE MARK

STRONGEST MADE. Less expense for broken parts replaced as well as time saved. Drop-forged from specially selected steel. Inserted jaw in handle easily and cheaply replaced when worn out, displacing the out-of-date and unsatisfactory method of drawing temper, filing and re-hardening when teeth are cut in the handle.

GOLD MEDAL
St. Louis, 1904.

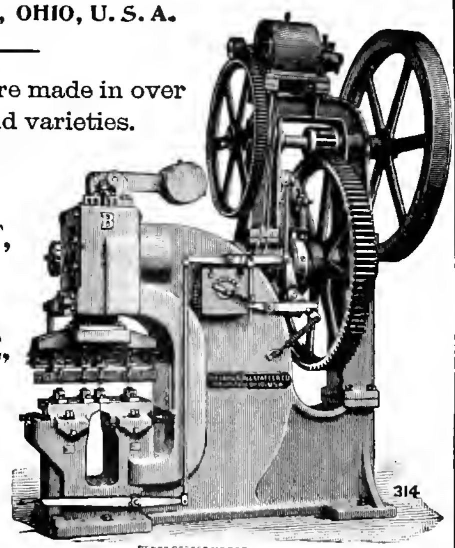
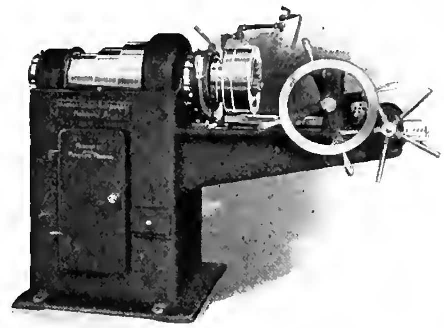
Railroad Shops,
Locomotive Shops,
Bridge Works,
Etc.



"Plurality Die" Bolt Cutters



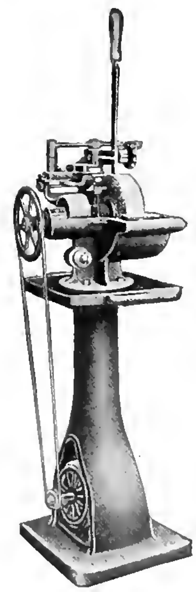
Simple, strong, compact, very few parts, no exposed gearing. Automatic throw-out opens the dies quickly with no jar to head.

THE "PLURALITY DIE" is the special feature of this machine, a single set doing the work of twelve of the ordinary kind. Will cut all commonly used threads from $\frac{1}{4}''$ to $1\frac{1}{2}''$. **Durability and Low Cost of Maintenance** strong points.

Keep your scrapers in good condition with the

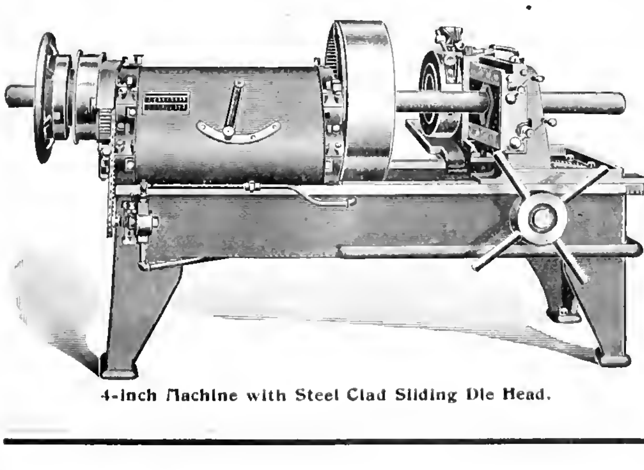
REVOLVING OILSTONE SHARPENER

This improved machine puts on a straight, keen edge that will stand much work without needing regrinding. Adapted for other work, easily portable and can be operated by unskilled labor. Ask for the catalogue.



Mummert, Wolf & Dixon Co.

HANOVER, PA.



4-inch Machine with Steel Clad Sliding Die Head.

A SLIDING DIE HEAD ON A PIPE THREADING MACHINE

is absolutely necessary to get the most and best work out of it. Pipe does not come perfectly round, neither is it straight. If the head can move it will follow the pipe and you will get better work with less wear on the machine and dies. ¶ You can also put the pipe in and take it out thro the die stand **without dragging it across the dies and taking the edge off.** ¶ You can also cut off closer to the gripping chuck which saves time and makes money.

The Stoever Foundry & Manufacturing Co.

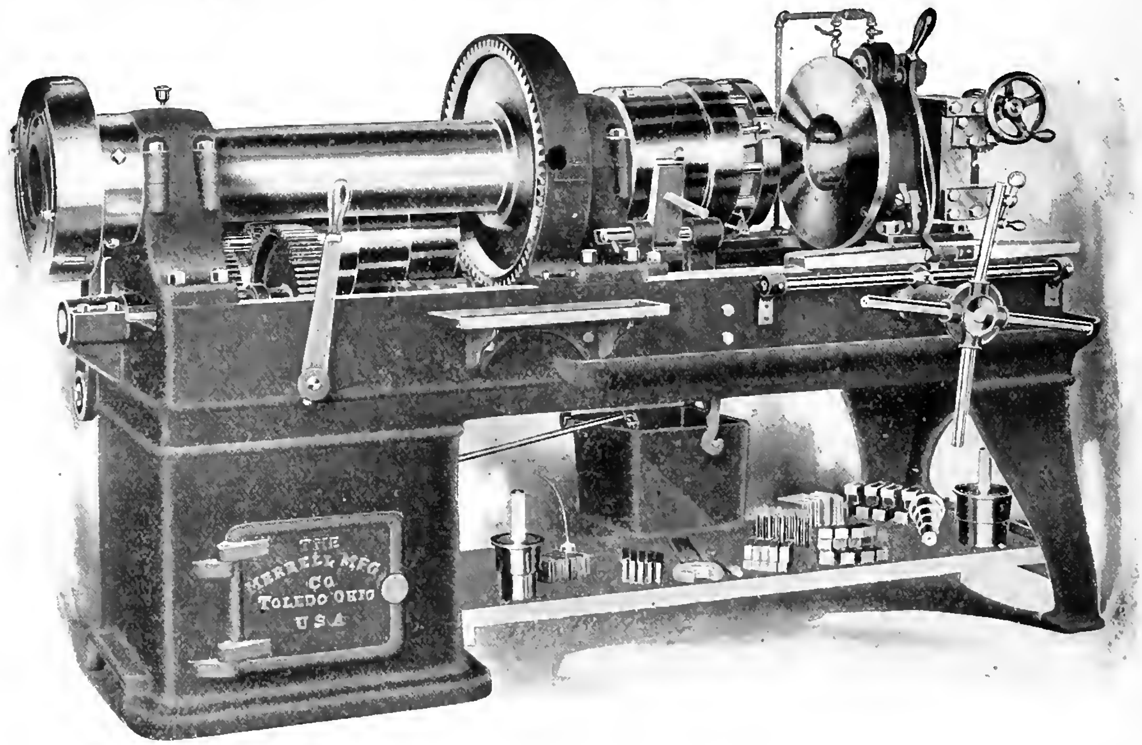
WHAT THE MERRELL MACHINE MEANS TO YOU:

Merrell Pipe Threading and Cutting Machines mean *greater* work, and *better* work. Merrell Machines mean more *economical* work, and easier work for the operator. Merrell Machines mean greater efficiency and economy, and extreme simplicity and ease of operation.



This Merrell Apex Nos. 1 and 2 is designed and built for the man who has great quantities of pipe of one size to be cut. It has a special arrangement for cutting very short pieces of pipe. It has a special threading gauge that automatically cuts the pipe when the desired length has been threaded. It will cut steel or iron pipe *equally well*. It will cut nipples satisfactorily. Why not let us tell you further about this Machine? Why not get the Merrell catalogue?

30 DAYS FREE TRIAL

THE MERRELL MFG. CO., 15 Curtis St., Toledo, O.

Pipe Threaders and Cutters

With efficiency as well as beauty.

Heavy—none more so; bed cast in one piece, no stands nor legs to work loose. No oil soaked floors; fire risk reduced.

Single speed pulley; all gear speed changes through semi-steel cut gears.

Deep chasers cutting long taper perfect threads in one cut as easily on steel as on iron pipe.

Let us prove to you that the higher cost of a modern tool is justified by the character and quantity of its product. Circulars for the asking.

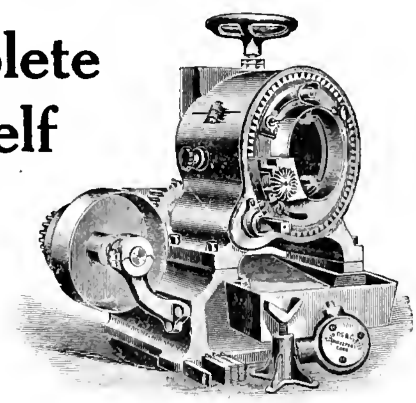
Catalog on request.

THE LOEW MFG. CO., Cleveland, O.

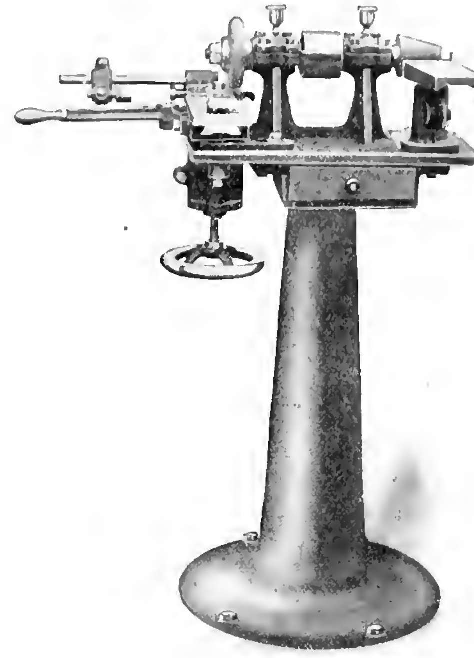
Complete in Itself



There are no vises or other accessories needed with the **Forbes Patent Die Stock**—it is a complete tool for cutting off and threading pipe, doing the work so easily that one man, unaided, can cut off and thread pipe up to 15 inches by hand. Machines are arranged for hand or power, are easily portable, especially convenient for use in cramped quarters and have all parts interchangeable.

Send for latest catalogue showing sizes, prices and capacities of our machines.

The Curtis & Curtis Company
8 Garden Street, Bridgeport, Conn.



DEBUT

It is needless to say that steel pipe requires a sharp, properly shaped die to cut a good thread. The little machine shown here is the

B. & K. Die Grinder

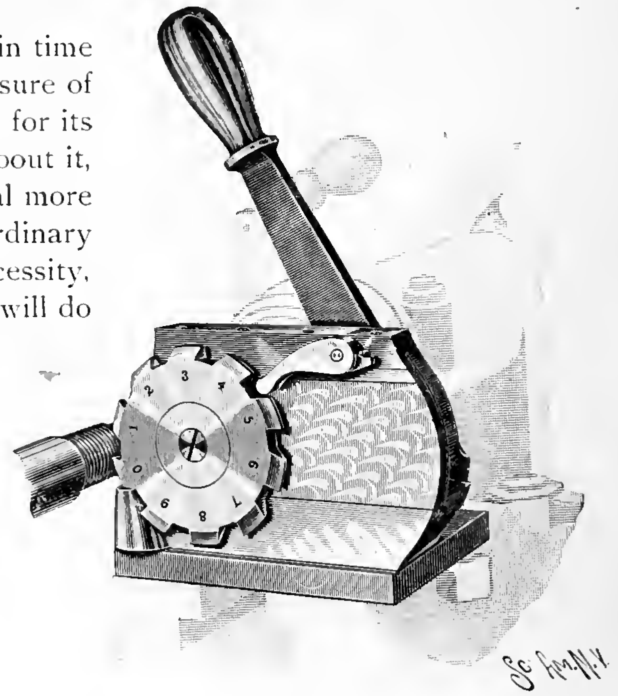
for the correct grinding of the dies. Simple to operate, moderate in price, and will save you dollars.

Get the folder.

Bignall & Keeler Mfg. Co.
EDWARDSVILLE, ILL.

THE RIVETT-DOCK THREADING TOOL

FOR ACCURATE THREADING AND DUPLICATE WORK



You not only save from 25 to 75 per cent. in time with this device, but you can be absolutely sure of exact results. Skilled labor is not required for its operation, there is nothing complicated about it, and a boy with this tool will do a great deal more and better work than an expert using the ordinary thread tool. Grinding is an infrequent necessity, with one sharpening the Rivett-Dock Tool will do as much work as a hundred of the single point variety. Practically a shop necessity and now in use in the best equipped plants in the country. As a labor saver it stands in the front rank and we shall be glad to send one on Thirty Days' Free Trial.
